This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

+ *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.

+ *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.

+ *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.

+ *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at `http://books.google.com/`

A TEXT-BOOK

OF

HUMAN PHYSIOLOGY.

STANDARD MEDICAL WORKS.

ANDERSON (Prof. T. McCall). A Treatise on Diseases of the Skin; with Special Reference to Diagnosis and Treatment. With several full-page Plates, two of which are colored, and numerous Wood Engravings. Octavo.
Cloth, $4.50; Leather, $5.50.

BYFORD (Prof. W. H.). The Diseases of Women. Fourth Edition. Revised and rewritten. With 306 Illustrations, over 100 of which are original with this work. Octavo. Cloth, $5.00; Leather, $6.00.

CAZEAUX AND TARNIER'S Midwifery, with Appendix by PAUL F. MUNDÉ. Eighth American, from the Eighth French and First Italian Editions. Elegantly Illustrated with seven beautifully colored and five other full-page Plates, and many Wood Engravings. Octavo. *Students' Edition.*
Cloth, $5.00; Leather, $6.00.

FAGGE (Chas. Hilton, M. D.). The Principles and Practice of Medicine. Edited by P. H. PYE-SMITH, M. D. Including a Section on Skin Diseases by the Editor, and a Chapter on Cardiac Diseases by SAMUEL WILKES, M. D. 2 Vols. Octavo. Cloth, $8.00; Leather, $10.00; Half Russia, $12.00.

GOWERS (Prof. Wm. R.). Manual of Diseases of the Nervous System. A Complete Text-book. 341 Illustrations. Octavo.
Cloth, $6.50; Leather, $7.50.

HOLDEN (Luther, F.R.C.S.). A Manual of Anatomy. Fifth Edition. Carefully revised and enlarged. 208 Illustrations. Octavo.
Oilcloth, $4.50; Cloth, $5.00; Leather, $6.00.

JACOBSON (W. H. A., F.R.C.S.). The Operations of Surgery. A Systematic Handbook for Practitioners, Students and Hospital Surgeons. 199 Illustrations (describing over 230 operations as performed at Guy's Hospital, London). Octavo. 1000 pages. Cloth, $5.00; Leather, $6.00.

MEYER (Dr. Edouard). A Manual of Diseases of the Eye. Translated from the Third Edition by A. FREEDLAND FERGUS, M. B. (Glasgow). 270 Illustrations and two Colored Plates (by LIEBREICH). Octavo.
Cloth, $4.50; Leather, $5.50.

ROBERTS (Prof. Fred.). The Theory and Practice of Medicine. Seventh Edition. Thoroughly revised and Enlarged. Illustrated. Octavo.
Cloth, $5.50; Leather, $6.50.

WINCKEL (Prof. F.). Text-book on Midwifery, including the Diseases of Childbed. Authorized Translation by J. CLIFTON EDGAR, M. D., Lecturer on Obstetrics, University Medical College, New York. With 190 Illustrations, the majority of which are original with this work. Octavo. *Nearly Ready.*

*** These books may be obtained through any bookseller, or upon receipt of the price any book will be sent, postage prepaid. Complete Catalogues upon application.

TO

SIR JOSEPH LISTER, BARONET,

M.D., D.C.L., LL.D., F.R.SS. (LOND. AND EDIN.),

PROFESSOR OF CLINICAL SURGERY IN KING'S COLLEGE, LONDON, SURGEON-EXTRAORDINARY TO THE QUEEN;

FORMERLY REGIUS PROFESSOR OF CLINICAL SURGERY IN THE UNIVERSITY OF EDINBURGH,

IN ADMIRATION OF

The Man of Science,

WHOSE BRILLIANT DISCOVERIES HAVE REVOLUTIONIZED

MEDICAL PRACTICE, AND CONTRIBUTED INCALCULABLY TO THE

WELL-BEING OF MANKIND;

AND IN GRATITUDE TO

The Teacher,

WHOSE NOBLE EARNESTNESS IN INCULCATING

THE SACREDNESS OF HUMAN LIFE

STIRRED THE HEARTS OF ALL WHO HEARD HIM:

This Work is respectfully Dedicated

BY HIS FORMER PUPIL,

THE TRANSLATOR.

54790

PREFATORY NOTE TO THE THIRD EDITION.

In offering to the Profession this Third English Edition, I would only say that the whole work has again been thoroughly revised and in many parts extended. In all respects I have endeavored to keep it abreast of the latest investigations in Physiology and their bearing on Practical Medicine and Surgery.

I have again to thank my publishers for enabling me to enhance the usefulness of the work by very numerous additions to the Illustrations, which now number 692 as compared with the 494 of the First Edition. Many of these new engravings are original; others are derived from the Sixth German Edition of the work, from Stöhr's *Lehrbuch der Histologie*, Quain's *Anatomy*, Ferrier's *Functions of the Brain* (Second Edition), H. Obersteiner's *Anleitung beim Studium des Baues der nervösen Centralorgane*, Rollett's Article on "Muscle" in the *Real-Encyclopædie*, Gowers' *Diseases of the Nervous System*, and most of those for the chapter on Reproduction from Haddon's *Introduction to Embryology*.

In addition, I have to tender special acknowledgments to my colleagues and friends, Professors A. H. Young, James Ross, A. W. Hare and Dr. Aug. D. Waller; as well as to Messrs. Carl Reichert, of Vienna; W. Petzold, of Leipzic; Rothe, of Prague; Maw, Cassella, Krohne and Sesemann, Evans & Wormall, of London, and Ferries & Co., of Bristol.

For the first time the work appears here in one volume—an arrangement adopted both to meet the wishes of Students and to facilitate easy reference. I can but express a hope that the present Edition, in its new form, will meet with the same very kind reception accorded to its predecessors.

WILLIAM STIRLING.

The Owens College,
Manchester.

PREFACE TO THE FIRST EDITION.

THE fact that Professor LANDOIS' "*Lehrbuch der Physiologie des Menschen*" has already passed through four large Editions since its first appearance in 1880, shows that in some special way it has met the wants of Students and Practitioners in Germany. The characteristic which has thus commended the work will be found mainly to lie in its eminent *practicality;* and it is this consideration which has induced me to undertake the task of putting it into an English dress for English readers.

Landois' work, in fact, forms a *Bridge* between Physiology and the Practice of Medicine. It never loses sight of the fact that the Student of to-day is the practicing Physician of to-morrow. Thus, to every Section is appended—after a full description of the normal processes—a short *résumé* of the pathological variations, the object of this being to direct the attention of the Student, from the outset, to the field of his future practice, and to show him to what extent pathological processes are a disturbance of the normal activities.

In the same way, the work offers to the busy physician in practice a ready means of refreshing his memory on the theoretical aspects of Medicine. He can pass *backward* from the examination of pathological phenomena to the normal processes, and, in the study of these, find new indications and new lights for the appreciation and treatment of the cases under consideration.

With this object in view, all the methods of investigation which may with advantage be used by the Practitioner, are carefully and fully described; and Histology, also, occupies a larger place than is usually assigned to it in Text-books of Physiology.

A word as to my own share in the present version:—

(1) In the task of translating, I have endeavored throughout to convey the author's meaning accurately, without a too rigid adherence to the original. Those who from experience know something of the difficulties of such an undertaking will be most ready to pardon any shortcomings they may detect.

(2) Very considerable additions have been made to the Histological, and also (where it has seemed necessary) to the Physiological sections. All such additions are enclosed within square brackets [ ]. I have to acknowledge my indebtedness to many valuable Papers in the various Medical Journals—British

and Foreign—and also to the Histological Treatises of Cadiat, Ranvier, and Klein; Quain's *Anatomy*, Vol. II, Ninth Edition; Hermann's *Handbuch der Physiologie;* and the Text-books on Physiology, by Rutherford, Foster, and Kirkes; Gamgee's *Physiological Chemistry;* Ewald's *Digestion;* and Roberts' *Digestive Ferments.*

(3) The Illustrations have been greatly increased in number, viz., from 275 in the Fourth German Edition to 494 in the English version. These additional Diagrams, with the sources whence derived, are distinguished in the List of Woodcuts by an asterisk.

There only remains for me now to express my thanks to all who have kindly helped in the progress of the work, either by furnishing Illustrations or otherwise —especially to Drs. Byrom Bramwell, Dudgeon, Lauder Brunton, and Knott; Mr. Hawksley; Professors Hamilton and McKendrick; to my esteemed teacher and friend, Professor Ludwig, of Leipzic; and, finally, to my friend, Mr. A. W. Robertson, M.A., formerly Assistant Librarian in the University, and now Librarian of the Aberdeen Public Library, for much valuable assistance while the work was passing through the press.

In conclusion—and forgetting for the moment my own connection with it—I heartily commend the work *per se* to the attention of Medical men, and can wish for it no better fate than that it may speedily become as popular in this country as it is in its Fatherland.

WILLIAM STIRLING.

ABERDEEN UNIVERSITY.

280. Accumulation and Retention of Urine, . . . 483
281. Retention and Incontinence of Urine, . . . 486
282. Comparative and Historical, . . . 486

IX. FUNCTIONS OF THE SKIN.

283. Structure of the Skin, Nails, and Hair, . . . 487
284. The Glands of the Skin, . . . 492
285. The Skin as a Protective Covering, . . . 493
286. Cutaneous Respiration and Secretion—Sweat, . . . 493
287. Conditions Influencing the Secretion of Sweat, . . . 495
288. Pathological Variations, . . . 497
289. Cutaneous Absorption—Galvanic Conduction, . . . 498
290. Comparative—Historical, . . . 499

X. PHYSIOLOGY OF THE MOTOR APPARATUS.

291. Ciliary Motion, Pigment Cells, . . . 500
292. Structure and Arrangement of the Muscles, . . . 502
293. Physical and Chemical Properties of Muscle, . . . 511
294. Metabolism in Muscle, . . . 513
295. Rigor mortis, . . . 515
296. Muscular Excitability, . . . 519
297. Changes in a Muscle during Contraction, . . . 524
298. Muscular Contraction, . . . 526
299. Rapidity of Transmission of a Muscular Contraction, . . . 537
300. Muscular Work, . . . 538
301. The Elasticity of Muscle, . . . 541
302. Formation of Heat in an Active Muscle, . . . 543
303. The Muscle Sound, . . . 545
304. Fatigue and Recovery of Muscle, . . . 545
305. The Mechanism of the Joints, . . . 547
306. Arrangement and Uses of the Muscles of the Body, . . . 549
307. Gymnastics—Pathological Motor Variations, . . . 553
308. Standing, . . . 554
309. Sitting, . . . 555
310. Walking, Running, and Leaping, . . . 555
311. Comparative, . . . 558

XI. VOICE AND SPEECH.

312. Voice and Speech, . . . 559
313. Arrangement of the Larynx, . . . 560
314. Organs of Voice—Laryngoscopy, . . . 565
315. Conditions Modifying the Laryngeal Sounds, . . . 568
316. Range of the Voice, . . . 569
317. Speech—The Vowels, . . . 569
318. The Consonants, . . . 572
319. Pathological Variations of Voice and Speech, . . . 573
320. Comparative—Historical, . . . 573

XII. GENERAL PHYSIOLOGY OF THE NERVES AND ELECTRO-PHYSIOLOGY.

321. Structure and Arrangement of the Nerve Elements, . . . 575
322. Chemical and Mechanical Properties of Nerve Substance, . . . 581
323. Metabolism of Nerves, . . . 582
324. Excitability of Nerves—Stimuli, . . . 583
325. Diminution of Excitability—Degeneration and Regeneration of Nerves, . . . 587

SECTION PAGE
326. The Galvanic Current, . . . 591
327. Action of the Galvanic Current—Galvanometer, . . . 593
328. Electrolysis, . . . 594
329. Induction—Extra-Current—Magneto-Induction, . . . 599
330. Du Bois-Reymond's Inductorium, . . . 601
331. Electrical Currents in Passive Muscle and Nerve, . . . 603
332. Currents of Stimulated Muscle and Nerve, . . . 607
333. Currents in Nerve and Muscle during Electrotonus, . . . 611
334. Theories of Muscle and Nerve Currents, . . . 613
335. Electrotonic Alteration of the Excitability, . . . 615
336. Electrotonus—Law of Contraction, . . . 617
337. Rapidity of Transmission of Nervous Impulses, . . . 620
338. Double Conduction in Nerves, . . . 623
339. Therapeutical Uses of Electricity—Reaction of Degeneration, . . . 624
340. Electrical Charging of the Body, . . . 629
341. Comparative —Historical, . . . 629

XIII. PHYSIOLOGY OF THE PERIPHERAL NERVES.

342. Classification of Nerve Fibres, . . . 631
343. Nervus Olfactorius, . . . 634
344. Nervus Opticus, . . . 634
345. Nervus Oculomotorius, . . . 637
346. Nervus Trochlearis, . . . 639
347. Nervus Trigeminus, . . . 640
348. Nervus Abducens, . . . 649
349. Nervus Facialis, . . . 649
350. Nervus Acusticus, . . . 653
351. Nervus Glosso-pharyngeus, . . . 655
352. Nervus Vagus, . . . 656
353. Nervus Accessorius, . . . 664
354. Nervus Hypoglossus, . . . 664
355. The Spinal Nerves, . . . 665
356. The Sympathetic Nerve, . . . 670
357. Comparative—Historical, . . . 673

XIV. PHYSIOLOGY OF THE NERVE CENTRES.

358. General, . . . 675
359. Structure of the Spinal Cord, . . . 676
360. Spinal Reflexes, . . . 686
361. Inhibition of the Reflexes, . . . 689

LIST OF ILLUSTRATIONS.

FIGURE		PAGE
1.	Human colored blood corpuscles,	44
2.	Apparatus of Abbé and Zeiss for estimating the blood corpuscles,	45
3.	Mixer,	45
*4.	Gower's hæmacytometer (*Hawksley*),	46
*5.	Crenation of human blood corpuscles,	47
6.	Red blood corpuscles showing various changes of shape,	48
*7.	Effect of reagents on blood corpuscles (*Stirling*),	49
8.	Vaso-formative cells,	52
9.	White blood corpuscles and fibrin,	54
*10.	White blood corpuscles (*Klein*),	55
11.	Amœboid movements of colorless corpuscles,	56
12.	Blood plates and their derivatives,	57
13.	Hæmoglobin crystals,	59
*14.	Gowers' hæmoglobinometer (*Hawksley*),	60
*15.	Fleischl's hæmometer (*Reichert*),	61
16.	Scheme of a spectroscope,	62
17.	Various spectra of hæmoglobin and its compounds,	63
18.	Hæmin crystals,	67
19.	Hæmin crystals prepared from traces of blood,	67
20.	Hæmatoidin crystals,	68
*21.	Hewson's experiment,	74
22.	Scheme of Pflüger's gas pump,	82
*23.	Micrococcus, bacterium, vibrio,	90
*24.	Bacillus anthracis,	90
25.	Scheme of the circulation,	91
26.	Muscular fibres from the heart,	92
27.	Muscular fibres in the left auricle,	93
28.	Muscular fibres in the ventricles,	94
*29.	Lymphatic from the pericardium (*Cadiat*),	95
*30.	Section of the endocardium (*Cadiat*),	95
*31.	Purkinje's fibres (*Ranvier*),	96
32.	Cast of the ventricles of the human heart,	99
33.	The closed semilunar valves,	100
*34.	Gaule's maximum and minimum manometer (*Gscheidlen*),	100
*35.	Manometer of Gaule (*Gscheidlen*),	100
*36.	Various cardiographs (*Hermann*),	103
*37.	Cardiogram,	103
*38.	Arteriogram and Cardiogram,	104
39.	Curves of the apex beat,	104
40.	Changes of the heart during systole, and sections of thorax,	105
*41.	Dog's heart, posterior surface (*Ludwig and Hesse*),	106
*42.	Left lateral surface (*Ludwig and Hesse*),	106
*43.	Anterior surface (*Ludwig and Hesse*),	106
*44.	Base of heart (*Ludwig and Hesse*),	107
*45.	Base of heart in systole and diastole (*Ludwig and Hesse*),	107
46.	Curves from a rabbit's ventricle,	108
*47.	Marey's registering tambour (*Hermann*),	109
48.	Curves obtained with a cardiac sound,	110
49.	Curves from the cardiac impulse,	111, 112
*50.	Scheme of cardiac cycle,	112
*51.	Position of the heart in the chest (*Luschka and Gairdner*),	115
*52.	Curves of excised rabbits' hearts (*Stirling, after Waller*),	116
*53.	Heart of frog from the front (*Ecker*),	118

FIGURE PAGE
*54. Heart of frog from behind (*Ecker*), . . . 118
*55. Auricular septum (*Ecker*), . . . 119
*56. Bipolar nerve cells from a frog's heart, . . . 119
*57. Scheme of frog's heart (*Brunton*), . . . 119
*58. Stannius's experiment (*Brunton*), . . . 119
*59. Luciani's groups of cardiac pulsations (*Hermann*), . . . 123
*60. Scheme of a frog manometer (*Stirling*), . . . 123
*61. Perfusion cannula (*Kronecker and Stirling*), . . . 124
*62. Roy's tonometer (*Stirling*), . . . 124
*63. Curves of a frog's heart at different temperatures (*Hermann*), . . . 125
64. Cardio-pneumograph of Landois, . . . 128
65. Apparatus for showing the effect of respiration, . . . 130
66. Cylindrical vessel filled with water, . . . 133
67. Cylindrical vessel with manometers, . . . 133
68. Small artery with its various coats, . . . 135
69. Capillaries injected with silver nitrate, . . . 135
*70. Longitudinal section of a vein at a valve (*Cadiat*), . . . 136
71. Sphygmometer of Herisson, . . . 139
72. Scheme of Marey's sphygmograph, . . . 140
*73. Marey's improved sphygmograph (*B. Bramwell*), . . . 140
*74. Ludwig's sphygmograph, . . . 141
*75. Dudgeon's sphygmograph (*Dudgeon*), . . . 141
76. Scheme of Brondgeest's pansphygmograph, . . . 142
77. Scheme of Landois' angiograph, . . . 142
78. Pulse curves of the carotid, radial, and posterior tibial arteries, . . . 143
*79. S. Mayer's gas sphygmoscope, . . . 143
80. Hæmautographic curve, . . . 143
*81. Sphygmogram of radial artery (*Dudgeon*), . . . 144
*82. Irregular pulse, mitral regurgitation, . . . 145
83. Sphygmograms of various arteries, . . . 146
*84. Pulse tracings after amyl nitrite (*Stirling, after Murrell*), . . . 147
*85. Aortic regurgitation, . . . 147
86. Pulsus dicrotus, P. caprizans, P. monocrotus, . . . 148
*87. Hyperdicrotic pulse, . . . 149
88. Pulsus alternans, . . . 150
89. Curves of the posterior tibial artery, . . . 151
90. Anacrotic pulse curves, . . . 152
91. Anacrotic pulse curves, . . . 152
92. Influence of the respiration on the sphygmogram, . . . 153
93. Pulse curves during Müller's and Valsalva's experiments, . . . 154
94. Pulsus paradoxus, . . . 155
95. Various radial curves altered by pressure, . . . 155
96. Pulse tracings of the radial artery, . . . 157
97. Tracings from the posterior tibial, and carotid arteries, . . . 157
98. Apparatus for registering the molar motions of the body, . . . 158
99. Vibration and heart curves, . . . 159
100. Ludwig and Fick's kymographs, . . . 162
*101. Ludwig's improved revolving cylinder (*Hermann*), . . . 162
*102. Blood-pressure tracing of the carotid of a dog (*Hermann*), . . . 163
*103. Fick's spring manometer, by Hering (*Hermann*), . . . 164
104. Fick's flat-spring kymograph, . . . 165
*105. Scheme of height of blood pressure, . . . 166
*106. Depressor curve (*Stirling*). . . . 167
*107. Blood pressure and respiration tracings taken simultaneously (*Stirling*), . . . 168
*108. Blood-pressure tracing during stimulation of the vagus (*Stirling*), . . . 170
*109. Apparatus of v. Kries for capillary pressure (*C. Ludwig*), . . . 171
*110. Scheme of the blood pressure, . . . 172
111. Volkmann's hæmadromometer, . . . 175
112. Ludwig and Dogiel's rheometer, . . . 175
113. Vierordt's hæmatachometer—Dromograph, . . . 176
114. Photohæmatachometer, . . . 177
*115. Scheme of sectional area (after *Yeo*), . . . 178
116. Diapedesis, . . . 182
117. Various forms of venous pulse, . . . 186
118. Mosso's plethysmograph, . . . 188

INTRODUCTION.

THE SCOPE OF PHYSIOLOGY AND ITS RELATIONS TO OTHER BRANCHES OF NATURAL SCIENCE.

PHYSIOLOGY is the science of the vital phenomena of organisms, or, broadly, it is the Doctrine of Life. Correspondingly to the divisions of organisms, we distinguish—(1) *Animal Physiology;* (2) *Vegetable Physiology;* and (3) the *Physiology of the Lowest Living Organisms*, which stand on the border line of animals and plants, *i. e.*, the so-called *Protistæ* of Haeckel, micro-organisms, and those elementary organisms or *cells* which exist on the same level.

The object of Physiology is to establish these phenomena, to determine their regularity and causes, and to refer them to the general fundamental laws of Natural Science, viz., the Laws of Physics and of Chemistry.

The following Scheme shows the relation of Physiology to the allied branches of Natural Science:—

BIOLOGY.

The science of organized beings or organisms (animals, plants, protistæ, and elementary organisms).

I. Morphology.

The doctrine of the **form** of organisms.

General Morphology.	Special Morphology.
The doctrine of the formed elementary constituents of organisms.	The doctrine of the *parts* and *organs* of organisms.
(**Histology**)—	(**Organology—Anatomy**)—
(*a*) Histology of Plants.	(*a*) **Phytotomy.**
(*b*) Histology of Animals.	(*b*) **Zootomy.**

II. Physiology.

The doctrine of the **vital phenomena** of organisms.

General Physiology.	Special Physiology.
The doctrine of vital phenomena in general—	The doctrine of the activities of the individual organs—
(*a*) Of Plants.	(*a*) Of Plants.
(*b*) Of Animals.	(*b*) Of Animals.

III. Embryology.

The doctrine of the **generation** and **development** of organisms.

Morphological part of the doctrine of development, *i. e.*, the doctrine of *form* in its stages of development—
(*a*) General.
(*b*) Special.

1. History of the development of *single* beings, of the individual (*e. g.*, of man) from the ovum onward (**Ontogeny**)—
   (*a*) In Plants.
   (*b*) In Animals.
2. History of the development of a *whole stock* of organisms from the lowest forms of the series upward (**Phylogeny**)—
   (*a*) In Plants.
   (*b*) In Animals.

Physiological part of the doctrine of development, *i. e.*, the doctrine of the *activity* during development—
(*a*) General.
(*b*) Special.

Morphology and **Physiology** are of equal rank in biological science, and a previous acquaintance with Morphology is assumed as a basis for the comprehen-

sion of Physiology, since the work of an organ can only be properly understood when its external form and its internal arrangements are known. **Development** occupies a middle place between Morphology and Physiology; it is a morphological discipline in so far as it is concerned with the description of the parts of the developing organism; it is a physiological doctrine in so far as it studies the *activities* and *vital phenomena* during the course of development.

MATTER.—The entire visible world, including all organisms, consists of matter, *i. e.*, of substance which occupies space.

We distinguish *ponderable* matter which has weight, and *imponderable* matter which cannot be weighed in a balance. The latter is generally termed *ether*.

In ponderable materials, again, we distinguish their *form, i.e.*, the nature of their limiting surfaces; further, their *volume, i. e.*, the amount of space which they occupy; and lastly, their *aggregate condition, i. e.*, whether they are solid, fluid, or gaseous bodies.

Ether.—The ether fills the space of the universe, certainly as far as the most distant visible stars. This ether, notwithstanding its imponderability, possesses distinct mechanical properties; it is infinitely more attenuated than any known kind of gas, and behaves more like a solid body than a gas, resembling a gelatinous mass rather than the air. It participates in the luminous phenomena due to the vibrations of the atoms of the fixed stars, and hence it is the transmitter of light, which is conducted by means of its vibrations, with inconceivable rapidity (42,220 geographical miles per second), to our visual organs (*Tyndall*).

Imponderable matter (ether) and ponderable matter are not separated sharply from each other; rather does the ether penetrate into all the spaces existing between the smallest particles of ponderable matter.

Particles.—Supposing that ponderable matter were to be subdivided continuously into smaller and smaller portions, until we reach the last stage of division in which it is possible to recognize the *aggregate* condition of the matter operated upon, we should call the finely-divided portions of matter in this state *particles*. Particles of iron would still be recognized as *solid*, particles of water as *fluid*, particles of oxygen as *gaseous*.

Molecules.—Supposing, however, the process of division of the particles to be carried further still, we should at last reach a limit, beyond which, neither by mechanical nor by physical means, could any further division be effected. We should have arrived at the *molecules*. A molecule, therefore, is the smallest amount of matter which can still exist in a free condition, and which as a unit no longer exhibits the *aggregate* condition.

Atoms.—But even molecules are not the final units of matter, since every molecule consists of a group of smaller units, called *atoms*. An atom cannot exist by itself in a free condition, but the atoms unite with other similar or dissimilar atoms to form groups, which are called molecules. Atoms are incapable of further subdivision, hence their name. We assume that the atoms are invariably of the same size, and that they are solid. From a chemical point of view, the atom of an elementary body (element) is the smallest amount of the element which can enter into a chemical combination. Just as ponderable matter consists in its ultimate parts of ponderable atoms, so does the ether consist of analogous small ether-atoms.

Ponderable and Imponderable Atoms.—The ponderable atoms within ponderable matter are arranged in a definite relation to the ether-atoms. The ponderable atoms mutually attract each other, and similarly they attract the imponderable ether-atoms; but the ether-atoms repel each other. Hence, in ponderable masses, ether-atoms surround every ponderable atom. These masses, in virtue of the attraction of the ponderable atoms, tend to come together, but only to the extent permitted by the surrounding ether-atoms. Thus the ponderable atoms can never come so close as not to leave interspaces. All matter must,

therefore, be regarded as more or less loose and open in texture, a condition due to the interpenetrating ether-atoms, which resist the direct contact of the ponderable atoms.

Aggregate Condition of Atoms.—The relative arrangement of the molecules, *i. e.*, the smallest particles of matter which can be isolated in a free condition, determines the aggregate condition of the body.

Within a **solid** body, characterized by the permanence of its volume as well as by the independence of its form, the molecules are so arranged that they cannot readily be displaced from their relative positions.

Fluid bodies, although their volume is permanent, readily change their shape, and their molecules are in a condition of continual movement.

When this movement of the molecules takes so wide a range that the individual molecules fly apart, the body becomes **gaseous,** and as such is characterized by the instability of its form as well as by the changeableness of its volume.

Physics is the study of these molecules and their motions.

FORCES.

1. Gravitation—Work done.—All phenomena appertain to matter. These phenomena are the appreciable expression of the forces inherent in matter. The forces themselves are not appreciable, they are the causes of the phenomena.

Gravitation.—The law of gravitation postulates that every particle of ponderable matter in the universe attracts every other particle with a certain force. This force is inversely as the square of the distance. Further, the attractive force is directly proportional to the amount of the attracting matter, without any reference to the quality of the body. We may estimate the intensity of gravitation by the extent of the movement which it communicates to a body allowed to fall, for one second, through a given distance, in a space free from air. Such a body will fall *in vacuo* 9.809 metres per second. This fact has been arrived at experimentally.

Let us represent $g = 9.809$ metres, the final velocity of the freely falling body at the end of one second. The velocity, V, of the freely falling body is proportional to the time, t, so that

$$V = gt \quad \ldots\ldots\ldots\ldots\ldots\ldots (1);$$

i. e., at the end of the 1st sec., and $V = g$, $1 = g = 9.809$ M—the distance traversed—

$$s = \frac{g}{2} t^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots (2):$$

i. e., the distances are as the square of the times. Hence, from (1) and (2) it follows (by eliminating t) that—

$$V = \sqrt{2gs} \quad \ldots\ldots\ldots\ldots\ldots\ldots (3).$$

The velocities are as the square roots of the distances traversed—

Therefore

$$\frac{V^2}{2g} = s \quad \ldots\ldots\ldots\ldots\ldots\ldots (4).$$

The freely falling body, and in fact every freely moving body, possesses **kinetic energy,** and is in a certain sense a magazine of energy. The kinetic energy of any moving body is always equal to the product of its weight (estimated by the balance), and the height to which it would rise from the earth, if it were thrown from the earth with its own velocity.

Let W represent the kinetic energy of the moving body, and P its weight, then $W = P.\ s$, so that from (4) it follows that—

$$W = P \frac{V}{2g} \quad \ldots\ldots\ldots\ldots\ldots\ldots (5).$$

Hence, the kinetic energy of a body is proportional to the square of its velocity.

Work.—If a force (pressure, strain, tension) be so applied to a body as to move it, a certain amount of *work* is performed. The amount of work is equal

to the product of the amount of the pressure or strain which moves the body, and of the distance through which it is moved.

Let K represent the force acting on the body, and S the distance, then the work W = KS. The attraction between the earth and any body raised above it is a source of work.

It is usual to express the value of K in kilogrammes, and S in metres, so that the "**unit of work**" is the **kilogramme-metre**, *i. e.*, the force which is required to raise 1 kilo. to the height of 1 metre.

2. Potential Energy.—*The transformation of Potential into Kinetic Energy, and conversely:* Besides kinetic energy, there is also "potential energy," or energy of position. By this term are meant various forms of energy, which are suspended in their action, and which, although they may *cause* motion, are not in themselves motion. A coiled watch-spring kept in this position, a stone resting upon a tower, are instances of bodies possessing potential energy, or the energy of position. It requires merely a push to develop kinetic from the potential energy, or to transform potential into kinetic energy.

Work, w, was performed in raising the stone to rest upon the tower.

$w = p, s$, where p = the weight and s = the height,
$p = m. g$, is = the product of the mass (m), and the force of gravity (g), so that $w = m\,g\,s$.

This is at the same time the expression for the potential energy of the stone. This potential energy may readily be transformed into kinetic energy by merely pushing the stone so that it falls from the tower. The kinetic energy of the stone is equal to the final velocity with which it impinges upon the earth.

$$\begin{aligned} V &= \sqrt{2g\,s} \text{ (see above (3)).} \\ V^2 &= 2g\,s. \\ mV^2 &= 2m\,g\,s. \\ \frac{m}{2}V^2 &= m\,g\,s. \end{aligned}$$

$m\,g\,s$ was the expression for the potential energy of the stone while it was still resting on the height; $\frac{m}{2}V_2$ is the kinetic energy corresponding to this potential energy (*Brücke*).

Potential energy may be transformed into mechanical energy under the most varied conditions; it may also be transferred from one body to another.

The movement of a pendulum is a striking example of the former. When the pendulum is at the highest point of its excursion, it must be regarded as absolutely at rest for an instant, and as endowed with potential energy, thus corresponding with the raised stone in the previous instance. During the swing of the pendulum this potential energy is changed into kinetic energy, which is greatest when the pendulum is moving most rapidly toward the vertical. As it rises again from the vertical position, it moves more slowly, and the kinetic energy is changed into potential energy, which once more reaches its maximum when the pendulum comes to rest at the utmost limit of its excursion. Were it not for the resistances continually opposed to its movements, such as the resistance of the air and friction, the movement of the pendulum, due to the alternating change of kinetic into potential energy and *vice versâ*, would continue uninterruptedly, as with a mathematical pendulum. Suppose the swinging ball of the pendulum, when exactly in a vertical position, impinged upon a resting but movable sphere, the potential energy of the ball of the pendulum would be transferred directly to the sphere, provided that the elasticity of the ball of the pendulum and the sphere were complete; the pendulum would come to rest, while the sphere would move onward with an equal amount of kinetic energy, provided there were no resistance to its movement. This is an example of the transference of kinetic energy from one body to another. Lastly, suppose that a stretched watch-spring on uncoiling causes another spring to become coiled; and we have another example of the transference of kinetic energy from one body to another.

The following general statement is deducible from the foregoing examples: If, in a system, the individual moving masses approach the final position of equilibrium, then in this system the sum of the *kinetic* energies increases; if, on the other hand, the particles move away from the final position of equilibrium, then

the sum of the *potential* energies is increased at the expense of the kinetic energies, *i. e.*, the *kinetic* energies diminish (*Brücke*).

The pendulum, which, after swinging from the highest point of its excursion, approaches the vertical position, *i. e.*, the position of equilibrium of a passive pendulum, has in this position the largest amount of potential energy; as it again ascends to the highest point of its excursion on the other side, it again gradually receives the maximum of potential energy at the expense of the gradually diminishing movement, and therefore of the kinetic energy.

3. **Heat.**—*Its Relation to Potential and Kinetic Energy.*—If a lead weight be thrown from a high tower to the earth, and if it strike an unyielding substance, the movement of the mass of lead is not only arrested, but the kinetic energy (which to the eye appears to be lost) is transformed into a lively vibratory movement of the atoms. When the lead meets the earth, heat is produced. The amount of heat produced is proportional to the kinetic energy which is transformed through the concussion. At the moment when the lead weight reaches the earth, the atoms are thrown into vibrations; they impinge upon each other; then rebound again from each other in consequence of their elasticity, which opposes their direct juxtaposition; they fly asunder to the maximum extent permitted by the attractive force of the ponderable atoms, and thus oscillate to and fro. All the atoms vibrate like a pendulum, until their movement is communicated to the ethereal atoms surrounding them on every side, *i. e.*, until the heat of the heated mass is "*radiated.*" *Heat is thus a vibratory movement of the atoms.*

As the amount of heat produced is proportional to the kinetic energy which is transformed through the concussion, we must find an adequate measure for both forces.

Heat-Unit.—As a standard of measure of heat, we have the "heat-unit" or **calorie.** The "heat-unit" or calorie is the amount of energy required to raise the temperature of 1 gramme of water 1° Centigrade. The "heat-unit" corresponds to 425.5 gramme-metres, *i. e.*, the same energy required to heat 1 gramme of water 1° C. would raise a weight of 425.5 grammes to the height of 1 metre; or, a weight of 425.5 grammes, if allowed to fall from the height of 1 metre, would by its concussion produce as much heat as would raise the temperature of 1 gramme of water 1° C. The "**mechanical equivalent**" of the heat-unit is, therefore, 425.5 gramme-metres.

It is evident that from the collision of moving masses an immeasurable amount of heat can be produced. Let us apply what has already been said to the earth. Suppose the earth to be disturbed in its orbit, and suppose further that, owing to the attraction of the sun, it were to impinge on the latter (whereby, according to J. R. Mayer, its final velocity would be 85 geographical miles per second), the amount of heat produced by the collision would be equal to that produced by the combustion of a mass of pure charcoal more than 5000 times as heavy (*Julius Robert Mayer, Helmholtz*).

Thus, the heat of the sun itself can be produced by the collision of masses of cold matter. If the cold matter of the universe were thrown into space, and there left to the attraction of its particles, the collision of these particles would ultimately produce the light of the stars. At the present time, numerous cosmic bodies collide in space, while innumerable small meteors (94,000 to 188,000 billions of kilos. per minute) fall into the sun. The force of gravity is perhaps, in fact, the only source of all heat (*J. R. Mayer, Tyndall*).

We have a homely example of the transformation of kinetic energy into heat in the fact that a blacksmith may make a piece of iron red hot by hammering it. Of the conversion of heat into kinetic energy we have an example in the hot watery vapor (steam) of the steam engine raising the piston. An example of the conversion of potential energy into heat occurs in a metallic spring, when it uncoils and is so placed as to rub against a rough surface, producing heat by friction.

4. **Chemical Affinity: Relation to Heat.**—While gravity acts upon the particles of matter without reference to the composition of the body, there is another atomic force which acts between atoms of a chemically different nature; this is **chemical affinity.** This is the force in virtue of which the atoms of chemically different bodies unite to form a **chemical compound.** The force itself varies greatly between the atoms of different chemical bodies; thus we speak

of strong chemical affinities and weak affinities. Just as we were able to estimate the potential energy of a body in motion from the amount of heat which was produced when it collided with an unyielding body, so we can measure the amount of heat which is formed when the atoms of chemically different bodies unite to form a chemical compound. As a rule, heat is formed when separate chemically-different atoms form a compound body. When, in virtue of chemical affinity, the atoms of 1 kilo. of hydrogen and 8 kilos. of oxygen unite to form the chemical compound *water*, an amount of heat is thereby evolved which is equal to that produced by a weight of 47,000 kilos. falling and colliding with the earth from a height of 1000 feet above the surface of the earth. If 1 gramme of H be burned along with the requisite amount of O to form water, it yields 34,460 heat-units or calories: and 1 gramme carbon burned to carbonic acid (carbon dioxide) yields 8080 heat-units. *Wherever, in chemical processes, strong chemical affinities are satisfied, heat is set free, i. e.*, chemical affinity is changed into heat. Chemical affinity is a form of potential energy obtaining between the most different atoms, which during chemical processes is changed into heat. Conversely, in those chemical processes where strong affinities are dissolved, and chemically-united atoms thereby pulled asunder, there must be a diminution of temperature, or, as it is said, *heat becomes latent*—that is, the energy of the heat which has become latent is changed into chemical energy, and this, after decomposition of the compound chemical body, is again represented by the chemical affinity between its isolated different atoms.

LAW OF THE CONSERVATION OF ENERGY.—Julius Robert Mayer and Helmholtz have established the important law that, in a system which does not receive any influence and impression from without, the sum of all the forces acting within it is always the same. *The various forms of energy can be transformed one into the other, so that kinetic energy may be transformed into potential energy and vice versâ, but there is never any part of the energy lost.* The transformation takes place in such measure that, from a certain definite amount of one form of energy a definite amount of another can be obtained.

The various **forms of energy** acting in organisms occur in the following modifications:—

1. **Molar motion** (ordinary movements), as in the movements of the whole body, of the limbs, or of the intestines, and even those observable microscopically in connection with cells.

2. **Movements of Atoms as Heat.**—We know, in connection with the vibration of atoms, that the number of vibrations in the unit of time determines whether the oscillations appear as heat, light, or chemically-active vibrations. Heat-vibrations have the smallest number, while chemically-active vibrations have the largest number, light-vibrations standing between the two. In the human body we only observe heat-vibrations, but some of the lower animals are capable of exhibiting the phenomena of light.

In the human organism the molar movements in the individual organs are constantly being transformed into heat, *e.g.*, the kinetic energy in the organs of the circulation is transformed by friction into heat. The measure of this is the "**unit of work**" = 1 gramme-metre, and the "**unit of heat**" = 425.5 gramme-metres.

3. **Potential Energy.**—The organism contains many chemical compounds which are characterized by the great complexity of their constitution, by the imperfect saturation of their affinities, and hence by their great tendency to split up into simpler bodies.

The body can transform the potential energy into heat as well as into kinetic energy, the latter always in conjunction with the former, but the former always by itself alone. *The simplest measure of the potential energy is the amount of heat* which can be obtained by complete combustion of the chemical compounds

representing the potential energy. The number of work-units can then be calculated from the amount of heat produced.

4. The phenomena of **electricity, magnetism,** and **diamagnetism** may be recognized in two directions, as movements of the smallest particles, which are recognized in the glowing of a thin wire when it is traversed by strong electrical currents (against considerable resistance), and also as molar movement, as in the attraction or repulsion of the magnetic needle. Electrical phenomena are manifested in our bodies by muscle, nerve, and glands, but these phenomena are relatively small in amount when compared with the other forms of energy. It is not improbable that the electrical phenomena of our bodies become almost completely transformed into heat. As yet experiment has not determined with accuracy "a unit of electricity" directly comparable with the "heat-unit" and the "work-unit."

It is quite certain that within the organism one form of energy can be transformed into another form, and that a certain amount of one form will yield a definite amount of another form; further, that new energy never arises spontaneously, nor is energy already present ever destroyed, so that in the organism the law of the conservation of energy is continually in action.

ANIMALS AND PLANTS.—The animal body contains a quantity of chemically-potential energy stored up in its constituents. The total amount of the energy present in the human body might be measured by burning completely an entire human body in a *calorimeter*, and thereby determining how many heat-units are produced when it is reduced to ashes (see *Animal Heat*).

The chemical compounds containing the potential energy are characterized by the complicated relative position of their atoms, by a comparatively imperfect saturation of the affinities of their atoms, by the relatively small amount of oxygen which they contain, by their great tendency to decomposition, and the facility with which they undergo decomposition.

If a man were not supplied with food he would lose 50 grammes of his body weight every hour; the material part of his body, which contains the potential energy, is used up, oxygen is absorbed, and a continual process of combustion takes place; by the process of combustion simpler substances are formed from the more complex compounds, whereby potential is converted into kinetic energy. It is immaterial whether the combustion is rapid or slow; the same amount of the same chemical substances always produces the same amonnt of kinetic energy, *i.e.*, of heat.

A person, when fasting, experiences after a certain time the disagreeable feeling of exhaustion of his reserve of potential energy, hunger sets in, and he takes food. *All food for the animal kingdom is obtained, either directly or indirectly, from the vegetable kingdom.* Even carnivora, which eat the flesh of other animals, only eat organized matter which has been formed from vegetable food. The existence of the animal kingdom presupposes the existence of the vegetable kingdom.

All substances, therefore, necessary for the food of animals occur in vegetables. Besides **water** and the **inorganic constituents,** plants contain, among other organic compounds, the following *three chief representatives of food-stuffs*—**fats, carbohydrates,** and **proteids.**

All these contain stores of potential energy, in virtue of their complex chemical constitution.

The **fats** contain:— $\left\{\begin{array}{l} C_nH_{2n-1}O(OH) = \text{fatty acids} \\ + C_3H_5(OH)_3 = \text{glycerin} \end{array}\right\}$ (§ 251).

The **carbohydrates** contain:—$C_6H_{10}O_5$ . . (§ 252).

The **proteids** contain per cent.:— $\left\{\begin{array}{l} \text{C. } 51.5\text{–}54.5 \\ \text{H. } 6.9\text{–} 7.3 \\ \text{N. } 15.2\text{–}17.0 \\ \text{O. } 20.9\text{–}23.5 \\ \text{S. } 0.3\text{–} 2.0 \end{array}\right\}$ (§§ 248 and 249).

A man who takes a certain amount of this food adds thereto **oxygen** from the air in the process of respiration. Combustion or oxidation then takes place, whereby chemically-potential energy is transformed into heat.

It is evident that the products of this combustion must be bodies of simpler constitution—bodies with less complex arrangement of their atoms, with the greatest possible saturation of the affinities of their atoms, of greater stability, partly rich in O, and possessing either no potential energy, or only very little. These bodies are **carbon dioxide**, CO_2; **water**, H_2O; and as the chief representative of the nitrogenous excreta, **urea** ($CO(NH_2)_2$), which has still a small amount of potential energy, but which outside the body readily splits into CO_2 and ammonia (NH_3).

The human body is an organism in which, by the phenomena of oxidation, the complex nutritive materials of the vegetable kingdom, which are highly charged with potential energy, are transformed into simple chemical bodies, whereby the potential energy is transformed into the equivalent amount of kinetic energy (heat, work, electrical phenomena).

But how do plants form these complex food-stuffs so rich in potential energy? It is plain that the potential energy of plants must be obtained from some other form of energy. This potential energy is supplied to plants by the **rays of the sun**, whose chemical light-rays are absorbed by plants. Without the rays of the sun there could be no plants. Plants absorb from the air and the soil CO_2, H_2O, NH_3, and N, of which carbon dioxide, water, and ammonia (from urea) are also produced by the excreta of animals. *Plants absorb the kinetic energy of light from the sun's rays and transform it into potential energy*, which is accumulated during the growth of the plant in its tissues, and in the food-stuffs produced in them during their growth. This formation of complex chemical compounds is accompanied by the simultaneous excretion of O.

Occasionally, kinetic energy, such as we universally meet with in animals, is liberated in plants. Many plants develop considerable quantities of heat in their flowers, *e.g.*, the arum tribe. We must also remember that during the formation of the solid parts of plants, when fluid juices are changed into solid masses, heat is set free. In plants, under certain circumstances, O is absorbed, and CO_2 is excreted, but these processes are so trivial as compared with the typical condition in the vegetable kingdom, that they may be regarded as of small moment.

Plants, therefore, are organisms which, by a reduction process, transform simple stable combinations into complex compounds, whereby potential solar energy is transformed into the chemically-potential energy of vegetable tissues. **Animals** are living beings, which by oxidation decompose or break up the complex grouping of atoms manufactured by plants, whereby potential is transformed into kinetic energy. Thus, there is a constant circulation of matter and a constant exchange of energy between plants and animals. All the energy of animals is derived from plants. All the energy of plants arises from the sun. Thus the sun is the cause, the original source of all energy in the organism, *i. e.*, of the whole of life.

As the formation of solar heat and solar light is explicable by the gravitation of masses, gravity is *perhaps* the original form of energy of all life.

We may thus represent the formation of kinetic energy in the animal body from the potential energy of plants. Let us suppose the atoms of the substances formed in organisms, as simple small bodies, balls, or blocks. As long as these lie in a single layer, or in a few layers, upon the surface, there is a stable arrangement, and they continue to remain at rest. If, however, an artificial tower be built of these blocks, so that an unstable erection is produced, and the same tower be afterward knocked down, then for this purpose we require (1) the motor power of the workman who lifts and carries the blocks; (2) a blow or other impulse from without applied to the unstable structure—when the atoms will fall together, and as they fall collide with each other and produce heat. Thus, the

energy employed by the workman is again transformed into the last-named form of energy.

In plants the complex unstable building of the groups of atoms is carried on, the constructer being the sun. In animals, which eat plants, the complex groups of the atoms are tumbled down, with the liberation of kinetic energy.

Vital Energy and Life.—The forces which act in organisms, in plants, and animals are exactly the same as are recognizable as acting in dead matter. A so-called "vital force," as a special force of a peculiar kind, causing and governing the vital phenomena of living beings, does not exist. The forces of all matter, of organized as well as unorganized, exist in connection with their smallest particles or atoms. As, however, the smallest particles of organized matter are, for the most part, arranged in a very complicated way, compared with the much simpler composition of inorganic bodies, so the forces of the organism connected with the smallest particles yield more complicated phenomena and combinations, whereby it is excessively difficult to ascribe the vital phenomena in organisms to the simple fundamental laws of physics and chemistry.

The Exchange of Material, or Metabolism (*"Stoffwechsel"*) *as a Sign of Life.*—Nevertheless, there appears to be a special exchange of matter and energy peculiar to living beings. This consists in the capacity of organisms to assimilate the matter of their surroundings, and to work it up into their own constitution, so that it forms for a time an integral part of the living being, to be given off again. The whole series of phenomena is called **metabolism** or **"Stoffwechsel,"** which consists in the introduction, assimilation, integration, and excretion of matter.

We have already shown that the metabolism of plants and that of animals are quite different. The processes, as already described, actually occur in the typical higher plants and animals.

But there is a large group of organisms which, throughout their entire organization, exhibit so low a degree of development, that by some observers they are considered as undifferentiated "ground-forms." They are regarded as neither plants nor animals, and are the most simple forms of animated matter. Haeckel has called these organisms **Protistæ**, as being the original and primitive forms.

We must assume that, corresponding with their simpler vital conditions, their metabolism is also simpler, but on this point we still require further observations and experiments.

PHYSIOLOGY OF THE BLOOD.

[THE blood is aptly described by Claude Bernard as an **internal medium** which acts as a "go-between" or **medium of exchange** for the outer world and the tissues. Into it are poured those substances which have been subjected to the action of the digestive fluids, and in the lungs or other respiratory organs it receives oxygen. It thus contains *new* substances, but in its passage through the tissues it gives up some of these new substances, and receives in exchange certain **waste products** which have to be got rid of. Its composition is thus highly complex. Besides carrying the *new* nutrient fluids *to* the tissues, it is also the great **oxygen carrier,** as well as the medium by which some of the waste products, *e. g.*, CO_2, urea, are removed *from* the tissues, and brought to the organs, *e. g.*, the lungs, kidneys, skin, which eliminate them from the body. It is at once a great pabulum-supplying medium and a channel for getting rid of useless materials. As the composition of the organs through which the blood flows varies, it is evident that its composition must vary in different parts of the circulatory system; and it also varies in the same individual under different conditions. Still, with slight variations, there are certain general physical, histological, and chemical properties which characterize blood *as a whole.*]

1. **PHYSICAL PROPERTIES.**—(1) **Color.**—The color of blood varies from a bright scarlet-red in the arteries to a deep, dark, bluish-red in the veins. Oxygen (and, therefore, the air) makes the blood bright red; want of oxygen makes it dark. Blood free from oxygen (and also venous blood) is *dichroic—i. e.*, by reflected light it appears dark red, while by transmitted light it is green. [Arterial blood is monochroic.]

In thin layers blood is **opaque,** as is easily shown by shaking blood so as to form bubbles, or by allowing blood to fall upon a plate with a pattern on it, and pouring it off again. [Printed matter cannot be read through a thin layer of blood spread on a glass slide.] Blood behaves, therefore, like an "opaque color," as its coloring matter is suspended in the form of fine particles—the blood corpuscles.

Hence, it is possible to separate the coloring matter from the fluid part of the blood by filtration. This is accomplished by mixing the blood with fluids which render the blood corpuscles sticky or rough. If mammalian blood be treated with one-seventh of its volume of solution of sodic sulphate, or if frog's blood be mixed with a 2 per cent. solution of sugar (*Joh. Müller*) and filtered, the shriveled corpuscles, now robbed of part of their water, remain upon the filter.

(2) **Reaction.**—The reaction is alkaline, owing to the presence of disodic phosphate, Na_2HPO_4, and bicarbonate of soda. After blood is shed, its alkalinity rapidly diminishes, and this occurs more rapidly the greater the alkalinity of the blood. This is due to the formation of an acid, in which, perhaps, the colored corpuscles take part, owing to the decomposition of their coloring matter. A high temperature and the addition of an alkali favor the formation of the acid (*N. Zuntz*).

The alkaline reaction of blood is diminished: (*a*) by great muscular exertion, owing to the [illegible] of a large amount of acid in the muscles; (*β*) during coagulation; (*γ*) in old blood, or [illegible]ved by water from old blood stains, such blood being usually acid; fresh cruor has a

stronger alkaline reaction than serum; (δ) after the prolonged use of soda the alkalinity is increased, after the use of acids it is decreased.

Methods.—Owing to the color of the blood we cannot employ ordinary litmus paper to test its reaction. One of the following methods may be used: (1) Moisten a strip of glazed red litmus paper with solution of common salt, and allow a drop of blood to fall on the paper; then rapidly wipe it off before its coloring matter has time to penetrate and tinge the paper (*Zuntz*). (2) Liebreich used thin plates of plaster-of-Paris of a perfectly neutral reaction. These are dried, and afterward moistened with a neutral solution of litmus. When a drop of blood is placed upon the porous plate, the fluid part of the blood passes into it, while the corpuscles are washed off with water, and the altered color of the litmus-stained slab is apparent. [(3) Schäfer uses dry, faintly-reddened, glazed litmus paper, and on it is placed a drop of blood, which is wiped off after a few seconds. The place where the blood rested is indicated by a blue patch upon a red or violet ground.]

Estimation of the Alkalinity.—A very dilute solution of tartaric acid (1 cubic centimetre combines with 3.1 milligrams of soda, *i. e.*, 1 litre of water contains 7.5 grams of crystallized tartartic acid) is added to blood until a blue litmus paper is turned red (by Zuntz's method). 100 grams of rabbit's blood have an alkalinity corresponding to 150 milligrams of soda; the blood of carnivora to about 180 milligrams (*Lassar*), while 100 c.c. of normal human blood have an alkalinity equal to 260–300 milligrams of soda (*v. Jaksch*).

The following method can be used with a few drops of blood: To neutralize the blood, tartaric acid in the above concentration is used. Prepare the following mixture by mixing it with a concentrated solution of sodic sulphate, and then adding sodic sulphate until the mixture is completely saturated. I, 10 parts of solution of tartaric acid to 100 parts of concentrated sodic sulphate solution; II, 20 parts tartaric acid solution to 90 sodic sulphate solution; III contains these substances in the proportion of 30 to 80; IV, 40 to 70; V, 50 to 60; VI, 60 to 50; VII, 70 to 40; VIII, 80 to 30; IX, 90 to 20; and X, 100 to 10. Excess of sodic sulphate is present in all the flasks.

A known volume of the blood to be investigated is mixed with an equal volume of each of the mixtures, in a small tube, which is made by drawing out a glass tube 1 millimetre in diameter to a fine point. To calibrate this tube, suck up water, say, to the height of 8 mm., make a mark on the tube with a fine file, then suck up the water until its lower level corresponds with the mark. Again mark the upper limit of the water. To test the blood, suck a drop of the mixture I up to the level of the first mark on the glass pipette, and, after wiping its point, suck up an equal quantity of blood. Again clean the point of the pipette, and blow its contents into a watch glass; then mix, and test the reaction with sensitive violet-colored litmus paper. Proceed in the same way with the several mixtures, II to X, until the alkaline reaction disappears or the acid appears. The narrow strips of litmus paper are dipped into each of the mixtures, the corpuscles remain in the wetted part of the paper, while the fluid permeates further and shows the reaction. As a rule, the degree of alkalinity in human blood corresponds to VI. Human blood can be sucked directly from a small wound made by a needle, either by attaching an elastic tube or a small hypodermic syringe to the pipette (*Landois*).

Pathological.—The alkalinity is increased during persistent vomiting, and decreased in pronounced anæmia, cachexia, uræmia, rheumatism, high fever, diabetes, and cholera. [Immediately before death by cholera it may be acid (*Cantani*).]

(3) **Odor.**—Blood emits a peculiar odor, the halitus sanguinis, which differs in animals and man.

It depends upon the presence of volatile fatty acids. If concentrated sulphuric acid be added to blood, whereby the volatile fatty acids are set free from their combinations with alkalies, the characteristic odor, somewhat similar to that of butyric acid, becomes much more perceptible.

(4) **Taste.**—Blood has a saline taste, depending upon the salts dissolved in the fluid of the blood.

(5) **Specific Gravity.**—The specific gravity is 1056–1059 in man, 1051–1055 in woman; in children less. The specific gravity of the blood corpuscles is 1105, that of the plasma 1027. Hence the corpuscles tend to sink.

Clinical Method.—A thin glass tube is drawn out till it is of small calibre, and then bent at a right angle, and closed above with a caoutchouc cap. Press slightly on the caoutchouc cap, and suck up a drop of the freshly-drawn blood obtained by pricking the finger. The fine capillary tube is at once immersed in a solution of sodic sulphate, and a drop of the blood expressed into the saline solution. It is necessary to prepare several solutions of sodic sulphate with specific gravities varying from 1050–1070. The solution in which the corpuscles remain suspended indicates the specific gravity of the blood (*Roy, Landois*).

The drinking of water and hunger diminish the specific gravity temporarily, while thirst and the digestion of dry food raise it. If blood be passed through an organ artificially, its specific gravity

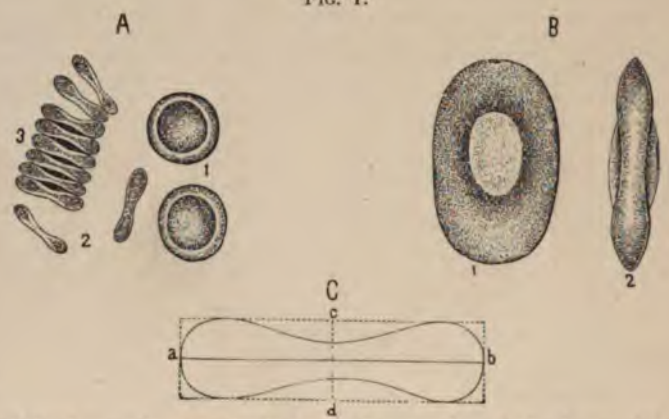
rises in consequence of the absorption of dissolved matters and the giving off of water. It falls after hemorrhage, and is diminished in badly-nourished individuals. [By working with solutions of glycerine, Jones finds that it is highest at birth, is at a minimum between the second week and the second year; it rises gradually until the 35th–45th year. It is usually higher in the male than the female, is diminished by pregnancy, the ingestion of solid or liquid food, and gentle exercise.]

[(6) **Temperature.**—Blood is viscid, and its temperature varies from 36.5° C. (97.7° F.) to 37.8° C. (100° F.). The warmest blood in the body is that of the hepatic vein (§ 210).]

2. MICROSCOPIC EXAMINATION.—[Blood, when examined by the microscope, is seen to consist of an enormous number of **corpuscles**—colored and colorless—floating in a transparent fluid, the **plasma**, or **liquor sanguinis.**

Human Red Blood Corpuscles.—(*a*) **Form.**—They are circular, coin-shaped, homogeneous disks, with saucer-like depressions on both surfaces, and with rounded margins; in other words, they are bi-concave, circular, non-nucleated disks.

FIG. 1.



A, human colored blood corpuscles—1, on the flat; 2, on edge; 3, rouleau of colored corpuscles. B, amphibian colored blood corpuscles—1, on the flat; 2, on edge. C, ideal transverse section of a human colored blood corpuscle magnified 5000 times linear—*ab*, diameter; *cd*, thickness.

(*b*) **Size.**—The diameter (*ab*) is 7.7μ,* (6.7–9.3μ) the greatest thickness (*cd*) 1.9μ (Fig. 1, C), [*i.e.*, it is $\frac{1}{3500}$ to $\frac{1}{3200}$ of an inch in diameter, and about one-fourth of that in thickness].

They are slightly **diminished** in size by septic fever, inanition, morphia, increased bodily temperature, and CO_2; and **increased** by O, watery condition of the blood, cold, consumption of alcohol, quinine, and hydrocyanic acid. *Compare* § 10, 3.

If the total amount of blood in a man be taken at 4400 cubic centimetres, the corpuscles therein contained have a surface of 2816 square metres, which is equal to a square surface with a side of 80 paces; 176 cubic centimetres of blood pass through the lungs in a second, and the blood corpuscles in this amount of blood have a superficies of 81 square metres, equal to a square surface with a side of 13 paces (*Welcker*).

(*c*) **The weight** of a blood corpuscle is 0·00008 milligramme.

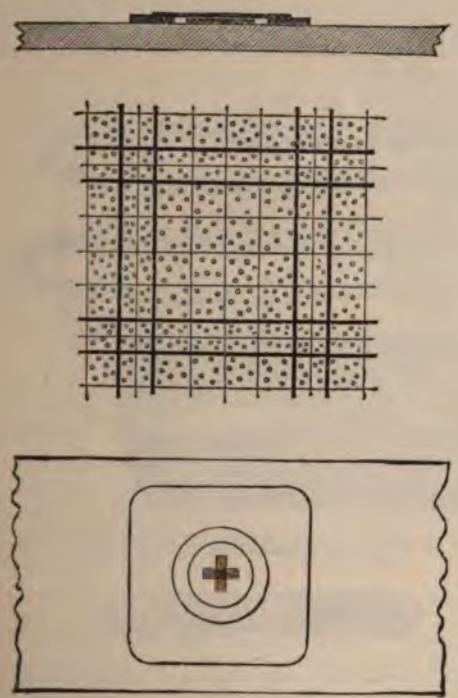
(*d*) **The number** exceeds 5,000,000 per cubic millimetre in the male, and 4,500,000 in the female; so that, in 10 lbs. of blood, there are 25 billions of corpuscles. The number is in inverse ratio to the amount of plasma; hence, the number must vary with the state of contraction of the blood vessels, the pressure, diffusion currents, and other conditions.

* The Greek letter μ represents one-thousandth of a millimetre ($\mu = 0{\cdot}001$ mm.), and is the sign of a *micro-millimetre*, or a *micron*.

The number of red corpuscles is **increased**; in venous blood (especially in the small cutaneous veins), after the use of solid food, after much sweating, and the excretion of much water by the bowel and kidneys; during inanition, because the blood plasma undergoes decomposition sooner than the blood corpuscles themselves; in the blood of the newly-born child, especially when the umbilical cord is long in being tied (§ 40), from the 4th day onward the number is diminished; in persons of robust constitution, and in those who live in the country. The number is **diminished**, during pregnancy, after copious draughts of water. In the earlier period of fœtal life the number is only ½–1 million in 1 cubic millimetre. (For the **pathological conditions** see § 10.)

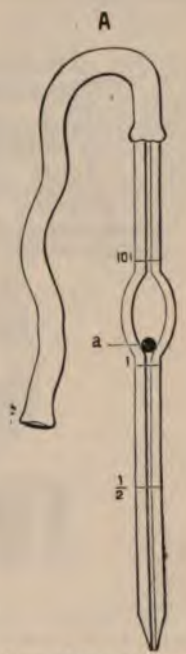
Methods of Counting the Blood Corpuscles.—The pointed end of a glass pipette (Fig. 3), the **mixer**, is dipped into the blood, and by sucking the elastic tube *f*, blood is drawn into the tube until it reaches the mark ½, on the stem of the pipette, or until the mark 1 is reached. The carefully-cleaned point of the pipette is dipped into the **artificial serum**, and this is sucked into the pipette

FIG. 2.



Apparatus of Abbé and Zeiss for counting the corpuscles. A, in section; C, surface view without cover-glass; B, microscopic appearance with the blood corpuscles.

FIG. 3.



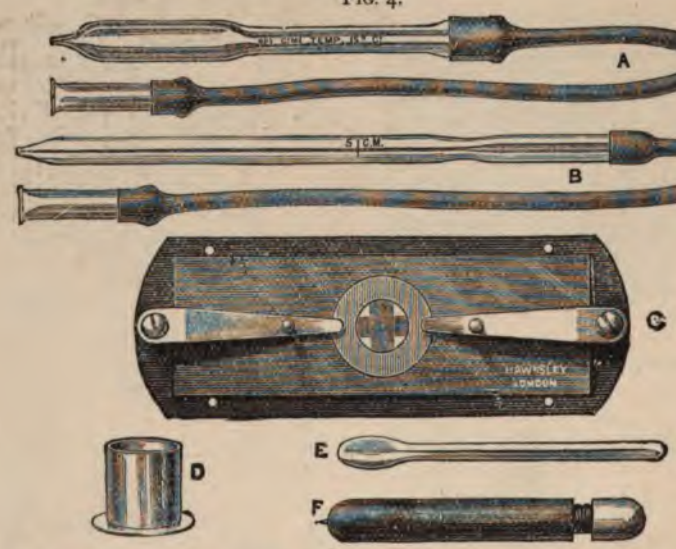
The *Melangeur*, pipette or mixer.

until it reaches the mark, 101. The artificial serum consists of 1 vol. of solution of gum arabic (sp. gr. 1020) and 3 vols. of a solution of equal parts of sodic sulphate and sodic chloride (sp. gr. 1020). The process of mixing the two fluids is aided by the presence of a little glass ball (*a*) in the bulb of the pipette. If blood is sucked up to the mark ½, the strength of the mixture is 1 : 200; if to the mark 1, it is 1 : 100; a small drop of the mixture is allowed to run into the **counting chamber** of Abbé and Zeiss (Fig. 2). The first portions are not used, in order to obtain a uniform sample from the bulb of the pipette. This chamber consists of a glass receptacle 0.1 mm. deep, with its base divided into squares and cemented to a glass slide, the whole being covered with a thin covering glass. The space over each square $= \frac{1}{4000}$ cubic millimetre. Count, with the aid of a microscope, the number of blood corpuscles in each square, and the number found, multiplied by 4000, will give the number of blood corpuscles in 1 c.mm. This number, again, must be multiplied by 100 or 200, according as the blood was diluted 100 or 200 times. To ensure greater accuracy, it is well to count the number in *several* squares, and to take the mean of these.

[**Gowers' Method.**—"The **Hæmacytometer** (Fig. 4) consists of (1) a small pipette, which, when filled to the mark on its stem, holds exactly 995 cubic millimetres. It is furnished with an india-rubber tube and mouthpiece to facilitate filling and emptying. (2) A capillary tube marked to contain exactly 5 cubic millimetres, with india-rubber tube for filling, etc. (3) A small glass jar in which the dilution is made. (4) A glass stirrer for mixing the blood and solution in the glass jar. (5) A brass stage plate, carrying a glass slip, on which is a cell, $\frac{1}{5}$ of a millimetre deep. The bottom of this is divided into $\frac{1}{10}$ millimetre squares. Upon the top of the cell rests the cover-glass, which is kept in its place by the pressure of two springs proceeding from the ends of the stage plate." The diluting solution used is a solution of sodic sulphate in distilled water, sp. gr. 1025, or the following—sodic sulphate, 104 grains; acetic acid, 1 drachm; distilled water, 4 oz.

"995 cubic millimetres of the solution are placed in the mixing jar; 5 cubic millimetres of blood are drawn into the capillary tube from the puncture in the finger, and then blown into the solution. The two fluids are well mixed by rotating the stirrer between the thumb and finger, and a small drop of this dilution is placed in the centre of the cell, the covering glass gently put upon the cell, and secured by the two springs, and the plate placed upon the stage of the microscope. The lens is then focused for the squares. In a few minutes the corpuscles have sunk to the bottom of the cell, and are seen at rest on the squares. The number in ten squares is then counted, and this, multiplied by 10,000, gives the number in a cubic millimetre of blood."

FIG. 4.



Gowers' apparatus. A, pipette for measuring the diluting solution; B, capillary tube for measuring the blood; C, cell with divisions on the floor, mounted on a slide; D, vessel in which the dilution is made; E, glass stirrer; F, guarded spear-pointed needle.

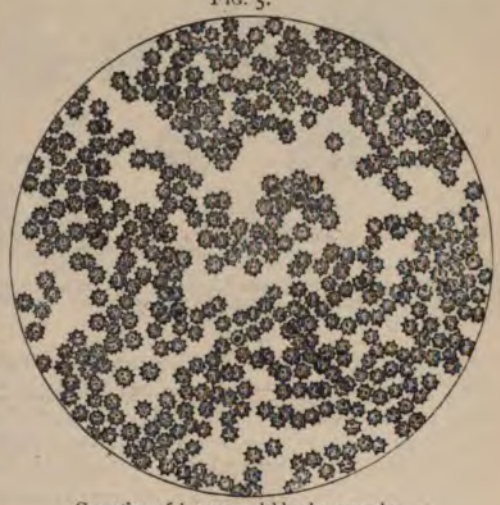
To estimate the **colorless** corpuscles only, mix the blood with 10 parts 0·5 per cent. solution of acetic acid, which destroys all the red corpuscles. (*Thoma*).

(*e*) Red blood corpuscles are characterized by their great **elasticity, flexibility,** and **softness.** [The elastic property is shown by the extent to which red corpuscles while circulating may be distorted, and yet resume their original form as soon as the pressure is removed.]

3. HISTOLOGY OF THE HUMAN RED BLOOD CORPUSCLES.—When observed singly, human red blood corpuscles are bi-concave circular disks of a yellow color with a slight tinge of green; they seem to be devoid of an envelope, are certainly non-nucleated, and appear to be homogeneous throughout. Each corpuscle consists (1) of a framework, an exceedingly pale, transparent, soft protoplasm—the **stroma;** and (2) of the **red pigment,** or hæmoglobin, which impregnates the stroma, much as fluid passes into and is retained in the interstices of a bath sponge.

4. EFFECT OF REAGENTS.—(A) **On their Vital Phenomena.**—The blood corpuscles present in shed blood—or even in defibrinated blood, when it is reintroduced into the circulation—retain their vitality and functions undiminished. **Heat** acts powerfully on their vitality, for if blood be heated to 52° C., the vitality of the red corpuscles is destroyed. Mammalian blood may be kept for four or five days in a vessel under iced water, and still retain its functions; but if it be kept longer, and reintroduced into the circulation, the corpuscles rapidly break up—a proof that they have lost their vitality. The red corpuscles in freshly shed blood sometimes exhibit a peculiar mulberry-like appearance (Figs. 5, 6, *g*, *h*). [This is called **crenation** of the colored corpuscles. It occurs in cases of poisoning with Calabar bean; and also by the addition of a 2 per cent. solution of common salt.] The blood of many persons crenates spontaneously—a condition ascribed to an active contraction of the stroma, but it is doubtful if this is the cause. The red corpuscles of the embryo chick undergo active contraction.

FIG. 5.



Crenation of human red blood corpuscles.

(B) **On their external characters.**—(*a*) The **color** is changed by many gases. O makes blood scarlet, want of O renders it dark bluish-red, CO makes it cherry-red, NO violet-red. There is no difference between the shape of the corpuscles in arterial and venous blood. All reagents (*e. g.*, a concentrated solution of sodic sulphate), which cause great shrinking of the colored corpuscles, produce a very bright scarlet or brick-red color. The red color so produced is quite different from the scarlet-red of arterial blood. Reagents which render blood corpuscles globular darken the blood, *e.g.*, water.

[The contrast is very striking, if we compare blood to which a 10 per cent. solution of common salt has been added with blood to which water has been added. With reflected light the one is bright red, and the other a very dark, deep crimson, almost black.

(*b*) **Formation of Rouleaux.**—A very common phenomenon in shed blood is the tendency of the corpuscles to run into rouleaux (Fig. 1, A, 3).

Conditions that increase the coagulability of the blood favor this phenomenon, which is ascribed by Dogiel to the attraction of the disks and the formation of a sticky substance. [The cause of the formation of rouleaux is by no means clear. The corpuscles may be detached from each other by gently touching the cover-glass, but the rouleaux may re-form. Lister suggested that the surfaces of the corpuscles were so altered that they became adhesive. Norris made experiments with corks weighted with tacks or pins, so as to produce partial submersion of the cork disks. These disks rapidly cohere, owing to capillarity, and form rouleaux. If the disks be completely submerged they remain apart, as occurs with unaltered blood corpuscles within the blood vessels. If, however, the corpuscles be dipped in petroleum, and then placed in water, rouleaux are formed.] If reagents which cause the corpuscles to swell up be added to the blood, the corpuscles become globular and the rouleaux break up. According to E. Weber and Suchard, the uniting medium is not fibrin (although it may sometimes assume a fibrous form), but belongs to the peripheral layer of the corpuscles.

(*c*) **Changes of Form.**—The **discharge of a Leyden jar** causes the corpuscles to crenate, so that their surfaces are beset with coarse or fine projections (Fig. 6, *c*, *d*, *e*, *g*, *h*); it also causes the corpuscles to assume a spherical form (*i*, *i'*),

and they become smaller than normal. The corpuscles so altered are sticky, and run together like drops of oil, forming larger spheres. The prolonged action of the electrical spark causes the hæmoglobin to separate from the stroma (*k*), whereby the fluid part of the blood is reddened, while the stroma is recognizable only as a faint shadow (*l*). Similar forms are to be found in decomposing blood, as well as after the action of many other reagents. **Heat.**—When blood is heated,

FIG. 6.

Red blood corpuscles. *a*, *b*, normal human red corpuscles, the central depression more or less in focus; *c*, *d*, *e*, mulberry, and *g*, *h*, crenated forms; *k*, pale corpuscles decolorized by water; *l*, stroma; *f*, frog's blood corpuscle acted on by a strong saline solution.

on a warm stage, to 52° C. the corpuscles exhibit remarkable changes. Some of them become spherical, others biscuit-shaped; some are perforated, while in others small portions become detached and swim about in the surrounding fluid, a proof that heat destroys the histological individuality of the corpuscles. If the heat be continued, the corpuscles are ultimately dissolved (§ 10, 3).

Heat acts like the addition of a concentrated solution of **urea** to blood. If strong pressure be exerted upon a microscopic preparation, the blood corpuscles may break in pieces. The latter process is called **hæmocytotrypsis**, in contradistinction to that of solution of the corpuscles or **hæmocytolysis**.

If a finger moistened with blood be rapidly drawn across a warm slip of glass, so that the fluid dries rapidly, the corpuscles exhibit very remarkable shapes, showing their great ductility and softness.

Cytozoon—Gaule's Experiment.—A few drops of freshly-shed frog's blood are mixed with 5 c.c. of 0.6 per cent. solution of common salt, and the mixture defibrinated by shaking it along with a few c.c. of mercury. A drop of the defibrinated blood is examined on a hot stage (30°–32° C.) under a microscope, when a protoplasmic mass, the so-called "*Würmchen*," escapes with a lively movement from many corpuscles, and ultimately dissolves. Similar "cytozoa" were discovered by Gaule in the epithelium of the cornea, of the stomach and intestine, in connective tissue, in most of the large glands, and in the retina (frog, triton). In mammals also he found similar but smaller structures. Most probably these structures are parasitic in their nature, as suggested by Ray Lankester, who called the parasite **Drepanidium ranarum.**

[**Staining Reagents.**—Such reagents as magenta, picro-carmine, carmine, and many of the aniline dyes, stain the nucleus deeply when such is present, and although they must traverse the hæmoglobin to reach the nucleus, the hæmoglobin itself is not stained. When no nucleus is present, therefore, the corpuscles are not stained. Magenta causes one or more small spots or maculæ to appear on the edge of the corpuscles (Fig. 7, *a*). What its significance is, is entirely unknown. Normal saline solution (0.6 per cent. NaCl), tinged with methyl violet, is a good staining and preservative agent.]

[**Agitation with Mercury.**—If ox blood be shaken up with mercury for 7 or 8 hours, the corpuscles completely disappear, no trace of stroma or corpuscles being found in the fluid (*Meltzer and Welch*). The addition of pyrogallic acid (20 per cent.) potassic chlorate (6 per cent.), and silver nitrate (3 per cent.), completely prevents dissolution of the corpuscles, even though the shaking be kept up for fourteen days.]

If blood be mixed with concentrated gum solution, and if concentrated salt solution be added to it under the microscope, the corpuscles assume elongated forms. Similar forms are obtained by

mixing blood with an equal volume of gelatine at 36° C., allowing it to cool, and then making sections of the coagulated mass. The corpuscles may be broken up by pressing firmly on the cover-glass. In all these experiments no trace of an envelope around the corpuscles is observed. [An excellent reagent for "fixing" the blood corpuscles is either a dilute solution or the vapor of osmic acid.]

Conservation of the Corpuscles.—In investigating blood with the microscope for **forensic purposes**, it is necessary to have a solvent for the blood when it occurs as stains on a garment or instrument. Dried stains are dissolved by a concentrated, or a 30 per cent. solution of caustic

FIG. 7.

a, *b*, human red blood corpuscles; *a*, acted on by magenta; *b*, by tannic acid. The others are amphibian red blood corpuscles; *c*, *d*, *e*, effect of tannic acid; *f*, of dilute acetic acid; *g*, of dilute alcohol; *d*, by boracic acid.—*Stirling*.

potash, or with one of the preserving fluids. If the stain be softened with concentrated tartaric acid, colorless corpuscles are specially distinct (*Struwe*). Nevertheless, corpuscles are often *not* found in such stains. If the corpuscles have become very pale, their color may be improved by adding a solution of iodide of potassium, a saturated solution of picric acid, 20 per cent. pyrogallic acid, or 3 per cent. solution of silver nitrate.

5. STROMA—LAKE-COLORED BLOOD.—Many reagents cause the hæmoglobin to separate from the stroma. The hæmoglobin dissolves in the serum; the blood becomes dark red and **transparent**, as it contains its coloring matter in solution, and hence it is called "**lake-colored**" (*Rollett*). The aggregate condition of the hæmoglobin is not altered when the corpuscles are dissolved—it only changes its place, leaving the stroma and passing into the serum. Hence, the temperature of the blood is not lowered thereby.

Methods.—To obtain a large quantity of the **stroma for chemical purposes**, add 10 vols. of a solution of common salt (1 vol. concentrated solution, and 15 to 20 vols. of water) to 1 vol. of defibrinated blood, when the stromata are thrown down as a whitish precipitate.

For **microscopical purposes**, mix blood with an equal volume of a concentrated solution of sodic sulphate, and cautiously add a 1 per cent. solution of tartaric acid.

The following reagents cause a separation of the stroma from the hæmoglobin, and thus make blood transparent:—

(*a*) **Physical Agents.**—1. Heating the blood to 60° C. (*Schultze*); the temperature, however, varies for the blood of different animals. 2. Repeated freezing and thawing of the blood (*Rollett*). 3. Sparks from an electrical machine (but not after the addition of salts to the blood) (*Rollett*); the constant and induced currents (*Neumann*).

(*b*) **Chemically active Substances produced within the Body.**—4. Bile (*Hünefeld*), or bile salts (*Plattner, v. Dusch*). 5. Serum of other species or animals (*Landois*); thus dog's serum and frog's serum dissolve the blood corpuscles of the rabbit in a few minutes. 6. The addition of lake-colored blood of many species of animals (*Landois*).

(*c*) **Other Chemical Reagents.**—7. Water. 8. The vapor of chloroform (*Böttcher*); ether (*v. Wittich*); amyls, small quantities of alcohol (*Rollett*); thymol (*Marchand*); nitrobenzol, ethylic ether, aceton, petroleum ether, etc. (*L. Lewin*). 9. Antimoniuretted hydrogen, arseniuretted hydrogen; carbon bisulphide; boracic acid (2 per cent.) added to amphibian blood, causes the red mass (which also encloses the nucleus when such is present), the so-called **zooid**, to separate from the **œcoid** (Fig. 7, *d*). The zooid may shrink from the periphery of the corpuscle, or it may pass out of the corpuscle altogether (*Brücke*); Brücke regards the stroma in a certain sense as a house, in which the remainder of the substance of the corpuscle, the chief part endowed with vital phenomena, lives. 11. Strong solutions of acids dissolve the corpuscles; more dilute solutions cause precipitates in the hæmoglobin. This is easily seen with carbolic acid (*Hüls and Landois, Stirling and Rannie*). 12. Alkalies of moderate strength cause sudden solution. A ten per cent. solution of potash, placed at the edge of a cover-glass, shows the process of solution going on under the microscope. At first the corpuscles become globular, and so appear smaller, but afterward they burst like soda bubbles. [13. NH_4Cl injected into the blood causes vacuolation of the red corpuscles (*Bobritzky*). 14. Sodic salicylate, benzoate and colchicin, dissolve the red corpuscles (*N. Paton*).]

[**Tannic Acid.**—A freshly prepared solution of tannic acid has a remarkable effect on the colored blood corpuscles of man and animals—causing a separation of the hæmoglobin from the stroma (*W. Roberts*). The usual effect is to produce one or more granular buds of hæmoglobin on the side of the corpuscles (Fig. 7, *b*, *c*); more rarely the hæmoglobin collects around the nucleus, if such be present (Fig. 7, *d*), or is extruded, as shown in Fig. 7, *e*.]

[**Ammonium or Potassium Sulpho-cyanide** removes the hæmoglobin, and reveals a reticular structure—*intra-nuclear* plexus of fibrils (*Stirling and Rannie*).]

The **Amount of Gases** in the blood exercises an important influence on their solubility. The corpuscles of venous blood, which contains much CO_2, are more easily dissolved than those of arterial blood; while between both stands blood containing CO. When the gases are completely removed from the blood, it becomes lake-colored.

Salts increase the resistance of the corpuscles to physical means of solution, while they facilitate the action of chemical solvents.

If certain salts be added in substance to blood, they make blood lake-colored; potassic sulphocyanide, sodic chloride, etc. (*Kowalewsky*).

Resistance to Solvents.—The red blood corpuscles offer a certain degree of resistance to the action of solvents.

Method.—Mix a small drop of blood with an equal volume of a 3 per cent. solution of sodic chloride, and then add distilled water until all the colored corpuscles are dissolved. Fill the mixer (Fig. 3) up to the mark 1 with blood obtained by picking the finger, and blow this blood into an equal volume of a 3 per cent. solution of NaCl previously placed in a hollow in a glass slide. Mix the fluids, and the corpuscles will remain undissolved. By means of the pipette add distilled water, and go on doing so until all the corpuscles are dissolved; which is ascertained with the microscope. In normal blood, solution of the corpuscles occurs after 30 volumes of distilled water have been added to the blood (*Landois*).

There are some individuals whose blood is more soluble than that of others; their corpuscles are soft, and readily undergo changes. Many conditions, such as cholæmia, poisoning with substances which dissolve the corpuscles, and a markedly venous condition of the blood, affect the corpuscles. Interesting observations may be made on the blood in infectious diseases, hæmoglobinuria, and in cases of burning. In anæmia and fever, the capacity for resistance seems to be diminished.

6. FORM AND SIZE OF THE BLOOD CORPUSCLES OF ANIMALS.—All mammals (with the exception of the camel, llama, alpaca, and their allies), and the cyclostomata among fishes, *e.g.*, Petromyzon, possess circular, bi-concave, *non-nucleated*, disk-shaped corpuscles. Elliptical corpuscles without a nucleus are found in the above-named mammals, while all birds, reptiles, amphibians (Fig. 1, B, 1, 2), and fishes (except cyclostomata) have *nucleated*, elliptical, bi-convex corpuscles.

Size (μ = 0.001 Millimetre)

Of the Disk-shaped Corpuscles.	Of the Elliptical Corpuscles.	
	Short Diameter.	Long Diameter.
Elephant, ... 9.4 μ	Llama, ... 4.0 μ	8.0 μ
Man, ... 7.7 "	Dove, ... 6.5 "	14.7 "
Dog, ... 7.3 "	Frog, ... 15.7 "	22.3 "
Rabbit, ... 6.9 "	Triton, ... 19.5 "	29.3 "
Cat, ... 6.5 "	Proteus, ... 35.0 "	58.0 "
Sheep, ... 5.0 "		
Goat, ... 4.1 "		
Musk-deer, ... 2.5 "		

The corpuscles of Amphiuma are nearly one-third larger than those of Proteus (*Riddel*).

Among **vertebrates**, amphioxus has colorless blood. The large blood corpuscles of many **amphibia**, *e.g.*, amphiuma, are visible to the naked eye. The blood corpuscles of the frog contain, in addition to a nucleus, a nucleolus (*Auerbach*, *Ranvier*), [and the same is true of the colored corpuscles of the newt (*Stirling*). The nucleolus is revealed by acting on the corpuscles with dilute alcohol (1, alcohol; 2, water; Ranvier's "*alcool au tiers*" (Fig. 7, *g*.).] It is evident that the larger the blood corpuscles are, the smaller must be the number and total superficies of the corpuscles in a given volume of blood. In **birds**, however, the number is relatively larger than in

other classes of vertebrates, notwithstanding the larger size of their corpuscles; this, doubtless, has a relation to the very energetic metabolism that takes place in birds (*Malassez*). Among **mammals**, carnivora have more blood corpuscles than herbivora. Goat's blood contains 9,720,000 corpuscles per cubic millimetre; llama's, 13,000,000; bullfinches, 3,600,000; lizard's, 1,420,000; frog's, 404,000; and that of proteus, 36,000 (*Welcker*). In **hibernating** animals, the number diminishes from 7,000,000 to 2,000,000 per cubic millimetre. No relation exists between the size of the animal and that of its blood corpuscles.

The **invertebrata** generally have colorless blood, with colorless corpuscles; but the earth-worm, and the larva of the large gnats, etc., have red blood whose plasma contains hæmoglobin, while the blood corpuscles themselves are colorless. Many invertebrates possess red, violet, brown or green opalescent blood with colorless corpuscles (amœboid cells). In cephalopods, and some crabs, the blood is blue, owing to the presence of a coloring matter (**hæmocyanin**), which contains copper, and combines with O.

7. ORIGIN OF THE RED BLOOD CORPUSCLES.—(A) **During Embryonic Life.**—Blood corpuscles are developed in the fowl during the first days of embryonic life. [They appear in groups within the large branched cells of the mesoblast, in the vascular area of the blastoderm, outside the developing body of the chick, where they form the "**blood-islands**" of Pander. The mother-cells form an irregular network by the union of the processes of adjoining cells, and meantime the central masses split up, and the nuclei multiply. The small nucleated masses of protoplasm, which represent the blood corpuscles, acquire a reddish hue, while the surrounding protoplasm, and also that of the processes, becomes vacuolated or hollowed out, constituting a branching system of canals; the outer part of the cells remaining with their nuclei to form the walls of the future blood vessels. A fluid appears within this system of branched canals in which the corpuscles lie, and gradually a communication is established with the blood vessels developed in connection with the heart. According to Klein, the nuclei of the protoplasmic wall also proliferate, and give rise to new cells, which are washed away to form blood corpuscles.] At first the corpuscles exhibit amœboid movements, are devoid of pigment, nucleated, globular, larger and more irregular than the permanent corpuscles. They become colored, retain their nucleus, and are capable of undergoing multiplication by division; Remak observed all the stages of the process of *division*, which is best seen from the third to the fifth day of incubation. Increase by division also takes place in the larvæ of the salamander, triton and toad (*Flemming*); and during the intra-uterine life of a mammal, in the spleen, bone-marrow, the liver, and the circulating blood (*Bizzozero*).

Neumann found in the **liver** of the embryo protoplasmic cells containing red blood corpuscles. Cells, some with, others without, hæmoglobin, but with large nuclei, have been found. These cells increase by division, their nucleus shrivels, and they ultimately form blood corpuscles (*Löwit*) The **spleen** is also regarded as a centre of their formation, but this seems to be the case only during embryonic life (*Neumann*). Here the red corpuscles are said to arise from yellow, round, nucleated cells, which represent transition forms. Foa and Salvioli found red corpuscles forming endogenously within large, protoplasmic cells in **lymphatic glands.** In the later period of embryonic life, the characteristic non-nucleated corpuscles seem to be developed from the nucleated corpuscles. The nucleus becomes smaller and smaller, breaks up, and gradually disappears. In the human embryo at the fourth week, only nucleated corpuscles are found; at the third month their number is still $\frac{1}{4}$–$\frac{1}{8}$ of the total corpuscles, while at the end of fœtal life nucleated blood corpuscles are very rarely found. Of course, in animals with nucleated blood corpuscles, the nucleus of the embryonic blood corpuscles remains.

(B) **During Post-Embryonic Life.**—Kölliker assumed that in the tail of the tadpole capillaries are formed by the anastomoses of the processes of branched and radiating connective-tissue corpuscles. These corpuscles lose their nuclei and protoplasm, become hollowed out, join with neighboring capillaries, and thus

form new blood channels. J. Arnold and Golubew oppose this view, asserting that the blood capillaries in the tail of the tadpole give off solid buds at different places, which grow more and more into the surrounding tissues, and anastomose with each other; after their protoplasm and contents disappear they become hollow, and a branched system of capillaries is formed in the tissues. Ranvier noticed the same mode of growth in the omentum of newly-born kittens.

Young rabbits, a week old, have, in their omentum, small white or milk spots (*Ranvier*), in which lie "**vaso-formative cells**," *i. e.*, highly refractive cells of variable shape, with long cylindrical protoplasmic processes (Fig. 8). In its refractive power the protoplasm of these cells resembles that of lymph corpuscles. Long rod-like nuclei lie within these cells (K, K), and also *red blood corpuscles* (*r*, *r*), and both are surrounded with protoplasm. These vaso-formative cells give off protoplasmic processes (*a*, *a*), some of which end free, while others form a network. Here and there elongated connective-tissue corpuscles lie on the branches, and ultimately form the adventitia of the blood vessel. The vaso-formative cells have many forms: they may be elongated cylinders ending in points, or more round and oval, resembling lymph cells, or modified connective-tissue corpuscles. *These cells are always the seat of origin of non-nucleated red blood corpuscles*, which arise in the protoplasm of vaso-formative cells, as chlorophyll grains or starch granules arise within the cells of plants. The corpuscles escape, and are washed into the circulation when the cells, by means of their processes, form connections with the circulatory system. Probably the vessels so formed in the omentum are only temporary. May it not be that there are many other situations in the body where blood is regenerated?

FIG. 8.

Formation of red blood corpuscles within "vaso-formative cells," from the omentum of a rabbit seven days old. *r*, *r*, the formed corpuscles; K, K, nuclei of the vaso-formative cell; *a*, *a*, processes which ultimately unite to form capillaries.

[The observations of Schäfer also prove the **intra-cellular origin** of red blood corpuscles, and although this mode usually ceases before birth, still it is found in the rat at birth. The protoplasm of the subcutaneous **connective-tissue corpuscles**, which are derived from the mesoblast, has in it small colored globules about the size of a colored corpuscle. The mother cells elongate, become pointed at their ends, and unite with processes from adjoining cells. The cells become vacuolated; fluid or plasma, in which the liberated corpuscles float, appears in their interior, and ultimately a communication is established with the general circulation.]

Neumann observed similar formations in the embryonic liver; Wissotzky in the rabbit's amnion; Klein in the embryo chick; and Bayerl in ossifying cartilage. All these observations go to show that at a certain early period of development blood corpuscles are formed within other large cells of the mesoblast, and that part of the protoplasm of these blood-forming cells remains to form the wall of the future blood vessel.

(C) **Later Formation.**—Most observers agree that the red blood corpuscles are formed from special nucleated cells, which gradually assume the form and color of the perfect red corpuscle. According to Neumann, however, these corpuscles are pigmented from the first. In the tailed amphibians and fishes, the **spleen,** in all other vertebrates the **red marrow of bone,** are the seats of formation of these corpuscles, which subsequently increase by division (*Neumann, Rindfleisch, Bizzozero*). In the red marrow of bone we can study all the stages

of the transformation; especially pale contractile cells similar to colorless corpuscles, and also red nucleated corpuscles, which are similar to the nucleated corpuscles of the embryo, and the progenitors of the red corpuscles. These transition cells are said by Erb to be more numerous after severe hemorrhage, the number of them occurring in the blood corresponding with the energy of the formative process. After copious hemorrhage, these transition forms appear in numbers in the blood stream. The small veins, and, perhaps, the capillaries of the red marrow of bone and the spleen have no proper walls, so that the red corpuscles when formed can pass into the circulation.

Red or **blood-forming marrow** occurs in the bones of the skull, and in most of the bones of the trunk, while the bones of the extremities either contain yellow marrow (which is essentially fatty in its nature), or, at most, it is only the heads of the long bones that contain red marrow. Where the blood-regeneration process is very active, however, the yellow marrow may be changed into red, even throughout all the bones of the extremities (*Neumann*).

8. DECAY OF THE RED BLOOD CORPUSCLES.—The blood corpuscles undergo decay within a limited time, and the **liver** is regarded as one of the chief places in which their disintegration occurs, because bile pigments are formed from hæmoglobin, and the blood of the hepatic vein contains fewer red corpuscles than the portal vein.

The **splenic pulp** contains cells which indicate that colored corpuscles are broken up within it. These are the so-called "blood-corpuscle-containing cells" (§ 102). Quincke's observations go to show that the red corpuscles—which may live from three to four weeks—when about to disintegrate, are taken up by the white blood corpuscles in the hepatic capillaries, by the cells of the spleen and the bone marrow, and are stored up chiefly in the **capillaries of the liver**, in the **spleen**, and in the **marrow of bone.** They are transformed, partly into colored, and partly into colorless proteids which contain iron, and are either deposited in a granular form, or are dissolved. Part of the products of decomposition is used for the formation of new blood corpuscles in the marrow and in the spleen, and also perhaps in the liver, while a portion of the iron is excreted by the liver in the bile.

That the normal red blood corpuscles and other particles suspended in the blood stream are not taken up in this way, may be due to their being smooth and polished. As the corpuscles grow older and become more rigid, they, as it were, are caught by the amœboid cells. As cells containing blood corpuscles are very rarely found in the general circulation, one may assume that the occurrence of these cells within the spleen, liver, and marrow of bone is favored by the slowness of the circulation in these organs (*Quincke*).

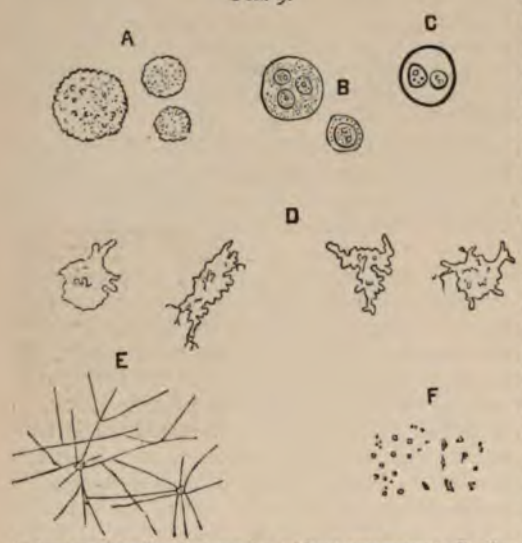
Pathological.—In certain pathological conditions, ferruginous substances derived from the red blood corpuscles are found in masses in the spleen, the marrow of bone, and the capillaries of the liver: (1) When the disintegration of blood corpuscles is increased, as in anæmia (*Stahel*). (2) When the formation of red blood corpuscles from the old material is diminished. If the excretion from the liver cells be prevented, iron accumulates within them; it is also more abundant in the blood serum, and it may even accumulate in the secretory cells of the cortex of the kidney and pancreas, in gland cells, and in the tissue elements of other organs. When the amount of blood in dogs is greatly increased, after four weeks an enormous number of granules containing iron occur in the leucocytes of the liver capillaries, the cells of the spleen, bone-marrow, lymph glands, liver cells, and the epithelium of the cortex of the kidney. The iron reaction in the last two situations occurs after the introduction of hæmoglobin, or of salts of iron into the blood (*Glaevecke, v. Stark*).

When we reflect how rapidly large quantities of blood are replaced after hemorrhage and after menstruation, it is evident that there must be a brisk manufactory somewhere. As to the number of corpuscles which daily decay, we have in some measure an index in the amount of bile pigment and urine pigment resulting from the transformation of the liberated hæmoglobin (§ 20).

9. COLORLESS CORPUSCLES, BLOOD PLATES AND GRANULES.—White Blood Corpuscles.—Blood, like many other tissues, contains a number of cells or corpuscles which reach it from without; the corpuscles

vary somewhat in form, and are called **colorless or white blood corpuscles**, or "**leucocytes**" (*Hewson*, 1770). Similar corpuscles are found in lymph, adenoid tissue, marrow of bone, and as wandering cells or leucocytes in connective tissue, and also between glandular and epithelial cells. So that these corpuscles are by no means peculiar to blood alone. They all consist of more or less spherical masses of protoplasm, which is sticky, highly refractile, soft, capable of movement, and devoid of an envelope (Fig. 9). When they are quite fresh (A) it is difficult to detect the nucleus, but after they have been shed for some time, or after the addition of water (B), or acetic acid, the nucleus (which is usually a compound one) appears; acetic acid clears up the perinuclear protoplasm, and reveals the presence of the nuclei, of which the number varies from one to four, although generally three are found. The subsequent addition of magenta solution causes the nuclei to stain deeply. Water makes the contents more turbid, and causes the corpuscles to swell up. One or more nucleoli may be present in the nucleus. The **size** of the corpuscles varies from 4–13 μ, and as a rule they are about $\frac{1}{2500}$ of an inch in diameter; in the smallest forms the layer of the protoplasm is extremely thin. They all exhibit **amœboid movements** which are very apparent in the larger corpuscles, and were discovered by Wharton Jones in the skate (1846), and by Davine in the corpuscles of man (1850). Max Schultze describes three different forms in **human blood**:—

FIG. 9.



A, human white blood corpuscles, without any reagent; B, after the action of water; C, after acetic acid; D, frog's corpuscles, changes of shape due to amœboid movement; E, fibrils of fibrin from coagulated blood; F, elementary granules.

(1) The smallest, spherical forms, less than the red corpuscles, with one or two nuclei, and a very small amount of protoplasm.

(2) Spherical forms, the same size as the colored blood corpuscles.

(3) The large amœboid corpuscles, with much protoplasm and distinctly evident movements.

[On examining human blood microscopically, more especially after the colored blood corpuscles have run into rouleaux, the colorless corpuscles may readily be detected, there being usually three or four of them visible in the field at once. They adhere to the glass slide, for if the cover-glass be moved, the colored corpuscles readily glide over each other, while the colorless can be seen still adhering to the slide.]

[**White Corpuscles of Newt's Blood.**—The characters of the colorless corpuscles are best studied in a drop of newt's blood, which contains the following varieties:—

(1) **The large, finely granular corpuscle**, which is about $\frac{1}{100}$ of an inch in diameter, irregular in outline, with fine processes or pseudopodia projecting from its surface. It rapidly changes its shape at the ordinary temperature, and in its interior a bi- or tri-partite nucleus may be seen, surrounded with fine granular protoplasm, whose outline is continually changing. Sometimes *vacuoles* are seen in the protoplasm.

(2) **The coarsely granular variety** is less common than the first-mentioned, but when detected its characters are distinct. The protoplasm contains, besides a nucleus, a large number of highly refractive granules, and the corpuscle usually exhibits active amœboid movements; suddenly the granules may be seen to rush from one side of the corpuscle to the other. The processes are

usually more blunt than those emitted by (1). The relation between these two kinds of corpuscles has not been ascertained.

(3) **The small colorless corpuscles** are more like the ordinary human colorless corpuscle, and they, too, exhibit amœboid movements.]

Two kinds of colorless corpuscles like (1) and (2) exist in **frog's blood**. In the coarsely granular corpuscles the glancing granules may be of a fatty nature, since they dissolve in alcohol and ether, but other granules exist which are insoluble in these fluids. The nature of the latter is unknown. Very large colorless corpuscles exist in the axolotl's blood.

[**Action of Reagents.**—(*a*) **Water,** when added slowly, causes the colorless corpuscles to become globular, and the granules within them to exhibit Brownian movements. (*b*) **Pigments,** such as magenta or carmine, stain the nuclei very deeply, and the protoplasm to a less extent. (*c*) **Dilute Acetic Acid** clears up the surrounding protoplasm and brings clearly into view the composite nucleus, which may be stained thereafter with magenta. (*d*) **Iodine** gives a faint port-wine color, especially in horse's blood, indicating the presence of glycogen. (*e*) **Dilute Alcohol** causes the formation of clear blebs on the surface of the corpuscles, and brings the nuclei into view (*Ranvier, Stirling*).]

FIG. 10.

Plexus of fibrils in a colorless blood corpuscle.

[A delicate plexus of the fibrils—**intra-nuclear plexus**—exists within the nucleus, just as in other cells. It is very probable that the protoplasm itself is pervaded by a similar plexus of fibrils, and that it is continuous with the intra-nuclear plexus (Fig. 10).] The colorless corpuscles divide, and in this way reproduce themselves.

The Number of Colorless Corpuscles is very much less than that of the red corpuscles, and is subject to considerable variations. It is certain that the colorless corpuscles are *very much fewer in shed blood* than in blood still within the circulation. Immediately after blood is shed, an enormous number of white corpuscles disappear (§ 31).

Al. Schmidt estimates the number that remain at $\frac{1}{10}$ of the whole originally present in the circulating blood. The proportion is greater in children than in adults. The following table gives the number in shed blood:—

Number of White in Proportion to Red Blood Corpuscles:—		
In Normal Conditions.	In Different Places.	In Different Conditions.
1 : 335 (*Welcker*). 1 : 357 (*Moleschott*).	Splenic Vein, 1 : 60 Splenic Artery, 1 : 2260 Hepatic Vein, 1 : 170 Portal Vein, 1 : 740 Generally more numerous in Veins than Arteries.	*Increased* by Digestion, Loss of Blood, Prolonged Suppuration, Parturition, Leukæmia, Quinine, Bitters. *Diminished* by Hunger, Bad Nourishment.

[The number also varies with the **Age** and **Sex**:—

Age. Sex.	White. Red.	General Conditions.	White. Red.
Girls, ...	1 : 405	While fasting, ...	1 : 716
Boys, ...	1 : 226	After a meal, ...	1 : 347
Adults, ...	1 : 335	During pregnancy, . . .	1 : 281]
Old Age, ...	1 : 381		

II. **The amœboid movements** of the white corpuscles (so called because they resemble the movements of amœba) consist in an alternate contraction and relax-

ation of the protoplasm surrounding the nucleus. Processes are given off from the surface, and are retracted again. There is an *internal current* in the protoplasm, and the nucleus has also been observed to change its form [and exhibit contractions without the corpuscle dividing. The karyokinetic aster, and convolution of the intranuclear plexus have been seen.] Two series of phenomena result from these movements: (1) The "**wandering**" or locomotion of the corpuscles due to the extension and retraction of their processes; (2) the **absorption of small particles** into their interior (fat, pigment, foreign bodies). The particles adhere to the sticky external surface, are carried into the interior by the internal currents, and may eventually be excreted, just as particles are taken up by amœba and the effete particles excreted. [Max Schultze observed that colored particles were readily taken up by these corpuscles. **Conditions for movement.**—In order that the amœboid movements of the leucocytes may take place, it is necessary that there be—(1) a certain temperature and normal atmospheric pressure; (2) the surrounding medium, within certain limits, must be "indifferent," and contain a sufficient amount of water and oxygen; (3) there must be a basis or support to move on.]

FIG 11.

Human leucocytes, showing amœboid movements.

Struggle between Microbes and the Organism.—Metschnikoff emphasizes the activity of the leucocytes in retrogressive processes, whereby the parts to be removed are taken up by them in fine granules, and, as it were, are "*eaten*." Hence, he calls such cells "**phagocytes.**" They may be found in the atrophied tails of batrachians, the cells containing in their interior whole pieces of nerve fibre and primitive muscular bundles. Schizomycetes which have found their way into the blood (§ 183) have been found to be partly taken up by the colorless corpuscles. [The spores of a kind of yeast are similarly attacked in the transparent tissues of the water flea by the leucocytes, and the connective-tissue cells also destroy microbes.]

Effect of Reagents.—On a hot stage (35°–40° C.) the colorless corpuscles of **warm-blooded animals** retain their movements for a long time; at 40° C. for two to three hours; at 50° C. the proteids are coagulated and cause "**heat rigor**" and death [when their movements no longer recur on lowering the temperature]. In **cold-blooded animals** (frogs), colorless corpuscles may be seen to crawl out of small coagula, in a moist chamber, and move about in the serum. [Draw a drop of newt's blood into a capillary tube, seal up the ends of the latter and allow the blood to coagulate. After a time, examine the tube in clove oil, when some of the colorless corpuscles will be found to have made their way out of the clot.] **Induction shocks** cause them to withdraw their processes and become spherical, and, if the shocks be not too strong, their movements recommence. Strong and continued shocks kill them, causing them to swell up, and completely disintegrating them.

Diapedesis.—These amœboid movements are of special interest on account of the "wandering out" (diapedesis) of colorless blood corpuscles through the walls of the blood vessels (§ 95).

[**Effect of Drugs.**—**Acids** and **Alkalies**, if very dilute, at first increase, but afterward arrest their movements. **Sodic chloride** in a 1 per cent. solution at first accelerates their movements, but afterward produces a tetanic contraction, and, it may be, expulsion of any food particles they contain. The **Cinchona alkaloids**—quinine, quinidine, cinchonidine (1 : 1500)—quickly arrest the locomotive movements, as well as the protrusion of pseudopodia, although the leucocytes of different animals vary somewhat in their resistance to the action of drugs. Quinine not only arrests the movements of the leucocytes when applied to them directly, but when injected into the circulation of a frog the leucocytes no longer pass through the walls of the capillaries (*Binz*).

The chyle contains leucocytes, which are more resistant than those of the blood, but less so than those of the coagulable transudations. The leucocytes of the lymphatic glands may also be dissolved (*Rauschenbach*).

Relation to Aniline Pigments.—Ehrlich has observed a remarkable relation of the white corpuscles to *acid* (eosin, picric acid, aurantia), *basic* (dahlia, acetate of rosanilin), or *neutral* (picrate of rosanilin) reactions. The smallest protoplasmic granules of the cells have different chemical affinities for these pigments. Thus Ehrlich distinguishes "eosinophile," "basophile," and "neutrophile" granules within the cells. Eosinophile granules occur in the leucocytes which come from bone marrow, the myelogenic leucocytes. The small leucocytes, *i. e.*, those about the size of a colored blood corpuscle or slightly larger, are formed in the lymphatic glands, the lymphogenic. The large amœboid multi-nucleated cells, which are found outside the vessels in inflammations, exhibit a neutrophile reaction. Their origin is unknown, and so is that of the large uni-nucleated cells, and the large cells with constricted nuclei. The eosinophile corpuscles are considerably increased in leukæmia. The *basophile* granules occur also in connective-tissue corpuscles, especially in the neighborhood of epithelium; they are always greatly increased where chronic inflammation occurs.

III. **Blood Plates.**—Special attention has recently been directed to a *third* element of the blood, the "**blood plates**" or "**blood tablets**" of Bizzozero; pale, colorless, oval, round, or lenticular disks of variable size (mean, 3 μ). In

FIG. 12.

"Blood plates" and their derivatives. 1, a red blood corpuscle on the flat; 2, on the side; 3, unchanged blood plates; 4, lymph corpuscle, surrounded by blood plates; 5, altered blood plates; 6, lymph corpuscle with two heads of fused blood plates and threads of fibrin; 7, group of fused blood plates; 8, small group of partially dissolved blood plates with fibrils of fibrin.

a healthy man Fusari found 18,000 to 250,000 in 1 cubic millimetre of blood. These blood plates may be recognized in the circulating blood of the mesentery of a chloralized guinea-pig and the wing of the bat. They are precipitated in enormous numbers upon threads suspended in fresh shed blood. They may be obtained from blood flowing directly from a blood vessel, on mixing it with 1 per cent. solution of osmic acid. They rapidly change in shed blood (Fig. 12, 5), disintegrating, forming small particles, and ultimately dissolving. When several occur together they rapidly unite, form small groups (7), and collect into finely granular masses. These masses may be associated in coagulated blood with fibrils of fibrin (Fig. 12).

[These blood plates are best seen in the shed blood of the guinea-pig, especially if it be mixed with a solution of sodic sulphate (sp. gr. 1022) or ¾ per cent. NaCl tinged with methyl-violet. Bizzozero regards them as the agents which immediately induce coagulation and take part in the formation of fibrin during coagulation of the blood; Eberth and Schimmelbusch ascribe the initial formation of white thrombi to them. According to Löwit they are formed from partially disintegrated leucocytes, as a consequence of alteration of the blood. Along with the leucocytes they are concerned in the formation of fibrin (*Hlava*). These structures were known to earlier observers; but their significance has been variously interpreted. Hayem called them **hæmatoblasts.** Halla

found that they increased in pregnancy, Afanassiew in conditions of regeneration of the blood, and Fusari in febrile anæmia; they are diminished in fever.

[As to the **hæmatoblasts**, or, as they have also been called, the "globules of Donné" by Pouchet, there seems to be some confusion, for both colored and colorless granules are described under these names. As Gibson suggests, the former are, perhaps, parts of disintegrated colored corpuscles, while the latter are the blood plates. The "invisible blood corpuscles" described by Norris seem to be simply decolorized red corpuscles (*Hart, Gibson*).]

IV. **Elementary Granules.**—Blood contains **elementary granules** (Fig. 9, F), [*i.e.*, the elementary particles of Zimmermann and Beale. They are irregular bodies, much smaller than the ordinary corpuscles, and appear to consist of masses of protoplasm detached from the surface of leucocytes, or derived from the disintegration of these corpuscles, or of the blood plates. Others, again, are completely spherical granules, either consisting of some proteid substance or fatty in their nature. The protoplasmic and the proteid granules disappear on the addition of acetic acid, while the fatty granules (which are most numerous after a diet rich in fats) dissolve in ether].

V. In **coagulated blood**, delicate threads of **fibrin** (Figs. 9, E, and 12, 6, 7, 8) are seen, more especially after the corpuscles have run into rouleaux. At the nodes of these fibres are found granules which closely resemble those described under III.

[When the blood-forming process is particularly active, "**nucleated colored corpuscles**" or the "corpuscles of Neumann," are sometimes found in the blood. They are identical with the nucleated colored blood corpuscles of the fœtus, being somewhat larger than the non-nucleated colored corpuscle (§ 7).]

10. **ABNORMAL CHANGES OF THE BLOOD CORPUSCLES.**—(1) **Hemorrhages diminish the number** of red corpuscles (at most one-half), and so does **menstruation.** The loss is partly covered by the absorption of fluid from the tissues. Menstruation shows us that a moderate loss of red corpuscles is replaced within twenty-eight days. When a large amount of blood is lost, so that all the vital processes are lowered, the time may be extended to five weeks. In **acute fevers**, as the temperature increases, the number of *red* corpuscles *diminishes*, while the *white* corpuscles *increase* in number. By greatly cooling peripheral parts of the body, as by keeping the hands in iced water, in some individuals possessing red blood corpuscles of low resisting power, these corpuscles are dissolved, the blood plasma is reddened, and even hæmoglobinuria may occur (§ 265).

Diminished production of new red corpuscles causes a decrease, since blood corpuscles are continually being used up. In **chlorotic females** there seems to be a congenital weakness in the blood-forming and blood-propelling apparatus, the cause of which is to be sought for in some faulty condition of the mesoblast. In them the heart and the blood vessels are small, and the absolute number of corpuscles may be diminished one-half, although the *relative* number may be retained, while in the corpuscles themselves the hæmoglobin is diminished almost one-third; but it rises again after the administration of iron (*Hayem*). The administration of iron increases the amount of hæmoglobin in the blood. [The action of iron in anæmic persons has been known since the time of Sydenham. Hayem also finds in certain forms of anæmia that there is considerable variation in the *size* of the red corpuscles, and that in chronic anæmia the mean diameter of the corpuscles is always less than normal (7 μ to 6 μ). There is, moreover, a persistent alteration in the *volume*, *coloring power*, and *consistence* of the corpuscles, consequently a want of accord between the *number* of the corpuscles and their coloring power, *i.e.*, the amount of hæmoglobin which they contain. In **pernicious anæmia**, in which the continued decrease in the red corpuscles may ultimately produce death, there is undoubtedly a severe affection of the blood-forming apparatus. The corpuscles assume many *abnormal* and bizarre forms, often being oval or tailed, irregularly shaped, and sometimes very pale; while numerous cells containing blood-corpuscles are found in the marrow of bone. In this disease, although the red blood corpuscles are diminished in number, some may be larger and contain more hæmoglobin than normal corpuscles. The number of colored corpuscles is also diminished in chronic poisoning by lead or miasmata, and also by the poison of syphilis.

(2) The **size** of the corpuscles varies in **disease** from 2.9–12.9 μ (mean 6–8 μ); "dwarf corpuscles" or **microcytes** (6 μ and less) are regarded as young forms, and occur plentifully in nearly all cases of anæmia. "Giant blood corpuscles" or **macrocytes** (10 μ and more) are constant in pernicious anæmia, and sometimes in leukæmia, chlorosis, and liver cirrhosis (*Gram*).

(3) **Abnormal forms** of the red corpuscles have been observed after severe **burns** (*Lesser*); the corpuscles are much smaller, and under the influence of the heat, particles seem to be detached from them just as can be seen happening under the microscope as the effect of heat. **Disintegra-**

tion of the corpuscles into fine droplets has been observed in various diseases, as in severe malarial fevers. The dark granules of a pigment closely related to hæmatin are derived from the granules arising from the disintegration of the blood corpuscles, and these particles float in the blood (**melanæmia**). This condition can be produced artificially by injecting bisulphide of carbon (7 to 70 of oil) subcutaneously into rabbits (*Schwalbe*). They are partly absorbed by the colorless corpuscles, but they are also deposited in the spleen, liver, brain, and bone marrow.

(4) Sometimes the red corpuscles are abnormally **soft**, and readily yield to pressure.

Parasites of Blood Corpuscles.—Within the red blood corpuscles of birds, fishes, and tortoises, parasites are occasionally developed in the form of round "pseudo-vacuoles" from which free parasites are subsequently discharged (*Danilewsky*). In malarial conditions in man, protozoon-like organisms have been seen within the red corpuscles, the plasmodium malariæ (*Marchiafava*).

The white corpuscles are enormously increased in number in **leukæmia** (*J. H. Bennett, Virchow*). In some cases the blood looks as if it were mixed with milk. The colorless corpuscles seem to be formed chiefly in bone-marrow (*E. Neumann*), and also in the spleen and lymphatic glands (myelogenic, splenic, and lymphatic leukæmia).

11. CHEMICAL CONSTITUENTS OF THE RED BLOOD CORPUSCLES.—(1) **The coloring matter or hæmoglobin** (Hb) is the cause of the red color of blood; it also occurs in muscle, and in traces in the fluid part of blood, but in the last case only as the result of the solution of some red corpuscles. Its **percentage composition** is: C 53.85, H 7.32, N 16.17, Fe 0.42, S 0.39, O 21.84 (dog). Its rational formula is unknown, but Preyer gives the empirical formula C_{600}, H_{960}, N_{154}, Fe, S_3, O_{179}. Although it is a colloid substance it **crystallizes** in all classes of vertebrates, according to the rhombic system, and chiefly in rhombic plates or prisms; in the guinea-pig in rhombic tetrahedra; in the squirrel, however, it yields hexagonal plates. The varying forms, perhaps, correspond to slight differences in the chemical composition in different cases. Crystals separate from the blood of all classes of vertebrata during the slow evaporation of lake-colored blood, but with varying facility (Fig 13).

FIG. 13.

Hæmoglobin crystals from blood. *a*, *b*, human; *c*, cat; *d*, guinea-pig; *e*, hamster; *f*, squirrel.

The coloring matter crystallizes very readily from the blood of man, dog, mouse, guinea-pig, rat, cat, hedgehog, horse, rabbit, birds, fishes; with difficulty from that of the sheep, ox, and pig. Colored crystals are not obtained from the blood of the frog. More rarely a crystal is formed from a single corpuscle enclosing the stroma. Crystals have been found near the nucleus of the large corpuscles of fishes, and in this class of vertebrates colorless crystals have been observed.

Dichroism.—Hæmoglobin crystals are **doubly refractive** and **pleo-chromatic**; they are bluish-red with transmitted light, scarlet-red by reflected light. They contain from 3 to 9 per cent. water of crystallization, and are soluble in water, but more so in dilute alkalies. They are insoluble in alcohol, ether, chloroform, and fats. The solutions are dichroic: red in reflected light, and green in transmitted light.

In the act of crystallization the hæmoglobin seems to undergo some internal change. Before it crystallizes it does not diffuse like a true colloid, and it also rapidly decomposes hydric peroxide. If it be redissolved after crystallization, it diffuses, although only to a small extent, but it no longer decomposes hydric peroxide, and is decolorized by it. [The presence of O favors crystallization.]

12. PREPARATION OF HÆMOGLOBIN CRYSTALS.—Method of Rollett.—Put defibrinated blood in a platinum capsule placed on a freezing mixture, freeze the blood, and then thaw it; pour the lake-colored blood into a plate, until it forms a stratum not more than 1½ mm. in thickness, and allow it to evaporate slowly in a cool place, when crystals will separate.

Method of Hoppe-Seyler.—Mix defibrinated blood with 10 volumes of a 20 per cent. salt solution, and allow it to stand for two days. Remove the clear upper fluid with a pipette, wash

the thick deposit of blood corpuscles with water, and afterward shake it for a long time with an equal volume of ether, which dissolves the blood corpuscles. Remove the ether, filter the lake-colored blood, add to it ¼ of its volume of cold alcohol (0°), and allow the mixture to stand in the cold for several days. The numerous crystals can be collected on a filter and pressed between folds of blotting paper.

Method of Gscheidlen.—Take defibrinated blood, which has been exposed for twenty-four hours to the air, and keep in a closed tube of narrow calibre for several days at 37° C. When the blood is spread on glass, the crystals form rapidly. [Vaccine tubes answer very well.]

[**Method of Stirling and Brito.**—It is in many cases sufficient to mix a drop of blood with a few drops of water on a glass slide, and to seal up the preparation. After a few days beautiful crystals are developed. The addition of water to the blood of some animals, such as the rat and the guinea-pig, is rapidly followed by the formation of crystals of hæmoglobin. Very large crystals may be obtained from the stomach of the leech several days after it has sucked blood.]

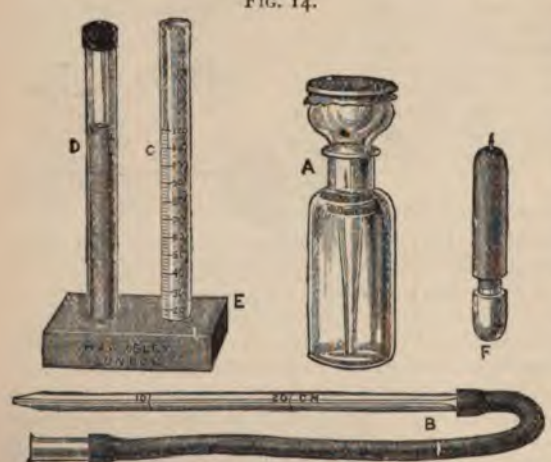
13. QUANTITATIVE ESTIMATION OF HÆMOGLOBIN.—(*a*) **From the Amount of Iron.**—As dry (100° C.) hæmoglobin contains 0.42 per cent. of iron, the amount of hæmoglobin may be calculated from the amount of iron. If m represents the percentage amount of metallic iron, then the percentage of hæmoglobin in blood is $= \frac{100\,m}{0.42}$. The procedure is the following: Calcine a weighed quantity of blood, and exhaust the ash with HCl to obtain ferric chloride, which is transformed into ferrous chloride. The solution is then titrated with potassic permanganate.

(*b*) **Colorimetric Method.**—Prepare a dilute watery solution of hæmoglobin crystals of a known strength. With this compare an aqueous dilution of the blood to be investigated, by adding water to it until the color of the test solution is obtained. Of course, the solutions must be compared in vessels with parallel sides and of exactly the same width, so as to give the same thickness of fluid (*Hoppe-Seyler*). [In the vessel with parallel sides, or **hæmatinometer**, the sides are exactly 1 centimetre apart. Instead of using a standard solution of oxyhæmoglobin, a solution of picro-carminate of ammonia may be used (*Rajewsky*, *Malassez*).]

(*c*) **By the Spectroscope.**—Preyer found that an 0.8 per cent. watery solution (1 cm. thick), allowed the red, the yellow, and the first strip of green to be seen (Fig. 17, 1). Take the blood to be investigated (about 0.5 c.cm.), and dilute it with water until it shows exactly the same optical effects in the spectroscope. If k is the percentage of Hb, which allows green to pass through (0.8 per cent.), b, the volume of blood investigated (about 0.5 c.cm.), w, the necessary amount of water added to dilute it, then x = the percentage of Hb in the blood to be investigated—

$$x = \frac{k(w + b)}{b}.$$

FIG. 14.



Gowers' hæmoglobinometer. A, pipette bottle for distilled water; B, capillary pipette; C, graduated tube; D, tube with standard dilution; F, lancet for pricking the finger.

It is very convenient to add a drop of caustic potash to blood and then to saturate it with CO.

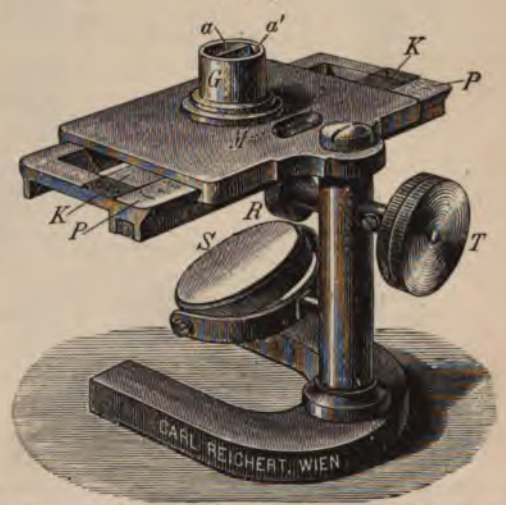
[(*d*) The **Hæmoglobinometer** of Gowers is used for the clinical estimation of hæmoglobin (Fig. 14). "The tint of the dilution of a given volume of blood with distilled water is taken as the index of the amount of hæmoglobin. The distilled water rapidly dissolves out all the hæmoglobin, as is shown by the fact that the tint of the dilution undergoes no change on standing. The color of a dilution of average normal blood one hundred times is taken as the standard. The quantity of hæmoglobin is indicated by the amount of distilled water needed to obtain the tint with the same volume of blood under examination as was taken of the standard. On account of the instability of a standard dilution of blood, tinted glycerine jelly is employed instead. This is perfectly stable, and by means of carmine and picro-carmine the exact tint of diluted blood can be obtained. The apparatus consists of two glass tubes of exactly the same size. One contains (D) a standard of the tint of a dilution of 20 cubic mm. of blood, in cubic centimetres of water (1 in 100). The second tube (C) is graduated, 100 degrees = 2

centimetres (100 times 20 cubic millimetres). The 20 cubic millimetres of blood are measured by a capillary pipette (B). This quantity of the blood to be tested is ejected into the bottom of the tube, a few drops of distilled water being first placed in the latter. The mixture is rapidly agitated to prevent the coagulation of the blood. The distilled water is then added drop by drop (from the pipette stopper of a bottle (A) supplied for that purpose), until the tint of the dilution is the same as that of the standard, and the amount of water which has been added (*i. e.*, the degree of dilution) indicates the amount of hæmoglobin."

"Since average normal blood yields the tint of the standard at 100 degrees of dilution, the number of degrees of dilution necessary to obtain the same tint with a given specimen of blood is the percentage proportion of the hæmoglobin contained in it, compared to the normal. For instance, the 20 cubic millimetres of blood from a patient with anæmia gave the standard tint of 30 degrees of dilution. Hence it contained only 30 per cent. of the normal quantity of hæmoglobin. By ascertaining with the hæmacytometer the corpuscular richness of the blood, we are able to compare the two. A fraction, of which the numerator is the percentage of hæmoglobin, and the denominator the percentage of corpuscles, gives at once the average value per corpuscle. Thus the blood mentioned above containing 30 per cent. of hæmoglobin, contained 60 per cent. of corpuscles; hence the average value of each corpuscle was $\frac{30}{60}$ or $\frac{1}{2}$ of the normal. Variations in the amount of hæmoglobin may be recorded on the same chart as that employed for the corpuscles. The instrument is only expected to yield approximate results, accurate within 2 or 3 per cent. It has, however, been found of much utility in clinical observation."]

(*e*) **Fleischl's Hæmometer.**—For **clinical purposes** this instrument (Fig. 15) is useful. A cylinder G, of two compartments *a* and *a'*, rests on a metallic table. Both compartments are filled with water, but in one (*a*) is placed a known quantity of blood measured in a measuring tube of known capacity. The red color of the solution of hæmoglobin thus obtained is compared with a red wedge of glass (K), which is moved by means of a wheel (R and T) under the other compartment (*a'*) until the two colors are identical. The illumination of the dilute blood solution and the red glass wedge is done from below by lamp light reflected from the white reflecting surface (S). The frame in which the red glass wedge is fixed bears numbers, and when the color is identical in the two compartments *a* and *a'*, the percentage of hæmoglobin as compared with normal blood can be read off directly. Suppose it to be 80 on the scale, then the blood examined contains 80 per cent. of the hæmoglobin of normal blood.

FIG. 15.



V. Fleischl's hæmometer. K, red colored wedge of glass moved by R; G, mixing vessel with two compartments *a* and *a'*; M, table with hole to read off the percentage of hæmoglobin on the scale P; T, to move K; S, mirror of plaster-of-Paris.

The **amount** of hæmoglobin in man is 13.77 per cent., in the woman 12.59 per cent., during pregnancy 9 to 12 per cent. (*Preyer*). According to Leichtenstern, Hb is in greatest amount in the blood of a newly-born infant, but after ten weeks the excess disappears. Between six months and five years it is smallest in amount; it reaches its second highest maximum between twenty-one and forty-five, and then sinks again. From the tenth year onward, the blood of the female is poorer in Hb. The taking of food causes a temporary decrease of the Hb, owing to the dilution of the blood.

In Animals.—In the dog, 9.7; ox, 9.9; sheep, 10.3; pig, 12.7; horse, 13.1; birds, 16–17 per cent.
Pathological.—A decrease is observable during recovery from febrile conditions, and also during phthisis, cancer, ulcer of the stomach, cardiac disease, chronic diseases, chlorosis, leukæmia, pernicious anæmia, and during the rapid mercurial treatment of syphilitic persons.

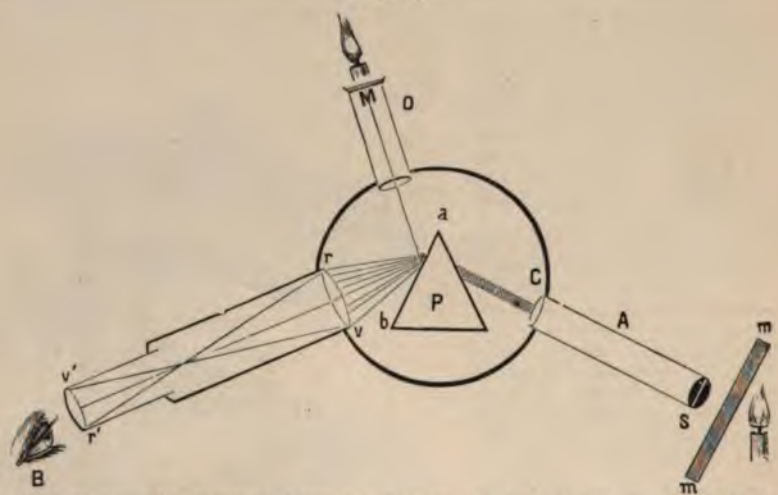
14. **THE SPECTROSCOPE.**—As the spectroscope is frequently used in the investigation of blood and other substances, a short description of the instrument is given here (Fig. 16). It

consists of—(1) a tube, A, which has at its peripheral end a **slit**, S (that can be narrowed or widened). At the other end a collecting lens, C (called a **collimator**), is placed, so that its focus is in exact line with the slit. Light (from the sun or a lamp) passes through the slit, and thus goes parallel through C to (2) the **prism**, P, which decomposes the parallel rays into a colored spectrum, *r*, *v*. (3) An astronomical **telescope** is directed to the spectrum *r*, *v*, and the observer, B, with the aid of the telescope, sees the spectrum magnified from six to eight times. (4) A third tube, D, contains a delicate **scale**, M, on glass, whose image, when illuminated, is reflected from the prism to the eye of the observer, so that he sees the spectrum, and over or above it the scale. To keep out other rays of light the inner ends of the three tubes are covered by metal or by a dark cloth (see also § 265).

[The **micro-spectroscope**, *e.g.*, as made by Browning or Zeiss, may be used when small quantities of a solution are to be examined. Every spectroscope ought to give two spectra, so that the position of any absorption band may be definitely ascertained. The spectroscope is fitted into the ocular end of the tube of a microscope instead of the eye-piece. Small cells for containing the fluid to be examined are made from short pieces of barometer tubes cemented to a plate of glass.]

Absorption Spectra.—If a colored medium (*e.g.*, a solution of blood) be placed between the slit and a source of light, all the rays of colored light do not pass through it—some are absorbed; many yellow rays are absorbed by blood, hence that part of the spectrum appears dark to the observer. On account of this absorption, such a spectrum is called an "*absorption spectrum*."

FIG. 16.



Scheme of a spectroscope for observing the spectrum of blood. A, tube; S, slit; *m*, *m*, layer of blood with flame in front of it; P, prism; M, scale; B, eye of observer looking through a telescope; *r*, *v*, spectrum.

Flame Spectra.—If mineral substances be burned on a platinum wire in a *non-luminous* flame or Bunsen's burner in front of the slit, the elements present in the mineral or ash give special colored band or bands, which have a definite position. Sodium gives a yellow, potassium a red and violet line. These substances are found on burning the ashes of almost all organs.

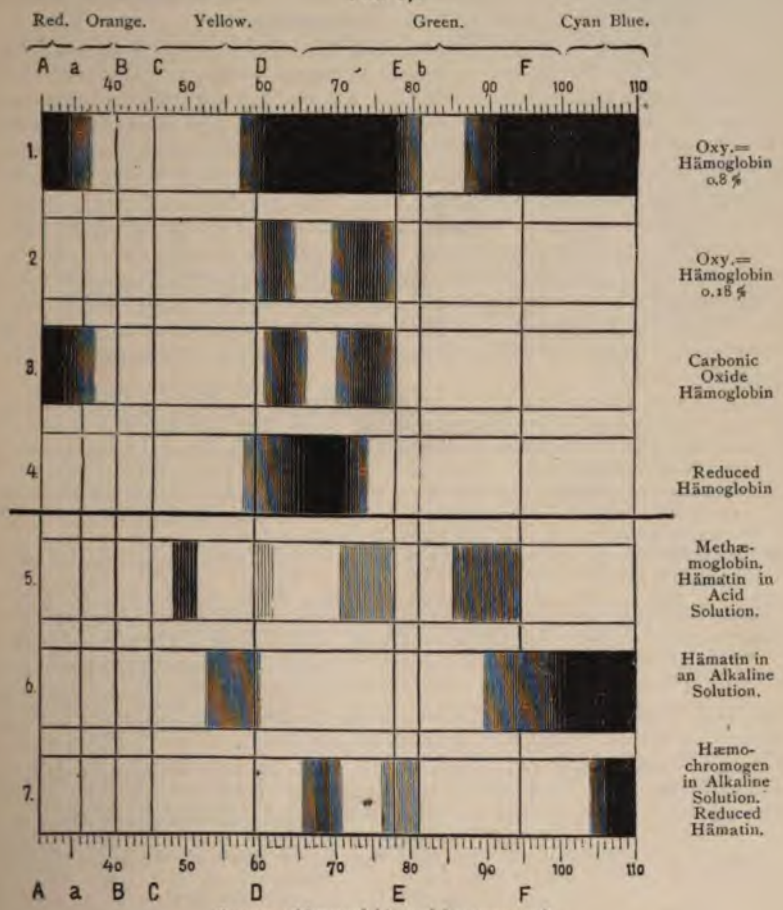
If **sunlight** be allowed to fall upon the slit, the spectrum shows a large number of lines (**Fraunhofer's lines**) which occupy definite positions in the colored spectrum. These lines are indicated by the letters A, B, C, D, etc., *a*, *b*, *c*, etc. (Fig. 17).

15. COMPOUNDS OF Hb WITH O; OXYHÆMOGLOBIN AND METHÆMOGLOBIN.—1. **Oxyhæmoglobin** (O_2Hb) behaves as a weak acid, and occurs to the extent of 86.78 to 94.30 per cent. in dry human red corpuscles (*Jüdell*). It is formed very readily whenever Hb comes into contact with O or atmospheric air. According to Bohr, 1 gramme Hb unites with 1.56 cubic centimetre of O at 0° and 760 mm. Hg pressure, the union being stronger in weak than in concentrated solutions. Oxyhæmoglobin is a very **loose chemical compound**, and is slightly less soluble than Hb; its **spectrum** shows in the *yellow* and the *green* **two dark absorption-bands**, whose length and breadth in an 0.18 per cent. solution are given in Fig. 17 (2).

It occurs in the blood corpuscles circulating in arteries and capillaries, as can be shown by the spectroscopic examination of the ear of a rabbit, of the prepuce, and the web of the fingers (*Vierordt*).

[**Spectrum of Oxyhæmoglobin.**—In the spectrum of a dilute solution of hæmoglobin crystals or arterial blood, part of the red and violet rays are absorbed, but **two** well-marked **absorption-bands** exist between D and E. The line nearest D, *i.e.*, next the red end of the spectrum, sometimes designated by the letter (α) is narrow, sharply defined, and black at its centre, and its position cor-

FIG. 17.



Spectra of hæmoglobin and its compounds.

responds to the wave-length 579. The other absorption-band near E, conveniently designated by (β), is broader, not so dark, and its edges are less sharply defined. Its centre corresponds to the wave-length 553.8. In very dilute solutions the α band is the only one visible. In a strong solution, as shown in Fig. 17, the two bands fuse, but are again made visible as two on dilution of the blood.]

Reduction of Oxyhæmoglobin.—It gives its O very readily, however, even when means which set free absorbed gases are used. It is **reduced** by the removal of the gases by the *air-pump*, by the *conduction* through its solution of *other gases*

(CO), and by *heating* to the boiling point. In the circulating blood its O is very rapidly given up to the tissues, so that in suffocated animals only *reduced hæmoglobin* is found in the arteries. Some constituents of the serum and sugar remove its O. By adding a solution of oxyhæmoglobin **reducing substances**—*e.g.*, ammonium sulphide, iron filings, or Stokes's fluid [tartaric acid, iron proto-sulphate, and excess of ammonia]—the two absorption-bands of the spectrum disappear, and *reduced hæmoglobin* (gas-free), with **one absorption-band,** is formed. The color changes from a bright red to a purplish or claret tint. The two bands are reproduced by shaking the reduced hæmoglobin with air, whereby O_2Hb is again formed. Solutions of oxyhæmoglobin are readily distinguished, by their scarlet color, from the purplish tint of reduced hæmoglobin.

[The single absorption-band (Fig. 17, 4) designated by the letter (γ), lying about midway between the position of the two previous bands, is broader, fainter, less deeply shaded, and its centre is about, but not quite, intermediate between D and E. It extends between the wave-lengths 595 and 538, and is blackest opposite the wave-length 550, so that it lies nearer D than E. At the same time more of the blue rays are transmitted. On dilution the band is not resolved into two, but simply becomes fainter and disappears.]

[Hæmoglobin has certain remarkable characters: (1) Although it is a crystalloid body it diffuses with difficulty through an animal membrane, owing to the large size of its molecule. (2) It readily combines with O to form an unstable and *loose* chemical compound, oxyhæmoglobin. (3) This O it gives up readily to the tissues or other deoxidizing reagents. (4) Its composition is very complex, for, in addition to the ordinary elements present in proteids, it contains a remarkable amount of iron (0.4 per cent).]

If a string be tied round the base of two fingers so as to intetrrupt the circulation, spectroscopic examination shows that the oxyhæmoglobin rapidly passes into reduced Hb (*Vierordt*). Cold delays this reduction; it is accelerated in youth, during muscular activity, or by suppressed respiration, and usually also during fever.

The spectroscopic examination of small **blood-stains** is often of the utmost forensic importance. A minimal drop is sufficient. Dissolve the stain in a few drops of distilled water, and place the solution in a thin glass tube in front of the slit of the spectroscope.

Para-hæmoglobin.—If O_2Hb be preserved under alcohol it passes into a modified form, which is insoluble in water (*Nencki and Sieber.*)

2. **Methæmoglobin** is a more stable, crystalline compound (*Hoppe-Seyler.*) It contains the same amount of O as O_2Hb, but in a different chemical union, while the O is also more firmly united with it. It shows **four absorption-bands** like hæmatin in acid solution (Fig. 17, 5), of which that between C and D is distinct; the second is very indistinct, while the third and fourth readily fuse, so that these last two bands are only well seen with good apparatus.

It is produced spontaneously in old brown blood stains, in the crusts of bloody wounds, in blood cysts, and in bloody urine. Chemically, it can be prepared from a solution of Hb, by the action of potassic ferri-cyanide (*Jäderholm*) or potassic chlorate (*Marchand*), [or by adding to a solution of Hb a freshly prepared solution of potassic permanganate], and in non-laky blood by alloxantin (*Kowalewsky*). It crystallizes if defibrinated blood is shaken with amyl nitrite and the mahogany-brown laky fluid be allowed to evaporate slowly (*Halliburton*).

If a trace of ammonia be added to a solution of methæmogoblin, it gives an alkaline solution of methæmogoblin, which shows two bands like oxyhæmoglobin, of which the first one is the broader, and extends more toward the red. If ammonium sulphide be added to the methæmoglobin solution, reduced Hb is formed.

[**Action of Nitrites.**—The addition of amyl nitrite dissolved in alcohol, or sodic potassic nitrite to defibrinated blood causes the latter to assume a chocolate color, which, on the addition of ammonia, changes to red. The chocolate-colored fluid shows one well-defined band in the red, and less distinctly other three bands like methæmoglobin (*Gamgee*).]

[The nitrites therefore form a compound with its oxygen more firmly fixed than the O in HbO_2, so that large doses of nitrites arrest the internal respiration and are poisonous. It is, however,

affected by the products formed in the blood during asphyxia, while CO-Hb is not, the methæmoglobin formed by the nitrites is reduced by these products to Hb, which as it passes through the lungs takes up O.]

16. **CARBONIC OXIDE HÆMOGLOBIN, POISONING WITH CO.**—3. **CO-Hæmoglobin** is a more stable chemical compound than the foregoing, and is produced at once when carbonic oxide is brought into contact with the pure Hb or O_2Hb (*Cl. Bernard*, 1857). It has an intensely florid or *cherry-red* color, is not dichroic, and its spectrum shows **two absorption-bands**, very like those of O_2Hb, but they are slightly closer together and lie more toward the violet (Fig. 17, 3). Reducing substances which act upon HbO_2, *e.g.*, ammonium sulphide or Stokes's fluid, do not affect these bands, *i.e.*, they cannot convert the CO-Hb into reduced Hb. If a 10 per cent. solution of caustic soda be added to a solution of CO-Hb, and heated, it gives a *cinnabar-red color;* while, with an HbO_2 solution, it gives a dark brown, greenish, greasy mass. Oxidizing substances [solutions of potassic permanganate (0.025 per cent.), potassic chlorate (5 per cent.), and dilute chlorine solution] make solutions of CO-Hb cherry-red in color, while they turn solutions of O_2Hb pale yellow. After this treatment both solutions show the absorption-bands of methæmogoblin, but those of the CO-Hb appear considerably later. If ammonium sulphide be added, O_2Hb and CO-Hb are re-formed.

On account of its **stability**, CO-Hb resists external influences and even putrefaction for a long time, and the two bands of the spectrum may be visible after many months. Landois obtained the soda test and spectroscopic bands in the blood of a woman poisoned eighteen months previously by CO, and after great putrefaction of the body had taken place. [Stirling has kept CO-Hb in a stoppered bottle for five years without putrefaction taking place.]

If CO or air containing it be inspired, it gradually displaces the O, volume for volume, out of the red blood corpuscles, and death soon occurs; 1000 c.cm. inspired at once will kill a man. A very small quantity in the air ($\frac{1}{400}$–$\frac{1}{1000}$) suffices, in a relatively short time, to form a large quantity of CO-Hb. As continued contact with other gases (such as the passing of O through it for a very long time) gradually separates the CO from the Hb, with the formation of O_2Hb, it happens that, in very partial poisoning with CO, the blood gradually gets rid of the CO by the respiratory organs. It is uncertain if any part is excreted as CO_2. [CO-Hæmoglobin, being a stable compound when once formed, circulates in the blood vessels; but it neither gives up oxygen to the tissues, nor takes up oxygen in the lungs, hence its very poisonous properties. The real cause of death in animals poisoned with it is, that the internal respiration is arrested.]

Poisoning with Carbonic Oxide.—Carbonic oxide is formed during the incomplete combustion of coal or coke, and passes into the air of the room, provided there is not a free outlet for the products of combustion. It occurs to the extent of 12–28 per cent. in ordinary gas, which largely owes its poisonous properties to the presence of CO. If the O be gradually displaced from the blood by the respiration of air containing CO, life can only be maintained as long as sufficient O can be obtained from the blood to support the oxidations necessary for life. Death occurs before all the O is displaced from the blood. CO has no effect when directly applied to muscle and nerve. When it is mixed with air, as in **coal-gas poisoning**, and inhaled, there is first stimulation and afterward paralysis of the nervous system, as shown by the symptoms induced, *e.g.*, violent headache, great restlessness, excitement, increased activity of the heart and respiration, salivation, tremors, and spasms. Later, unconsciousness, weakness, and paralysis occur, labored respiration, diminished heart-beat, and lastly, complete loss of sensibility, cessation of the respiration and heart-beat, and death. At first the temperature rises several tenths of a degree, but it soon falls 1° or more. The pulse is also increased at first, but afterward it becomes very small and frequent. In poisoning with **pure CO** there is no dyspnœa, but sometimes muscular spasms occur, the coma not being very marked. There is also temporary but pronounced paralysis of the limbs, followed by violent spasms. After death the heart and brain are congested with intensely florid blood. In poisoning with the **vapor of charcoal**, where CO and CO_2 both occur, there is a varying degree of coma; pronounced dyspnœa, muscular spasms which may last several minutes, gradual paralysis and asphyxia, moniliform contractions and subsequent dilatation of the blood vessels, with congestion of various organs, occur, accompanied by a fall of the blood pressure (*Klebs*), indicating initial stimulation and subsequent paralysis of the vaso-motor centre. This also explains the variations in

the temperature and the occasional occurrence of sugar in the urine after poisoning with CO. After death, the blood vessels are found to be filled with fluid blood of an exquisitely bright cherry-red color, while all the muscles and viscera and exposed parts of the body (such as the lips) have the same color. The brain is soft and friable; there is catarrh of the respiratory organs and degeneration of the muscles, and great congestion and degeneration of the liver, kidneys, and spleen. The spots of lividity, *post-mortem*, are bright red. After recovery from poisoning with CO there may be paraplegia and (although more rarely) disturbances of the cerebral activity.

17. OTHER COMPOUNDS OF HÆMOGLOBIN.—4. **Nitric Oxide Hæmoglobin** (NO-Hb) is formed when NO is brought into contact with Hb (*L. Hermann*).

As NO has a great affinity for O, red fumes of nitrogen peroxide (NO_2) being formed whenever the two gases meet, it is clear that, in order to prepare NO-Hb, the O must first be removed. This may be done by passing H through it [or ammonia may be added to the blood, and a stream of NO passed through it; the ammonia combines with all the acid formed by the union of the NO with the O of the blood]. NO-Hb is a *more stable chemical compound* than CO-Hb, which, as we have seen, is again more stable than O_2Hb. It has a *bluish-violet* tint, and also gives two absorption-bands in the spectrum similar to those of the other two compounds, but not so intense. These bands are *not* abolished by the action of reducing agents. As NO-Hb cannot be formed in the body, it has no practical significance.

The three compounds of Hb, with O, CO, and NO are **crystalline**, like reduced Hb; they are **isomorphous**, and their solutions are **not dichroic.** All three gases unite in equal volumes with Hb. If O be conducted through a concentrated solution of Hb devoid of gases, a crystalline mass of O_2Hb is thereby readily formed.

5. **Cyanogen**, CNH (*Hoppe-Seyler*), and **acetylene**, C_2H_4 (*Bistrow and Liebreich*), form easily decomposable compounds with Hb. The former occurs in poisoning with hydrocyanic acid, and has a spectrum nearly identical with that of O_2Hb, and, like O_2Hb, it is reduced, but very slowly, by special reagents. [The existence of these compounds is, however, highly doubtful (*Gamgee*).]

18. DECOMPOSITION OF HÆMOGLOBIN.—In solution and in the dry state Hb gradually becomes decomposed, whereby the iron-containing pigment hæmatin (along with certain bye-products, formic, lactic, and butyric acids) is formed. Hæmoglobin, however, may be decomposed at once into (1) **Hæmatin**, a body containing iron, and (2) a colorless proteid closely related to **globulin**; by (*a*) the addition of all acids, even by CO_2 in the presence of plenty of water; (*b*) strong alkalies; (*c*) all reagents which coagulate albumin, and by heat at 70°–80° C.; (*d*) by ozone.

(A) **Hæmatin**, $C_{32}H_{32}N_4FeO_4$ (*Nencki and Sieber*), is a bluish-black amorphous body, which forms about 4 per cent. of hæmoglobin (dog). It is *insoluble* in water, alcohol, and ether; *soluble* in dilute alkalies and acids, and in acidulated ether and alcohol.

(1) **Acid Hæmatin.**—Lecanu extracted it from dry blood corpuscles by using alcohol containing sulphuric and tartaric acids. [If acetic acid be added to a solution of Hb and slightly heated, a mahogany-brown fluid is obtained, containing *hæmatin in acid solution*, which gives a spectrum with **one absorption-band** to the red side of D near C (Fig. 17, 5). There is at the same time a considerable absorption of the blue end of the spectrum. If an **ethereal extract** of the acid hæmatin be made, the ether is colored brown and shows **four absorption-bands**, as in Fig. 17, 5.]

(2) **Alkali Hæmatin.**—[If to the above solution ammonia or caustic soda be added, on heating gently, the color changes, and the fluid becomes dichroic, showing a greenish tinge. On mixing the solution thoroughly with air the spectrum of oxy-alkali hæmatin is obtained, *i. e.*, **one absorption-band** just to the red side of D (Fig. 17, 6), so that it is much nearer D than the corresponding band of acid hæmatin. Much of the blue end of the spectrum is absorbed as well.]

[(3) **Reduced Alkali Hæmatin** or **Hæmochromogen.**—If the solution of alkali hæmatin be reduced by ammonium sulphide, the spectrum of hæmochro-

mogen is obtained, viz., **two absorption-bands** between D and E, but they are nearer the violet end than in the case of HbO_2 and Hb-CO (Fig. 17, 7).]

[(4) **Hæmatoporphyrin** or **Iron-free Hæmatin.**—On adding blood to concentrated sulphuric acid a clear purplish-red solution is obtained, which shows **two absorption-bands,** one close to and on the red side of D, and a second half-way between D and E. If water be added a brown precipitate is thrown down. When this precipitate is dissolved in caustic soda, it gives a fluid which shows *four* absorption-bands.]

Action of CO_2.—If CO_2 be passed through a solution of oxyhæmoglobin for a considerable time, reduced Hb is first formed; but if the process be prolonged the Hb is decomposed, a precipitate of globulin is thrown down, and an absorption-band, similar to that obtained when Hb is decomposed with acids, is observed (p. 66).

An alkaline solution of hæmatin, when reduced by tin and hydrochloric acid, yields **urobilin** (compare § 261).

When hæmoglobin is extravasated into the subcutaneous tissue, it becomes so altered that at first hæmatoidin (§ 20), and ultimately hydrated oxide of iron, appear in its place.

19. HÆMIN AND BLOOD TESTS.—In 1853 Teichmann prepared crystals of **hæmin** from blood, which Hoppe-Seyler showed to be **chloride of**

FIG. 18.

Hæmin crystals. 1, human; 2, seal; 3, calf; 4, pig; 5, lamb; 6, pike; 7, rabbit.

FIG. 19.

Hæmin crystals prepared from traces of blood.

hæmatin (Hæmatin, + 2HCl), with the formula $C_{32}H_{31}ClN_4FeO_3$ (*Nencki and Sieber*). The presence of these crystals is used as a test for blood stains or blood in solution. They (Fig. 18) are prepared by adding a small crystal of common salt to dry blood on a glass slide, and then an excess of *glacial* acetic acid; the whole is gently heated until bubbles of gas are given off. On allowing the preparation to cool, the characteristic hæmin crystals are obtained.

Characters.—When well formed, the crystals are small microscopic rhombic plates, or rods; sometimes they are single—at other times they are aggregated in groups, often crossing each other. Some kinds of blood (ox and pig) yield very irregular, scarcely crystalline, masses. The crystalline forms of hæmin are identical in all the different kinds of blood that have been examined. They are **doubly refractive**; under the polarization microscope they are a glancing yellow, appearing raised on the dark field, with a strong absorption of the light parallel to the long axis of the crystals (*Falk and Morache*). They are **pleochromatic**; by transmitted light they are mahogany-brown, and by reflected light bluish-black, glancing like steel.

(1) **Preparation from Dry Blood Stains.**—Place a few particles of the blood stain on a glass slide, add 2 to 3 drops of *glacial* acetic acid and a small crystal of common salt; cover with a cover-glass, and heat gently over the flame of a spirit lamp until bubbles of gas are given off. On cooling, the crystals appear in the preparation (Fig. 19).

(2) **From Stains on Porous Bodies.**—The stained object (cloth, wood, blotting paper, earth) is extracted with a small quantity of dilute caustic potash, and afterwards with water in a watch-glass. Both solutions are carefully filtered, and tannic acid and glacial acetic acid are added until an acid reaction is obtained. The dark precipitate which is formed is collected on a filter and washed. A small part of it is placed on a microscope slide, a granule of common salt is added, and the whole dried; the dry stain is treated as in (1) (*Struwe*).

(3) **From Fluid Blood.**—Dry the blood slowly at a low temperature, and proceed as in (1).

(4) **From Dilute Solutions of Hæmoglobin.**—(*a*) *Struwe's Method.*—Add to the fluid, ammonia, tannic acid, and afterwards glacial acetic acid, until it is acid; a black precipitate of tannate of hæmatin is thrown down. This is isolated, washed, dried, and treated as in (1), but instead of NaCl a granule of ammonium chloride is added.

Hæmin crystals may sometimes be prepared from putrefying or lake-colored blood, but they are very small, and the test often fails. When mixed with iron-rust, as on iron weapons, the blood crystals are generally not formed. In such cases, scrape off the stains and boil them with dilute caustic potash. If blood be present, the dissolved hæmatin forms a fluid, which in a thin layer is green, in a thick layer red (*H. Rose*).

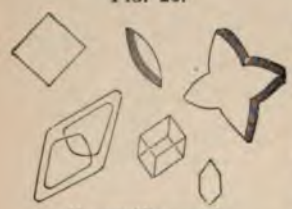
Hæmin crystals have been prepared from all classes of vertebrates and from the blood of the earth-worm. From the blood of the ox and pig they may be almost amorphous.

Chemical Characters.—They are insoluble in water, alcohol, ether, chloroform; but concentrated H_2SO_4 dissolves them, expelling the HCl, and giving a violet-red color. Ammonia also dissolves them, and if the resulting solution be evaporated, heated to 130° C., and treated with boiling water (which extracts the ammonium chloride), **hæmatoporphyrin**—identical with Mulder's **iron-free hæmatoin**, and with Preyer's **hæmatoin**, is obtained (*Hoppe-Seyler*). It is a bluish-black substance, which on being pounded forms a brown and amorphous powder. Its solutions in caustic alkalies are dichroic; in reflected light, brownish-red; in transmitted light, in a thick stratum, red—in a thin one, olive-green. The acid solutions are monochromatic and brown.

Preparation in Bulk.—To obtain it in quantity, heat dried horse's blood with 10 parts of formic acid. If the crystals be suspended in methyl alcohol, on adding iodine and heating them they dissolve with a purple color; after adding bromine, brown; and after passing chlorine gas, green; all these give a characteristic spectrum (*Axenfeld*).

The glacial acetic acid may be replaced by oxalic or tartaric acid, the common salt by salts of iodine or bromine; in the latter case similar bromine- or iodine-hæmatin is formed (*Bikfalvi*).

FIG. 20.



Hæmatoidin crystals.

20. HÆMATOIDIN.—Virchow discovered this important derivative of hæmoglobin. It occurs in the body wherever blood stagnates outside the circulation, and becomes decomposed—as when blood is extravasated into the tissues—*e.g.*, the brain—in solidified blood plugs or thrombi; especially in veins; invariably in the Graafian follicles. It contains no iron ($C_{32}H_{36}N_4O_6$), and crystallizes in clino-rhombic prisms (Fig. 20) of a yellowish-brown color. It is soluble in warm alkalies and chloroform. Very probably it is *identical* with the bile-pigment—**bilirubin.** [When acted upon by impure nitric acid (Gmelin's reaction), it gives the same play of colors as bile.]

Pathological.—In cases where a large amount of blood has undergone solution within the blood vessels (as by injecting foreign blood) hæmatoidin crystals have been found in the urine. For their occurrence in the urine in jaundice (§ 180), and in the sputum (§ 138).

21. (B.) **THE COLORLESS PROTEID OF HÆMOGLOBIN.**—It is closely related to **globulin**; but, while the latter is precipitated by all acids, even by CO_2, and re-dissolved on passing O through it, the proteid of hæmoglobin, on the other hand, is not dissolved after precipitation on passing through it a stream of O.

As crystals of hæmoglobin can be decolorized under special circumstances, it is probable that these owe their crystalline form to the proteid which they contain. Landois placed crystals of hæmoglobin along with alcohol in a dialyser, putting ether acidulated with sulphuric acid outside, and thereby obtained colorless crystals. [If frogs' blood be sealed up on a microscopic slide along

with a few drops of water for several days, long, colorless, acicular crystals are developed in it (*Stirling and Brito*).]

22. II. **PROTEIDS OF THE STROMA.**—**Dry** red human blood corpuscles contain from 5.10–12.24 per cent. of these proteids, but little is known about them (*Füdell*). One of them is **globulin**, which is combined with a body resembling nuclein (*Wooldridge*), and traces of a **diastatic ferment** (*v. Wittich*). The stroma tends to form masses which resemble fibrin.

L. Brunton found a body resembling mucin in the nuclei of red blood corpuscles, and Miescher detected **nuclein** (§ 250, 2).

23. **OTHER CONSTITUENTS OF RED BLOOD CORPUSCLES.**—III. **Lecithin** (0.35–0.72 per cent.) in dry blood corpuscles (§ 250, 2). **Cholesterin** (0.25 per cent.) (§ 250, III.), **no Fats.**

Lecithin is regarded as a **glycero-phosphate of neurin**, in which, in the radical of glycero-phosphoric acid, two atoms of H are replaced by two of the radical of stearic acid. By gentle heat glycero-phosphoric acid is split up into glycerine and phosphoric acid (§ 250).

These substances are obtained by extracting old stromata or isolated blood corpuscles with ether. When the ether evaporates, the characteristic globular forms ("myelin-forms") of lecithin, and crystals of cholesterin are recognized. The amount of lecithin may be determined from the amount of phosphorus in the ethereal extract.

IV. **Water** (681.63 per 1000—*C. Schmidt*).

V. **Salts** (7.28 per 1000), chiefly compounds of *potash and phosphoric acid;* the phosphoric acid is derived only from the burned lecithin; while the greater part of the sulphuric acid is derived from the burning of the hæmoglobin in the analysis.

Analysis of Blood.—1000 parts, by weight, of **horse's blood** contain—
344.18 blood corpuscles (containing about 128 per cent. of solids).
655.82 plasma (containing about 10 per cent. of solids).

1000 parts, by weight, of **moist blood corpuscles** contain—

Solids,	367.9 (pig);	400.1 (ox).
Water,	632.1 "	599.9 "

The solids are—

	Pig.	Ox.
Hæmoglobin,	261	280.5
Proteids,	86.1	107
Lecithin, Cholesterin, and other Organic Bodies,	12.0	7.5
Inorganic salts,	8.09	4.8
Including **Potash,**	5.543	0.747
Including Magnesia,	0.158	0.017
Including Chlorine,	1.504	1.635
Including **Phosphoric Acid,**	2.067	0.703
Including Soda,	0	2.093 (*Bunge*).

[An approximate estimate of the composition of **human blood** is given in the following table:—

Composition of Human Blood as a Whole.

Water,		780
Solids—of these—		
Corpuscles,	134	
Serum-albumin, Serum-globulin,	70	
Fibrin of Clot (? Fibrinogen),	2.2	220
Inorganic Salts (of serum),	6.0	
Extractives,	6.2	
Fatty matters,	1.4	
Gases, O, CO_2, N.]		

24. **CHEMICAL COMPOSITION OF THE WHITE CORPUSCLES.**—Investigations have been made on pus cells, which closely resemble colorless blood corpuscles. They contain several **proteids**; alkali-albuminate, a

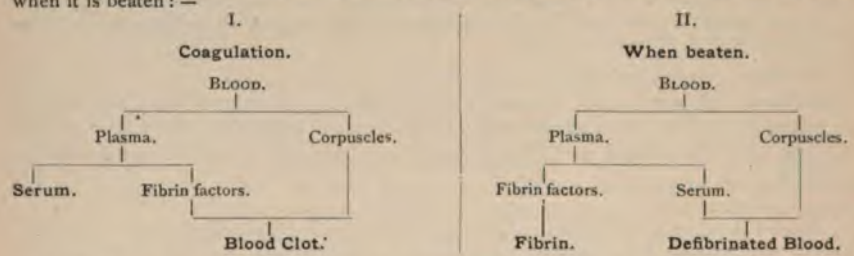
proteid which coagulates at 48° C., an albuminate resembling myosin, paraglobulin, peptone, and a coagulating ferment; **nuclein** in the nuclei (§ 250, 2), glycogen (§ 252), lecithin, cerebrin, cholesterin, and fat.

100 parts, by weight, of dry pus, contain the following **Salts**:—

Earthy Phosphates,	0.416	Potash,	0.201
Sodic Phosphate,	0.606	Sodic Chloride,	0.143

25. BLOOD PLASMA AND ITS RELATION TO SERUM.—The unaltered fluid in which the blood corpuscles float is called **blood plasma,** or **liquor sanguinis.** This fluid, however, after blood is withdrawn from the vessels, rapidly undergoes a change, owing to the formation of a solid fibrous substance—**fibrin**. After this occurs, the new fluid which remains, no longer coagulates spontaneously (it is plasma, *minus* the fibrin factors), and is called **serum.** Apart from the presence of the fibrin factors, the chemical composition of plasma and serum is the same.

[When blood coagulates, Table I shows what takes place, while Table II shows what occurs when it is beaten: —



Plasma is a clear, transparent, slightly thickish fluid, which, in most animals (rabbit, ox, cat, dog), is almost colorless; in man it is yellow, and in the horse citron yellow.

26. PREPARATION OF PLASMA.—(A) **Without Admixture.**—Taking advantage of the fact that plasma, when cooled to 0° outside the body, does not coagulate for a considerable time, Brücke prepares the plasma thus: The blood of the horse (because it coagulates slowly, and its corpuscles sink rapidly to the bottom) is received, as it flows from an artery, into a tall, narrow glass, placed in a freezing mixture, and cooled to 0°. The blood remains fluid, the colored corpuscles subside in a few hours, while the plasma remains above as a clear layer, which can be removed with a cooled pipette. If this plasma be then passed through a cooled filter, it is robbed of all its colorless corpuscles. [Burdon-Sanderson uses a vessel consisting of three compartments—the outer and inner contain ice, while the blood is caught in the central compartment, which does not exceed half an inch in diameter.] The *quantity* of plasma may be roughly (but only roughly) estimated by using a tall, graduated measuring glass. If the plasma be warmed, it soon coagulates (owing to the formation of the fibrin), and passes into a trembling jelly. If, however, it be beaten with a glass rod, the fibrin is obtained as a white, stringy mass, adhering to the rod. The quantity of fibrin in a given volume of plasma is very small (p. 71), although it varies much in different cases.

(B) **With Admixture.**—Blood flowing from an artery is caught in a tall vessel containing $\frac{1}{7}$ of its volume of a concentrated solution of sodic sulphate (*Hewson*) —or in a 25 per cent. solution of magnesic sulphate (1 vol. to 4 vols. blood—*Simmer*)—or 1 vol. blood with 2 vols. of a 4 per cent. solution of monophosphate of potash (*Masia*). When the blood is mixed with these fluids and put in a cool place, the corpuscles subside, and the clear stratum of plasma mixed with the salts

may be removed with a pipette. [The plasma so obtained is called "**salted plasma.**"] If the salts be removed by dialysis, coagulation occurs; or it may be caused by the addition of water (*Joh. Müller*). Blood which is mixed with a 4 per cent. solution of common salt does not coagulate, so that it also may be used for the preparation of plasma. [For frogs' blood Johannes Müller used a ½ per cent. solution of cane sugar, which permits the corpuscles to be separated from the plasma by filtration. The plasma mixed with the sugar coagulates in a short time.]

27. **FIBRIN—COAGULATION OF THE BLOOD—General Characters.—Fibrin** is that substance which, becoming solid in shed blood, in plasma and in lymph causes **coagulation** of these fluids. In these fluids, when left to themselves, fibrin is formed, consisting of innumerable, excessively delicate, closely packed, microscopic, doubly refractive fibrils (Fig. 7, E). These fibrils entangle the blood corpuscles as in a spider's web, and form with them a jelly-like solid mass called the **blood clot** or **placenta sanguinis**. At first the clot is very soft, and after the first 2 to 15 minutes a few fibres may be found on its surface; these may be removed with a needle, while the interior of the clot is still fluid. The fibres ultimately extend throughout the entire mass, which, in this stage, has been called *cruor*. After from 12 to 15 hours the fibrin contracts, or, at least, shrinks more and more closely round the corpuscles, and a fairly solid, trembling, jelly-like clot, which can be cut with a knife, is formed. During this time the clot takes the shape of the vessel in which the blood coagulates, and expresses from its substance a fluid—the **blood serum.** Fibrin may be obtained by washing away the corpuscles from the clot with a stream of water.

Crusta Phlogistica.—If the corpuscles subside very rapidly, and if the blood coagulates slowly, the upper stratum of the clot is not red, but only yellowish, on account of the absence of colored corpuscles. This is regularly the case in horse's blood, and in human blood it is observed especially in inflammations; hence this layer has been called **crusta phlogistica.** Such blood contains more fibrin, and so coagulates more slowly.

The crusta is formed under other circumstances, *e.g.*, with increased sp. gr. of the corpuscles, or diminished sp. gr. of the plasma (as in hydræmia and chlorosis), whereby the corpuscles sink more rapidly, and also during pregnancy. The taller and narrower the glass, the thicker is the crusta (compare § 41). The upper end of the clot, where there are few corpuscles, shrinks more, and is therefore smaller than the rest of the clot. This upper, lighter-colored layer is called the "**buffy coat;**" but it gradually passes, both in size and color, into the normal dark-colored clot. [Sometimes the upper surface of the clot is concave or "**cupped.**" The older physicians attached great importance to this condition, and also to the occurrence of the buffy coat.]

Defibrinated Blood.—If freshly-shed blood be beaten or whipped with a glass rod, or with a bundle of twigs, fibrin is deposited on the rod or twigs in the form of a solid, fibrous, yellowish-white, elastic mass, and the blood which remains is called "*defibrinated blood*" (p. 70). [The twigs and fibrin must be washed in a stream of water to remove adhering corpuscles.]

Coagulation of Plasma.—Plasma shows phenomena exactly analogous, save that the clot is not so well marked, owing to the absence of the resisting corpuscles; there is, however, always a soft trembling jelly formed when plasma coagulates. [In Hewson's experiment on the blood of a horse tied in a vein, he found that the plasma coagulated—fibrin being formed, so that he showed coagulation to be due to changes in the plasma itself (§ 29).]

Properties of Fibrin.—Although the fibrin appears voluminous, it only occurs to the extent of 0.2 per cent. (0.1 to 0.3 per cent.) in the blood. The amount varies considerably in two samples of the same blood. It is insoluble in water and ether; alcohol shrivels it by extracting water; dilute hydrochloric acid (0.1 per cent.) causes it to swell up and become clear, and changes it into syntonin

or acid albumin (§ 249, III). When fresh, it has a grayish-yellow, fibrous appearance, and is elastic; when dried, it is horny, transparent, brittle, and friable.

When fresh it dissolves in 6–8 per cent. solutions of sodium nitrate or sulphate, in dilute alkalies, and in ammonia, thus forming alkali-albuminate. Heat does not coagulate these solutions. [It is also soluble in, or rather decomposed by, 5–10 per cent. solutions of neutral salts, *e.g.*, NaCl, yielding two fibro-globulins (*Green*).] Hydric peroxide is rapidly decomposed by fibrin into water and O (*Thénard*). Fibrin which has been exposed to the air for a long time is no longer soluble in solution of potassic nitrate, but in neurin (*Mauthner*). During putrefaction it passes into solution, albumin being formed. Fibrin contains, entangled in it, ferric, calcic, and magnesic phosphates, and calcium sulphate whose origin is unknown.

Time for Coagulation.—The first appearance of a coagulum occurs in man's blood after 3 minutes 45 seconds, in woman's blood after 2 min. 20 sec. (*H. Nasse*). Age has no effect; withdrawal of food accelerates coagulation (*H. Vierordt*).

28. GENERAL PHENOMENA OF COAGULATION.—I. Blood in direct contact with living unaltered blood vessels does not coagulate. [Hewson (1772) found that when he tied the jugular vein of a horse in two places, and excised it, the blood did not coagulate for a long time.] Brücke filled the heart of a tortoise with blood which had stood 15 minutes exposed to the air at 0°, and kept it in a moist chamber; at 0° C. the blood was still uncoagulated in the contracting heart after eight days. Blood in a contracting frog's heart preserved under mercury does not coagulate. If the wall of the vessel be altered by **pathological processes** (*e.g.*, if the intima becomes rough and uneven, or undergoes inflammatory change), coagulation is apt to occur at these places. Blood rapidly coagulates in a *dead* heart, or in blood vessels (but not in capillaries) or other canals (*e.g.*, the ureter). If blood stagnates in a living vessel, coagulation begins in the central axis, because here there is no contact with the wall of the living blood vessel.

II. **Conditions which Hinder or Delay Coagulation.**—(*a*) The addition of small quantities of *alkalies*, *ammonia*, or concentrated solutions of *neutral salts of the alkalies and earths* (alkaline chlorides, sulphates, phosphates, nitrates, carbonates). Magnesic sulphate acts most favorably in delaying coagulation (1 vol. solution of 28 per cent. to 3½ vols. blood of the horse).

(*b*) Precipitation of the fibrino-plastin by adding weak acids, or CO_2.

By the addition of *acetic acid* until the reaction is acid, coagulation is completely arrested. A large amount of CO_2 delays it, hence venous blood coagulates more slowly than arterial, and the blood of *suffocated* persons remains fluid for the same reason.

(*c*) The addition of *egg-albumin*, *syrup*, *glycerine*, and much *water*. If uncoagulated blood be brought into contact with a layer of already-formed fibrin, coagulation occurs later.

(*d*) By *cold* (0° C.) coagulation may be delayed for one hour. If blood is frozen at once, after thawing it is still fluid, and then coagulates (*Hewson*). When shed blood is under *high pressure* it coagulates slowly.

(*e*) Blood of *embryo fowls* does not coagulate before the twelfth or fourteenth day of incubation (*Boll*); that of the *hepatic vein* very slightly; *menstrual blood* shows little tendency to coagulate when alkaline mucus from the vagina is mixed with it. If it be rapidly discharged, it coagulates in masses. Fœtal blood at the moment of birth coagulates soon.

(*f*) *Blood rich in fibrin* from inflamed parts coagulates slowly, but the clot so formed is firm.

(*g*) [Blood coagulates more slowly in a smooth than a rough vessel, and also in a shallow vessel than in a deep one.]

Hæmophilia.—A very slight scratch in some persons may cause very free bleeding. These persons are called colloquially "**bleeders**," and are said to have **hæmophilia** or the **hemorrhagic diathesis**. In "bleeders" coagulation seems not to take place, owing to a want of the substances producing fibrin; hence, in these cases, wounds of vessels are not plugged with fibrin. [A tendency to hemorrhage occurs in scurvy, purpura, in some infectious diseases, such as typhus, plague, yellow fever, and in poisoning with phosphorus.]

Injection of Peptones.—Albertoni observed that if tryptic pancreas ferment (dissolved in glycerine) be injected into the blood of an animal, the blood does not coagulate. Schmidt-Mülheim found that after the injection of *pure peptone* into the blood (0.5 gram per kilo.) of a dog, the blood lost its power of coagulating. [This occurs in the dog, but not in the rabbit. Peptonized blood coagulates when it is treated with CO_2 or water. It appears, however, that it is not the peptone which prevents the coagulation, but the albumoses adhering to it which do so.] A substance is formed in the plasma, which prevents coagulation, but which is precipitated by CO_2. Lymph behaves similarly (*Fano*). After peptones are injected, there is a great solution of leucocytes in the blood (*v. Samson-Himmelstjerna*). The secretion of the mouth of the medicinal leech [although its action is not due to a ferment (*Haycraft*)] and snake poison also prevent coagulation (*Wall*). [Diastatic ferment also prevents coagulation (*Salvioli*).]

III. **Coagulation is accelerated**—(*a*) **By contact with foreign Substances of all kinds**, but only when the blood adheres to them, hence, threads or needles introduced into arteries are rapidly covered with fibrin. Blood does not coagulate in contact with bodies covered with fat or vaseline (*Freund*). Even the introduction of air bubbles into the circulation or the passage of indifferent gases, N or H, through blood, accelerates it. The pathologically altered wall of a vessel acts like a foreign body. Blood shed from an artery rapidly coagulates on the walls of vessels, on the surfaces exposed freely to air, and on the rods or twigs used to beat it.

(*b*) The products of the retrogressive metabolism of proteids (uric acid, glycin, leucin, taurin, kreatin, sarkin, but not urea) favor coagulation by increased ferment formation; but if they are added in excess, they retard the process.

From a watery extract of the testis or thymus, on the addition of acetic acid, is precipitated a substance which is soluble in sodic carbonate. It is a mixture of **lecithin** and albumin, and when it is injected into the blood stream it causes almost instantaneous death by intravascular coagulation (*Wooldridge*).

(*c*) During rapid hemorrhage, the last portions of blood coagulate most rapidly (*Holzmann*).

(*d*) Heating the blood from 39° to 55° C. (*Hewson*).

(*e*) Agitation of the blood (*Hewson and Hunter*).

[(*f*) The addition of a small quantity of water.

(*g*) A *watery* condition of the blood. The clot is small and soft.

(*h*) Contact with oxygen.]

IV. **Rapidity of Coagulation.**—Among vertebrates, the blood of birds (especially of the pigeon) coagulates almost momentarily; in cold-blooded animals coagulation occurs much more slowly, while mammals stand midway between the two.

[The blood of a fowl begins to coagulate in ½ to 1½ minute; pig, sheep, rabbit, in ½ to 1½ minute; dog, 1 to 3 minutes; horse and ox, 5 to 13 minutes; man, 3 to 4 minutes; solidification is completed in 9 to 11 minutes (*Nasse*).] The blood of invertebrates, which is usually colorless when it is oxidized (§ 32), forms a soft, whitish clot of fibrin. Even in *lymph* and *chyle*, a small soft clot is formed.

V. When coagulation occurs, the aggregate condition of the fibrin factors is altered, so that **heat must be set free** (*Valentin*, 1844).

VI. In blood shed from an artery, the degree of **alkalinity diminishes** from the time of its being shed until coagulation is completed (*Pflüger and Zuntz*). This is probably due to a decomposition in the blood, whereby an acid is developed, which diminishes the alkalinity (p. 72).

VII. During coagulation there is a **diminution of the O** in the blood, although a similar decrease also occurs in non-coagulated blood. Traces of *ammonia* are also given off, which Richardson erroneously supposed to be the cause of the coagulation of the blood.

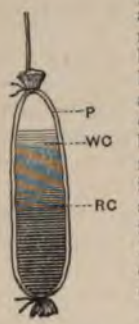
[This is refuted—(1) by the fact that blood, when collected under mercury (whereby no escape of ammonia is possible), also coagulates; and (2) by the following experiment of Lister: He placed two ligatures on a vein containing blood, moistening one-half of the outer surface of the

vein with ammonia, leaving the other half intact. The blood coagulated in the first half, and not in the other, owing to the properties of the wall of the vein of the former being altered. Neither the decrease of O nor the evolution of ammonia seems to have any causal connection with the formation of fibrin.]

Pathological.—When the blood coagulates within the vessels during life, the process is called **thrombosis**, and the coagulum or plug so formed is termed a **thrombus.** When a clot of blood or other body is carried by the blood stream to another part of the vascular system where it blocks up a vessel, the plug is called an **embolus**, and the result **embolism.**

29. **CAUSE OF THE COAGULATION OF BLOOD.**—[**Hewson's Experiments** (1772.)—Hewson tied the jugular vein of a horse between two ligatures, removed it, and then suspended it by one end (Fig. 21). He found that the blood remained fluid for a long time (48 hours), the red corpuscles sank (R C) and left a clear layer of plasma on the surface (P). On drawing off some of this clear plasma it coagulated, thus proving coagulation to be due to changes in the plasma. Lister repeated this experiment, and found that, even if the upper end of the tube be opened and the blood freely exposed to the air, coagulation is but slightly hastened. He showed that the blood might be poured from one vein into another, just as one might pour fluid from one test tube into another. In this case there were two test tubes, *i. e.*, the veins—and although the blood, on being poured from the one to the other, came into contact with the air, it did not coagulate. Hewson, however, found that blood poured from the vein into a glass vessel coagulated, so that, in his opinion, the blood vessels exerted a restraining influence on coagulation. By cooling the blood and preventing it from coagulating, he proved that coagulation was not due to the loss of heat. Nor could it be a vital act, as sodic sulphate or other neutral salt prevented coagulation indefinitely, but coagulation took place when the blood was diluted with water.]

FIG. 21.



Vein of horse tied between two ligatures. P, plasma; W C, white, and R C, red corpuscles.

[**Buchanan's Researches.**—The serous sacs of the body contain a fluid which in some respects closely resembles lymph. The pericardial fluid of some animals coagulates spontaneously (*e. g.*, in the rabbit, ox, horse, and sheep) if the fluid be removed *immediately after death.* If this be not done till *several hours after death* the fluid does not coagulate spontaneously. The fluid of the tunica vaginalis of the testis sometimes accumulates to a great extent, and constitutes *hydrocele*, but this fluid shows no tendency to coagulate spontaneously. Andrew Buchanan found, however, that if to the fluid of ascites, pleuritic fluid, or hydrocele fluid, there be added clear blood serum, then coagulation takes place, *i. e.* two fluids—neither of which shows any tendency *by itself* to coagulate—form a clot when they are mixed (1831). He also found, that if "washed blood clot" (which consists of a mixture of fibrin and colorless corpuscles) be added to hydrocele fluid, coagulation occurred. He compared the action of washed blood clot to the action of rennet in coagulating milk, and he imagined *the agents which determined the coagulation to be colorless corpuscles.* Thus, the buffy coat of horses' blood is a powerful agent, and it contains numerous colorless corpuscles. He finally concluded that some constituent in the plasma, to which he gave the name of a "soluble fibrin," is acted upon by the colorless corpuscles and converted into fibrin. The soluble fibrin of Buchanan is comparable to the fibrinogen in Hammarsten's theory. Buchanan, however, did not separate the substance.]

[**Denis's Plasmine** (1859).—Denis mixed uncoagulated blood with a saturated solution of sodic sulphate, and allowed the corpuscles to subside. The salted plasma thus obtained he precipitated with sodic chloride. The precipitate, when washed with a saturated solution of sodic chloride, he called **plasmine.** If plasmine be mixed with water, it coagulates spontaneously, resulting in the formation of fibrin, while another proteid remains in solution. According to the view of Denis, fibrin is produced by the splitting up of plasmine into two bodies—fibrin and a soluble proteid.]

[**A. Schmidt's Researches** (1861).—This observer re-discovered the chief facts already known to Buchanan, viz., that some fluids which do not coagulate spontaneously, clot when mixed with other fluids which show no tendency to coagulate spontaneously, *e. g.*, hydrocele fluid and blood serum. He isolated from these fluids the bodies described as fibrinogen and fibrino-plastin. The bodies so obtained were not pure, but Schmidt supposed that the formation of fibrin was due to the interaction of these two proteids. The reason hydrocele fluid does not coagulate, he says, is that it contains fibrinogen and no fibrino plastin, while blood serum contains the latter, but not the former. Schmidt afterwards discovered that these two substances may be present in a fluid, and yet coagulation may not occur (*e.g.*, occasionally in hydrocele fluid). He supposed, therefore, that blood or blood serum contained some other constituent necessary for coagulation. This he afterwards isolated in an impure condition and called *fibrin-ferment.*]

A. Schmidt's theory is that fibrin is formed by the coming together of *two proteid substances* which occur dissolved in the plasma, viz.: (1) **fibrinogen,**

i. e., the substance which yields the chief mass of the fibrin, and (2) **fibrino-plastic substance** or fibrino-plastin (serum-globulin or paraglobulin, § 32). In order to determine the coagulation a ferment seems to be necessary, and this is supplied by (3) the **fibrin-ferment.**

1. **Properties.**—Fibrinogen and fibrino-plastin belong to the group of proteids called **globulins**, *i. e.*, they are insoluble in pure water, but are soluble in dilute solutions of common salt (§ 249), and are not distinguished from each other by well-marked chemical characters. Still they differ, as follows:—

Fibrino-plastin is more easily precipitated from its solutions than fibrinogen. It is more readily redissolved when once it is precipitated. It forms when precipitated a very light granular powder.

Fibrinogen adheres as a sticky deposit to the side of the vessel. It coagulates at 56° C.

On account of their great similarity, both substances are not usually prepared from blood plasma. *Fibrinogen* is prepared from *serous* transudations (pericardial, abdominal, or pleuritic fluid, or the fluid of hydrocele), which contain no fibrino-plastin. *Fibrino-plastin* is most readily prepared from *serum*, in which there is still plenty of fibrino-plastin, but no fibrinogen.

2. **Preparation of Fibrino-plastin, Serum-globulin, or Paraglobulin.**—(*a*) Dilute **blood serum** with twelve times its volume of ice-cold water, and almost neutralize it with acetic acid [add 4 drops of a 25 per cent. solution of acetic acid to every 120 c. c. of diluted serum]; or (*b*) pass a stream of carbon dioxide through the diluted serum, which soon becomes turbid; after a time a fine white powder, copious and granular, is precipitated.

[(*c*) **Method of Hammarsten.**—All the fibrino-plastin in serum is not precipitated either by adding acetic acid or by CO_2. Hammarsten found, however, that if crystals of magnesium sulphate be added to complete saturation, it precipitates the whole of the serum-globulin, but does not precipitate serum-albumin; serum-globulin is more abundant than serum-albumin in the serum of the ox and horse, while in man and the rabbit the reverse obtains; (compare § 32).]

Schmidt found that 100 c.c. of the serum of ox blood yielded 0.7 to 0.8 grm.; horse's serum, 0.3 to 0.56 grm. of dry fibrino-plastin. Fibrino-plastin occurs not only in serum, but also in red blood corpuscles, in the fluids of connective tissue, and in the juices of the cornea.

3. **Preparation of Fibrinogen.**—This is best prepared from **hydrocele fluid**, although it may also be obtained from the fluids of serous cavities, *e.g.*, the pleura, pericardium, or peritoneum. It does not exist in blood serum, although it does exist in blood plasma, lymph, and chyle, from which it may be obtained by a stream of CO_2, after the paraglobulin is precipitated. (*a*) Dilute hydrocele fluid with ten to fifteen times its volume of water, and pass a stream of CO_2 through it for a long time. (*b*) Add powdered *common salt* to saturation to a serous transudation, when a sticky, glutinous (not very abundant) precipitate of fibrinogen is obtained.

[Hammarsten and Eichwald find that, although paraglobulin and fibrinogen are soluble in solutions of common salt (containing 5 to 8 per cent. of the salt), a saline solution of 12 to 16 per cent. is required to precipitate the fibrinogen, leaving still in solution paraglobulin, which is not precipitated until the amount of salt exceeds 20 per cent.]

Properties of the Fibrin Factors.— They are insoluble in pure water, but dissolve in water containing O in solution. Both are soluble in very dilute alkalies, *e. g.*, caustic soda, and are precipitated from this solution by CO_2. They are soluble in dilute common salt—like all globulins—but if a certain amount of common salt be added in excess, they are precipitated. Very dilute hydrochloric acid dissolves them, but after several hours they become changed into a body resembling syntonin or acid albumin (§ 249, III.). Fibrinogen held in solution by common salt coagulates at 52° to 55° C. [Frédéricq finds that fibrinogen

exists *as such* in the plasma; it coagulates at 56° C., and the plasma thereafter is uncoagulable.]

4. Preparation of the Fibrin-Ferment.—(*a*) Mix blood serum (ox) with twenty times its volume of strong alcohol, and after one month filter off the deposit thereby produced. The deposit on the filter consists of coagulated insoluble albumin and the ferment; dry it carefully over sulphuric acid, and reduce to a powder. Triturate 1 gram of the powder with 65 c.c. of water for ten minutes, and filter. The ferment is dissolved by the water, and passes through the filter, while the coagulated albumin remains behind (*Schmidt*).

[(*b*) **Gamgee's Method.**—Buchanan's "washed blood clot" (p. 74) is digested in an 8 per cent. solution of common salt. The solution so obtained possesses in an intense degree the properties of Schmidt's fibrin-ferment.]

In the preparation of fibrino-plastin, the ferment is carried down with it mechanically. The ferment seems to be formed first in fluids outside the body, very probably by the solution of the colorless corpuscles. More ferment is formed in the blood the longer the interval between its being shed and its coagulation. It is destroyed at 70° C. Blood flowing directly from an artery into alcohol contains no ferment. It is also formed in other protoplasmic parts (*Rauschenbach*), *e.g.*, in dead muscle, brain, suprarenal capsule, spermatozoa, testicle (*Foa and Pellacani*), and in vegetable micro organisms [*e.g.*, yeast] and protozoa (*Grohmann*) [so that it would seem to be a general product of protoplasm. As the ferment does not pre-exist in colorless blood corpuscles, it seems to be formed from some mother substance in them, the blood plasma itself decomposing this substance.]

Coagulation Experiments.—According to A. Schmidt, if pure solutions of (1) fibrinogen, (2) fibrino-plastin, and (3) fibrin-ferment be mixed, fibrin is formed. The process goes on best at the temperature of the body; it is delayed at 0°; and the ferment is destroyed at the boiling point. The presence of O seems necessary for coagulation. The amount of the ferment appears to be immaterial; large quantities produce more rapid coagulation, but the amount of fibrin formed is not greater.

[Foa and Pellacani find that a filtered watery extract of fresh brain, capsule of the kidneys, testes, and some other tissues, when injected into the blood vessels of a rabbit, causes coagulation of the blood in the pulmonary circulation and the heart, death being caused by the action of a substance identical with the fibrin-ferment.]

The **amount of salts** present has a remarkable relation to coagulation. Solutions of the fibrin factors deprived of salts, and redissolved in very dilute caustic soda, when mixed, do not coagulate until sufficient NaCl be added to make a 1 per cent. solution of this salt (*Schmidt*). [Green finds that calcium sulphate brings about coagulation in plasma which shows little or no tendency to clot, while coagulation in its absence is almost or quite prevented.]

When blood or blood plasma coagulates, all the fibrinogen is used up, so that the serum contains only fibrino-plastin and fibrin-ferment; hence, the addition of hydrocele fluid (which contains fibrinogen) to serum causes coagulation.

[**Hammarsten's Theory.**—Hammarsten's researches led him to believe that fibrino-plastin is quite unnecessary for coagulation. According to him, fibrin is formed from *one* body, viz., *fibrinogen*, which is present in plasma when it is acted upon by the *fibrin-ferment;* the latter, however, has not been obtained in a pure state. Neither he nor Schmidt asserts that this body is of the nature of a ferment, although they use the term for convenience. It is quite certain that fibrin may be formed when no fibrino-plastin is present, coagulation being caused by the addition of calcic chloride or casein prepared in a special way. But, whether *one* or *two* proteids be required, in all cases it is clear that a certain quantity of salts, especially of NaCl, is necessary.]

[The main drift of the foregoing evidence points to the presence of one proteid —*fibrinogen*—in the plasma, which under certain circumstances yields fibrin. In shed blood this act seems to be determined by a ferment, perhaps derived from the disintegration of colorless corpuscles.]

[**Theory of Wooldridge.**—Wooldridge attributes great importance to **lecithin.** In shed blood the coagulation is brought about by the interaction of the plasma and the colorless corpuscles. If lecithin (which is present in considerable amount in the colorless corpuscles) diffuses into the blood, coagulation takes place. When peptone is injected into the blood of the dog, the blood does not clot; this is due, according to Wooldridge, to the peptone "preventing the interaction of leucocytes and plasma." If, however, the corpuscular elements are removed by the centrifugal machine, the peptone plasma can be made to clot. He also believes that fibrin-ferment does not pre-exist in normal plasma, but that "it may make its appearance in that plasma in the absence of all cellular elements, and must therefore come from some constituent or constituents of the plasma itself."]

30. **SOURCE OF THE FIBRIN FACTORS.**—Al. Schmidt maintains that all the three substances out of which fibrin is said to be formed, arise from the breaking up of colorless blood corpuscles. In the blood of man and mammals, fibrinogen exists dissolved in the circulating blood as a dissolution product of the retrogressive changes of the white corpuscles. Plasma contains dissolved fibrinogen and serum-albumin. The circulating blood is very rich in colorless blood corpuscles, much richer, indeed, than was formerly supposed. As soon as blood is shed from an artery, enormous numbers of the colorless corpuscles are dissolved —according to Al. Schmidt 71.7 per cent. (horse). First the body of the cell disappears, and then the nucleus. The products of their dissolution are dissolved in the plasma, and one of these products is *fibrino-plastin.* At the same time the fibrin-ferment is also produced, so that it would seem not to exist in the intact blood corpuscles. Fibrino-plastin and fibrin-ferment are also produced by the "*transition forms*" of blood corpuscles, *i. e.*, those forms which are intermediate between the red and the white corpuscles. They seem to break up immediately after blood is shed. The *blood plates* (p. 57) are also probably sources of these substances.

In amphibians and birds the *red* nucleated corpuscles rapidly break up after blood is shed, and yield the substance or substances which form fibrin. Al. Schmidt convinced himself that in these animals fibrinogen is originally a constituent of the blood corpuscles.

It is clear, therefore, according to Schmidt's view, that as soon as the blood corpuscles, white or red, are dissolved, the fibrin factors pass into solution, and the formation of fibrin by the interaction of the three substances will ensue.

If a large number of leucocytes be introduced into the circulation of an animal, the leucocytes are dissolved in great numbers in the blood, so that death takes place by diffuse coagulation. Should the animal survive the immediate danger of death, the blood, owing to the want of leucocytes, is completely incapable of coagulating (*Groth*).

[And. Buchanan thought that the potential element of his "washed blood clot" resided in the colorless corpuscles, "primary cells or vesicles." He, like Schmidt, found that the buffy coat of horses' blood, which is very rich in white corpuscles, produced coagulation rapidly. Buchanan compared the action of his washed clot to that of rennet in coagulating milk.]

Pathological.—Al. Schmidt and his pupils have shown that *some* ferment, probably derived from the dissolution of colorless corpuscles, is found in circulating blood, and that it is more abundant in venous than in arterial blood, while it is most abundant in shed blood. It is specially remarkable that in *septic fever* the amount of ferment in blood may increase to such an extent as to permit the occurrence of spontaneous coagulation (thrombosis), which may even produce death (*Arn. Köhler*). In febrile cases generally, the amount of ferment is somewhat more abundant (*Edelberg and Birk*). After the injection of ichor into the blood an enormous number of colorless corpuscles are dissolved (*F. Hoffmann*). The injection of peptone, Hb, and to a less degree of distilled water, is followed by dissolution of numerous leucocytes.

There are changes in the blood, constituting true blood diseases, in which the physiological metabolism of the colorless corpuscles is enormously increased, so that the metabolic products accumulate in the blood (*Alex. Schmidt*). The result of this is spontaneous coagulation within the circulatory system, and death even may occur; there is always an increase of temperature. After such a condition, the coagulability of the blood is diminished.

31. **FORMATION OF FIBRIN.**—After several observers had shown that the red blood corpuscles (bird, horse, frog) participate in the production of fibrin, Landois observed, in 1874, under the microscope, that the stromata of the red blood corpuscles of mammals passed into fibrin. If a

drop of defibrinated rabbit's blood be placed in serum of frog's blood, without mixing them, the red corpuscles can be seen collecting together; their surfaces are sticky, and they can only be separated by a certain pressure on the cover-glass, whereby some of the now spherical corpuscles are drawn out into threads. The corpuscles soon become spherical, and those at the margin allow the hæmoglobin to escape, the decolorization progresses, from the margin inward, until at last there remain masses of stroma adhering together. The stroma substance is very sticky, but soon the cell contours disappear, and the stromata adhere and form fine fibres. Thus (according to Landois) the formation of fibrin from red blood corpuscles can be traced step by step. The red corpuscles of man and animals, when dissolved in the serum of other animals, show much the same phenomena.

Stroma-Fibrin and Plasma-Fibrin.—Landois calls fibrin formed direct from stroma, *stroma-fibrin*; fibrin formed in the usual way *plasma-fibrin*. The stroma-fibrin is closely related chemically to stroma itself; as yet, however, the two kinds of fibrin have not been sharply distinguished chemically. Substances which rapidly dissolve red corpuscles cause extensive coagulation, *e. g.*, injection of bile or bile salts, or lake-colored blood, into arteries. After the injection of foreign blood the newly-injected blood often breaks up in the blood vessels of the recipient, while the finer vessels are frequently found plugged with small thrombi (§ 102).

Coagulable Fluids.—With regard to coagulability, fluids containing proteids may be classified thus:—

(1) Those that *coagulate spontaneously*, *i. e.*, blood, lymph, chyle.
(2) Those *capable of coagulating*, *e. g.*, fluids secreted pathologically in serous cavities; for example, hydrocele fluid, which, as usually containing fibrinogen only, does not coagulate spontaneously, but it coagulates on the addition of fibrino-plastin and ferment (or of blood serum in which both occur).
(3) Those which *do not coagulate*, *e. g.*, milk or seminal fluid, which do not seem to contain fibrinogen.

32. CHEMICAL COMPOSITION OF PLASMA AND SERUM.—I. **Proteids** occur to the amount of 8 to 10 per cent. in the plasma. Only 0.2 per cent. of these go to form fibrin. After the formation of the fibrin the plasma is converted into serum. The sp. gr. of human serum is 1027 to 1029. It contains several proteids. [According to Hammarsten, *human* serum contains 9.207 per cent. of solids,—of these, 3.103 = serum-globulin, and 4.516 = serum-albumin, *i. e.*, in the ratio of 1 : 1.511. In horse serum the proportion is 4.5 : 2.6, in ox serum 4.16 : 3.29, and rabbit serum 6.22 : 1.78. The total amount of proteids in blood seems to be much more constant than are the relative proportions of serum-albumin and serum-globulin (*Salvioli*).]

(*a*) **Serum-globulin** or **Paraglobulin** (2 to 4 per cent.). If crystals of magnesium sulphate be added to saturation to serum at 35° C., serum-globulin is precipitated, but not serum-albumin. It is soluble in 10 per cent. solution of common salt, and coagulates at 69–75° C. Its specific rotatory power is — 47.8° (*Frédéricq*).

[Serum-globulin was described by Panum under the name of "serum-casein"; by Al. Schmidt, as "fibrino-plastic substance"; and by Kühne, as "paraglobulin."] During hunger the globulin increases and the albumin diminishes.

(*b*) **Serum-albumin** (3–4 per cent.). Its solutions begin to be turbid at 60° C., and coagulation occurs at 73° C., the fluid becoming slightly more alkaline at the same time. If sodium chloride be cautiously added to serum, the coagulating temperature may be lowered to 50° C. Its specific rotatory power is from — 62.6 to 64.5° (*Starke*). It is changed into syntonin or acid albumin by the action of dilute HCl, and by dilute alkalies into alkali-albuminate.

Serum-albumin is absent from the blood of starving snakes; and reappears after they are fed (*Tiegel*).

[**Serum-Albumin** *v.* **Egg-Albumin**—Although serum-albumin is closely related to egg-albumin they differ—(*a*) as regards their action upon polarized light; (*b*) the precipitate produced by adding HCl or HNO_3 is readily soluble in 4 c.c. of the reagent in the case of serum-albumin, while the precipitate in egg-albumin is dissolved with very great difficulty; (*c*) egg-albumin, injected into the veins, is excreted in the urine as a foreign body, while serum-albumin is not; (*d*) serum-albumin is not coagulated by ether, while egg-albumin is, if the solution

is not alkaline (§ 249). Serum-albumin has never been obtained free from salts, even when it is dialysed for a very long time.]

After all the serum-globulin in serum is precipitated by magnesium sulphate, serum-albumin still remains in solution. If this solution is heated to 40 or 50° C. a copious precipitate of non-coagulated serum-albumin is obtained, which is soluble in water. If the serum-albumin be filtered from the fluid, and if the clear fluid be heated to over 60° C., Frédéricq found that it becomes turbid from the precipitation of other proteids; the amount of these other bodies, however, is small.

[**Proteids of the Serum.**—Halliburton has shown by the method of "**fractional heat coagulation**" (*i. e.*, ascertaining the temperature at which a proteid is coagulated, filtering the fluid and again heating the filtrate to a higher temperature), that from the same fluid perhaps two or more proteids, all with different temperatures of coagulation, may be obtained. Care must be taken to keep the reaction constant. He finds that serum-globulin coagulates at 75° C., while serum-albumin in reality consists of three proteids, which coagulate at different temperatures; (α) at 73°, (β) at 77°, and (γ) at 84° C.]

[**Precipitation by Salts.**—Sulphate of magnesia not only precipitates serum-globulin but also fibrinogen. The fluid must be shaken for several hours to get complete saturation. Sodic sulphate, when added to serum deprived of its globulin by $MgSO_4$, precipitates serum-albumin, but it produces no precipitate with pure serum. In this way serum-albumin may be obtained in a pure, uncoagulated, and still soluble condition. Serum-globulin is thrown down by sodic nitrate, acetate, or carbonate; while *all* the proteids of the serum are precipitated by potassic acetate or phosphate, and the same result is brought about by adding two salts, *e.g.*, $MgSO_4$ and Na_2SO_4 (in this case sodio-magnesic sulphate is formed); $MgSO_4$ and $NaNO_3$; $MgSO_4$ and KI; NaCl and Na_2SO_4. After serum-globulin is thrown down by $MgSO_4$, the addition of $MgSO_4$ and Na_2SO_4 or the double-salt, precipitates the serum-albumin, which is still soluble in water. As sulphate of ammonia precipitates all the proteids except peptones, it may be used (*Halliburton*).]

[**The plasma of Invertebrata** (decapod crustaceans, some gasteropods, cephalopods, etc.) clots like vertebrate blood, and contains fibrinogen, but, in addition, there is found in it a substance corresponding to hæmoglobin, and called by Frédéricq, **hæmocyanin.** It exists like Hb in two conditions, one reduced and the other oxy-hæmocyanin, the former being colorless, the latter blue. In its general characters it resembles Hb, although it contains *copper* instead of iron, and gives no absorption-bands (*Halliburton*). In the blood of some decapod crustaceans there is a reddish pigment, **tetronerythrin,** which is identical with that in the exoskeleton and hypoderm. It belongs to the group of lipochromes, like some of the pigments of the retina. The hæmocyanin is respiratory in function, and it is remarkable that it is contained in the plasma, and not in the formed elements like the Hb of vertebrates. So that, stated broadly, in these invertebrates the plasma is both nutritive and respiratory in its functions, while in vertebrates the red blood corpuscles chiefly are respiratory and the plasma nutritive.]

II. **Fats** (0.1 to 0.2 per cent.).—**Neutral fats** (tristearin, tripalmitin, triolein) occur in the blood in the form of small microscopic granules, which, after a meal rich in fat (or milk) render the serum quite milky.

[The amount of fat in the serum of fasting animals is about 0.2 per cent.; during digestion 0.4 to 0.6 per cent.; and in dogs fed on a diet rich in fat it may be 1.25 per cent. There are also minute traces of *fatty acids* (succinic). Röhrig showed that *soluble soaps*, *i.e.*, alkaline salts of the fatty acids, cannot exist in the blood. **Cholesterin** may be considered along with the fats. It occurs in considerable amount in nerve tissues, and, like fats, is extracted by ether from the dry residue of blood serum. Hoppe-Seyler found 0.019 to 0.314 per cent. in the serum of the blood of fattened geese. There is no fat in the red blood corpuscles. **Lecithin** (its decomposition products, glycerin-phosphoric acid and protagon) occur in serum and also in the blood corpuscles.]

III. Traces of **Grape Sugar** [0.1 to 0.15 per cent. (more in the hepatic vein, 0.23 per cent.)] derived from the liver and muscles, and increased after hemorrhage (§ 175); some **glycogen,** and another reducing fermentative substance also increased by hemorrhage.

The amount of grape sugar in the blood increases with the absorption of sugar from the intestine, and this increase is most obvious in the blood of the portal and hepatic veins; there is also a slight increase in the arterial blood, but there it is rapidly changed. The presence of sugar is ascertained by coagulating blood by boiling it with sodium sulphate, pressing out the

fluid and testing it for sugar with Fehling's solution (*Cl. Bernard*). Pavy coagulates the blood with alcohol.

IV. **Extractives.**—Kreatin, urea (0.016 per cent., increased after nitrogenous food), succinic acid, and uric acid (more abundant in gouty conditions), guanin (?), carbamic acid, sarcolactic acid; all occur in very small amounts.

V. **Salts** (0.85 per cent.), especially *sodic chloride* (0.5 per cent.) and *sodic carbonate*. [It is most important to note that the *soda* salts are far more abundant in the serum than the potassium salts. The ratio may be as high as 10 : 1.] Animal diet increases the amount of salts, vegetable food diminishes it temporarily.

Salts in human blood serum (*Hoppe-Seyler*).

Sodic Chloride, ...	4.92 per 1000	Sodic Phosphate, . . .	0.15 per 1000
" Sulphate, ...	0.44 "	Calcic Phosphate, . . . }	0.73 "
" Carbonate, ...	0.21 "	Magnesic " . . . }	

If large quantities of salts are introduced into the blood, they almost entirely disappear from the blood stream within a few minutes, chiefly by diffusion into the tissues. They are gradually eliminated by the kidneys. The same is true of sugar and peptones (*Ludwig and Klicowicz*).

VI. **Water** about 90 per cent.

VII. A yellow **pigment.**

The pigment may be extracted with methylic alcohol. It shows two absorption-bands of a lipochrome like lutein (*Krukenberg*). Thudichum regards the pigment of the serum as lutein; Maly, as hydrobilirubin; and MacMunn as choletelin.

33. **THE GASES OF THE BLOOD.—Absorption by Solid Bodies.**—A considerable attraction exists between the particles of solid porous bodies and gases, whereby the latter are attracted and condensed within the pores of solid bodies, *i. e.*, the gases are *absorbed*. Thus, 1 volume of boxwood charcoal (at 12° C. and ordinary barometric pressure) absorbs 35 volumes CO_2, 9.4 vol. O, 7.5 vol. N, 1.75 vol. H. *Heat* is always formed when gases are absorbed, and the amount of heat evolved bears a relation to the energy with which the absorption takes place. Non-porous bodies are similarly invested by a layer of condensed gases *on their surface*.

By Fluids.—*Fluids* can also absorb gases. *A known quantity of fluid at different pressures* always absorbs the *same volume of gas*. Whether the pressure be great or small, the *volume* of the gas absorbed is equally great (*W. Henry*). But according to Boyle (1662) and Mariotte's law (1679) on the compression of gases, when the pressure within the same *volume* of gas is increased, the *volume varies inversely as the pressure*. Hence it follows that, with *varying pressure*, the *volume* of gas absorbed remains the same, but the *quantity of gas* (*weight*) *is directly proportional to the pressure*. If the pressure = 0, the weight of the gas absorbed must also = 0. As a necessary result of this, we see that (1) *fluids can be freed of their absorbed gases in a vacuum under an air-pump*.

Coefficient of Absorption means the *volume* of a gas (0° C.) which is absorbed by a unit of volume of a liquid (at 760 mm. Hg) at a given temperature. The *volume* of a gas absorbed, and therefore the coefficient of absorption, is quite independent of the pressure, while the *weight* of the gas is proportional to it. *Temperature* has an important influence on the coefficient of absorption. With a low temperature it is greatest; it diminishes as the temperature increases; and at the *boiling point* it = 0. Hence, it follows that (2) *absorbed gases may be expelled from fluids simply by causing the fluids to boil*. The coefficient of absorption diminishes for different fluids and gases, with increasing temperature, in a *special*, and by no means uniform, manner, which must be determined empirically for each liquid and gas. Thus the coefficient of absorption for CO_2 in water diminishes with an increasing temperature, while that for H in water remains unchanged between 0° and 20° C.

Diffusion of Gases.—Gases which do not enter into chemical combinations with each other mix with each other in definite proportions. If the necks of two flasks be placed in communication by means of a glass or other tube, and if the lower flask contain CO_2, and the upper one H, the gases mix *quite independently of their different specific gravities*, both gases forming in each flask a perfectly uniform mixture. The phenomenon is called the *diffusion of gases*. If a *porous membrane* be previously inserted between the gases, the exchange of gases still goes on through the membrane. But (as with endosmosis in fluids) the gases pass with unequal rapidity through the pores, so that at the beginning of the experiment a larger amount of gas is found on one side of the membrane than on the other. According to Graham, the rapidity of the diffusion of the gases through the pores is inversely proportional to the square root of their specific gravities. (According to Bunsen, however, this is not quite correct.)

Different Gases in a Gaseous Mixture do not Exert Pressure upon one another.—Gases, therefore, pass into a space filled with another gas, as they would pass into a vacuum. If the surface of a fluid containing absorbed gases be placed in contact with a very large quantity of another gas, the absorbed gases diffuse into the latter. Hence, absorbed gases can be removed by (3) *passing a stream of another gas through the fluid, or by merely shaking up the fluid with another gas.*

Partial Pressure.—If *two or more gases are mixed* in a closed space over a fluid, as the different gases existing in a gaseous mixture exert no pressure upon each other, the several gases are absorbed. The weight of each absorbed is proportional to the pressure under which each gas would be, were it the only gas in the space. This pressure is called the *partial pressure* of a gas (*Bunsen*). The absorption of gases from their mixtures, therefore, is *proportional to the partial pressure.* The partial pressure of a gas in a space is at the same time the expression for the tension of the gas absorbed by a fluid.

The air contains 0.2096 volume of O, and 0.7904 volume N. If 1 volume of the air be placed under a pressure, P, over water, the partial pressure under which O is absorbed = 0.2096 P; that for N = 0.7904 P. At 0° C., and 760 mm. pressure, 1 volume of water absorbs 0.02477 volume of air, consisting of 0.00862 volume O, and 0.01615 volume N. It contains, therefore, 34 per cent. O and 66 per cent. N. *Therefore, water absorbs from the air a mixture of gases containing a larger percentage of O than the air itself.*

34. EXTRACTION OF THE BLOOD GASES.—[The blood to be analyzed must be collected over mercury so as to avoid contact with air. This is done by means of a special apparatus, consisting of a graduated tube filled with mercury and communicating with a glass globe also filled with mercury, which can be lowered as the blood flows into the graduated tube.] The extraction of the gases from the blood, and their collection for chemical analysis, are carried out by means of the mercurial pump (*C. Ludwig*). Fig. 22 shows in a diagrammatic form the arrangement of Pflüger's gas pump.

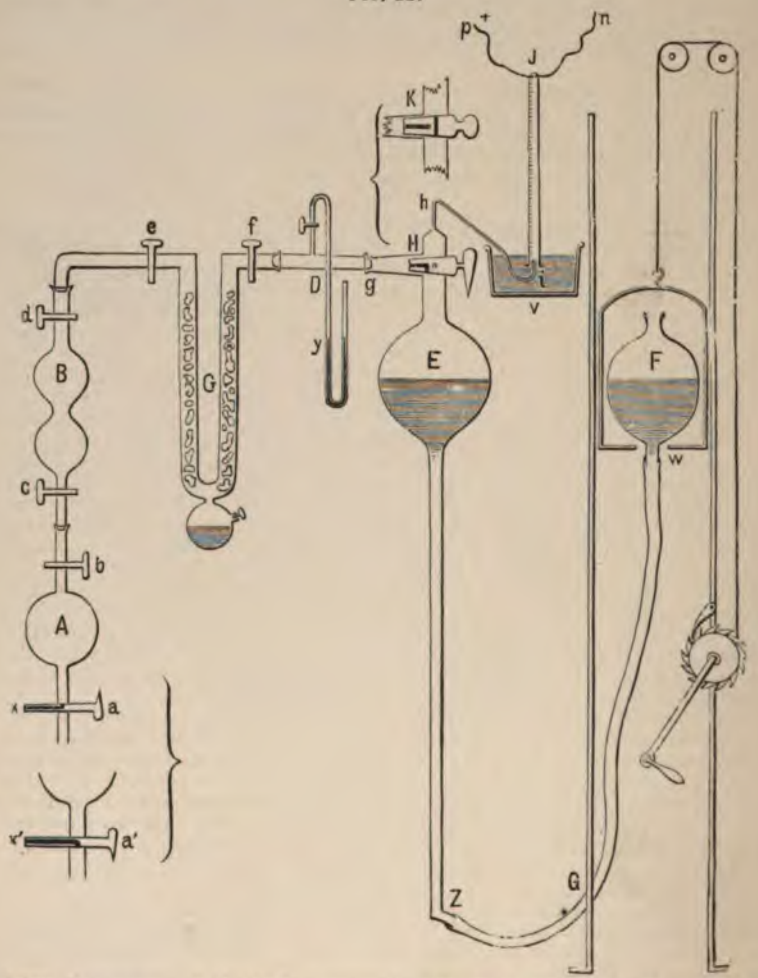
It consists of a receptacle for the blood, or "**blood-bulb**" (A), a *glass globe* capable of containing 250 to 300 c.c., connected above and below with tubes, each of which is provided with a stop-cock, *a* and *b*; *b* is an ordinary stop-cock, while *a* has through its long axis a perforation which opens at *x*, and is so arranged that, according to the position of the handle, it leads up into the blood-bulb (position *x*, *a*), or downward through the lower tube (position *x'*, *a'*). This blood-bulb is first completely emptied of air (by means of a mercurial air pump), and then carefully weighed. One end (*x'*) of it is tied into an artery or a vein of an animal, and when the lower stop-cock is placed in the position *x*, *a*, blood flows into the receptacle. When the necessary amount of blood is collected, the lower stop-cock is put into the position *x'*, *a'*, and the blood-bulb, after being cleaned most carefully, is weighed to ascertain the weight of the amount of blood collected. The second part of the apparatus consists of the **froth-chamber**, B, leading upward and downward into tubes, each of which is provided with an ordinary stop-cock, *c* and *d*. The froth-chamber, as its name denotes, is to catch the froth which is formed during the energetic evolution of the gases from the blood. The lower aperture of the froth-chamber is connected by means of a well-ground tube with the blood-bulb, while above it communicates with the third part of the apparatus, the **drying-chamber**, G. This consists of a U-shaped tube, provided below with a small glass bulb, which is half filled with sulphuric acid, while in its limbs are placed pieces of pumice-stone also moistened with sulphuric acid. As the blood gases pass through this apparatus (which may be shut off by the stop-cocks *e* and *f*), they are freed from their *watery vapor* by the sulphuric acid, so that they pass quite dry through the stop-cock, *f*. The short, well-ground tube, D, is fixed to *f*, and to the former is attached the small *barometric tube* or *manometer*, *y*, which indicates the extent of the vacuum. From D we pass to the pump proper. This consists of two large glass bulbs, which are continued above and below into open tubes; the lower tubes, Z and *w*, being united by a caoutchouc tube, G. Both the bulbs and the caoutchouc tube contain mercury—the bulbs being about half full, and F being larger than E. The bulb, E, is fixed; but F can be raised or lowered by means of a pulley with a rack and pinion motion. If F be raised, E is filled; if F be lowered, E is emptied. The upper end of E divides into two tubes, *g* and *h*, of which *g* is united to D. The ascending tube, *h* (gas-delivery tube), is very narrow, and is bent so that its free end dips into a vessel containing mercury, *v* (a pneumatic trough), and the opening is placed exactly under the tube for collecting the gases, the **eudiometer**, J, which is also filled with mercury. Where *g* and H unite, there is a two-way stop-cock, which in one position, H, places E in communication with A, B, G, D, the chambers to be exhausted, and in the position K shuts off A, B, G, D, and places the bulb, E, in communication with the gas-delivery tube, *h*, and the eudiometer, J. B, G, D are completely emptied of air, thus: The stop-cock is placed in the position, K; raise F until drops of mercury issue from the fine tube, *i* (not yet placed under J); place the stop-cock in the position H, lower F; stop-cock in position, K, and so on until the barometer, *y*, indicates a complete vacuum. J is now placed over *i*. Open the cocks, *c* and *b*, so that the blood-bulb, A, communicates with the rest of the apparatus, and the blood gases froth up in B, and after being dried in G pass toward E. Lower F, and they pass into E; stop-cock in position, K, raise F, and the gases are collected in J under mercury. The repeated lowering and raising of F with the corresponding position of the stop-cocks ultimately drives all the

gases into J. The removal of the gases is greatly facilitated by placing the blood-bulb, A, in a vessel containing water at 60° C.

It is well to remove the gases from the blood immediately after it is collected from a blood vessel, because the O undergoes a diminution if the blood be kept. Of course, in making several analyses, it is difficult to do this, and the best plan to pursue in that case is to keep the receptacles containing the blood on ice.

Mayow (1670) observed that gases were given off from blood *in vacuo*. Magnus (1837) investi-

FIG. 22.



Scheme of Pflüger's gas-pump. A, blood-bulb; *a*, stop-cock, with a longitudinal perforation opening upward; *a'*, the same opening downward; *b* and *c*, stop-cocks; B, froth-chamber; *d*, *e*, *f*, stop-cocks; G, drying-chambers, containing sulphuric acid and pumice-stone; D, tube, with manometer, *y*.

gated the percentage composition of the blood gases. The more important recent investigations have been made by Lothar Meyer (1857), and by the pupils of C. Ludwig and E. Pflüger.

35. QUANTITATIVE ESTIMATION OF THE BLOOD GASES.—The gases obtained from blood consist of O, CO_2, and N. Pflüger obtained (at 0° C. and 1 metre Hg pressure) 47.3 volumes per cent., consisting of—

O, 16.9 per cent.; **CO_2**, 29 per cent.; **N**, 1.4 per cent.

As is shown in Fig. 22, J, the gases are obtained in an **eudiometer**, *i.e.*, in a narrow tube, closed at one end, and with a very exact scale marked on it, and having two fine platinum wires melted into its upper end, with their free ends projecting into the tube (*p* and *n*).

(1) **Estimation of the CO_2.**—A small ball of *fused caustic potash*, fixed on a platinum wire, is introduced into the mixture of gases through the lower end of the eudiometer under cover of the mercury. The surface of the potash ball is moistened before it is introduced. The CO_2 unites with the potash to form potassium carbonate. The potash bulb is withdrawn after 24 hours. The diminution in volume indicates the amount of CO_2 absorbed.

(2) **Estimation of the O.**—(*a*) Just as in estimating the CO_2, a ball of *phosphorus* on a platinum wire is introduced into the eudiometer; it absorbs the O and forms phosphoric acid. Another plan is to employ a small papier-maché ball saturated with *pyrogallic acid in caustic potash*, which rapidly absorbs O. After the ball is removed, the diminution in volume indicates the quantity of O.

(*b*) The O is most easily and accurately estimated by *exploding it in the eudiometer.* Introduce a sufficient quantity of H into the eudiometer, and accurately ascertain its volume; an electrical spark is now passed between the wires, *p* and *n*, through the mixture of gases; the O and H unite to form water, which causes a diminution in the volume of the gases in the eudiometer, of which ⅓ is due to the O used to form water (H_2O).

(*c*) **Estimation of the N.**—When the CO_2 and O are estimated by the above method, the *remainder* is pure N.

36. **THE BLOOD GASES**—[In human blood, the average total gases are estimated to be, at 0° C. and 1 metre pressure,

	O	CO_2	N
Arterial blood,	17	30	1 to 2 per cent.
Venous blood,	6 to 10	35	1 to 2 "

or, calculated at 0° C. and 760 mm. pressure,

Arterial blood,	20	39	1.4 per cent.
Venous blood,	8 to 12	46	1.4 "]

1. **Oxygen** exists in **arterial** blood (dog) on an average to the extent of 17 volumes per cent. (at 0° C. and 1 metre Hg pressure) (*Pflüger*). According to Pflüger, arterial blood (dog) is saturated to $\frac{9}{10}$ with O, while, according to Hüfner, it is saturated to the extent of $\frac{14}{15}$. In **venous** blood the quantity varies very greatly; in the blood of a passive muscle 6 volumes per cent. have been found; while in the blood after asphyxia it is absent, or occurs only in traces. It is certainly more abundant in the comparatively red blood of active glands (salivary glands, kidney), than in ordinary dark venous blood.

[**Modifying Conditions.**—The amount of O obtainable from the blood depends upon the organ from which the blood comes, or whether the organ be active or at rest. Thus the O present in the

Carotid artery is . .	21 per cent.	Renal vein (kidney active),	17 per cent.
Renal artery, . .	19 "	Renal vein (kidney at rest),	6 "

Bert finds that increase of the *atmospheric pressure* from 1 to 10 atmospheres raises the amount of O in arterial blood from 20 to over 24 per cent., and the N from 1.8 to over 9 per cent., while the CO_2 is but slightly affected.]

The O in Blood occurs—(*a*) *simply absorbed* in the plasma. This is only a minimal amount, and does not exceed what distilled water at the temperature of the body would take up at the partial pressure of the O in the air of the lungs (*Lothar Meyer*).

(*b*) *Almost the total O of the blood is* **chemically united,** and therefore not subject to the law of absorption. It is *loosely* united to the hæmoglobin of the red corpuscles, with which it forms *oxyhæmoglobin* (§ 15). With regard to the taking up of O, the total quantity of blood behaves exactly like a solution of hæmoglobin free from O (*Preyer*). The absorption of O is more rapid in blood than in a solution of Hb.

The absorption of this quantity of O is completely **independent of pressure**; hence, animals confined in a closed space, until they are nearly asphyxiated, can use up almost all the O from the

surrounding atmosphere. The fact of the union being independent of pressure is proved by the following: The blood only gives off copiously its chemically united O when the atmospheric pressure is lowered to 20 millimetres, Hg (*Worm Müller*); and, conversely, blood only takes up a little more O when the pressure is increased to 6 atmospheres (*Bert*).

Physical Methods of Obtaining O from Blood.—Notwithstanding the chemical union between the Hb and O, all the O of the blood can be expelled from its state of combination by those means which set free absorbed gases—(*a*) by introducing blood into a Torricellian vacuum; (*b*) by boiling; (*c*) by the conduction of other gases [H, N, CO, or NO] through the blood, because the oxyhæmaglobin compound is so loose that it is decomposed even by these physical means.

Reducing Reagents.—Among *chemical* reagents the following *reducing* substances—ammonium sulphide, sulphuretted hydrogen, alkaline solutions of sub-salts or Stokes's fluid, iron filings, etc., rob blood of its O (§ 15).

Relation to Fe.—The amount of **iron in the blood** (0.55 in 1000 parts) stands in direct relation to the amount of Hb; this to the quantity of blood corpuscles; and this, in turn, to the specific gravity of the blood. The amount of O in the blood, therefore, is nearly proportional to the specific gravity of the blood, and it is also in proportion to the amount of iron in the blood. Picard affirms that 2.36 grams of iron in the blood can fix chemically 1 gram O; while, according to Hoppe-Seyler, the proportion is 1 atom iron to 2 atoms O.

During morphia narcosis the amount of O in the blood is diminished (*Ewald*); after hemorrhage the arterial blood is saturated with O (*J. G. Ott*).

Disappearance of O in Shed Blood.—Even immediately after blood is shed, there is a slight disappearance of O, as a physiological index of respiration of the tissues within the living blood itself (§ 132). When blood is kept long outside of the blood vessels, the quantity of O gradually diminishes, and if it be kept for a length of time at a high temperature it may disappear altogether. This depends upon decomposition occurring in the blood, whereby reducing substances are formed which consume the O. All kinds of blood, however, do not act with equal energy in consuming O, *e.g.*, venous blood from active muscles acts most energetically, while that from the hepatic vein has very little effect. CO_2 appears in the blood in place of the O, and the color darkens. The amount of CO_2 produced is sometimes greater than that of the O consumed.

Relation to Acids.—If blood (or a solution of oxyhæmoglobin) be acted upon by *acids* (*e.g.*, tartaric acid) until it is strongly acid, O can be pumped out in considerably less amount, while the formation of CO_2 is not increased. We must, therefore, assume that, during the decomposition of the Hb caused by the acids (§ 18), a decomposition product becomes more highly oxidized by the intense chemical union of the O at the moment of its origin (*Lothar Meyer, Zuntz, Strassburg*). The same phenomenon occurs when oxyhæmoglobin is decomposed by *boiling*.

37. IS OZONE PRESENT IN BLOOD?—On account of the numerous and energetic oxidations which occur in connection with the blood, the question has often been raised as to whether the O of the blood exists in the form of ozone (O_3). Ozone, however, is contained neither in the blood itself (*Schönbein*) nor in the blood gases obtained from it. Nevertheless, the red corpuscles (and Hb) have a distinct relation to ozone.

(1) **Tests for Ozone.**—Hæmoglobin acts as a *conveyer of ozone*, *i.e.*, it is able to remove the active O of other bodies and to *convey* or transfer it at once to other easily oxidizable substances. (*a*) Turpentine which has been exposed to the air for a long time always contains ozone. The tests for the latter are starch and potassium iodide, the ozone decomposing the iodide, when the iodine strikes a blue with the starch. (*b*) Freshly-prepared tincture of guaiacum is also rendered blue by ozone. If some tincture of guaiacum be added to turpentine there is no reaction, but on adding a drop of blood a deep blue color is immediately produced, *i.e.*, blood takes the ozone from the turpentine and *conveys* it at once to the dissolved guaiacum, which becomes blue. It is immaterial whether the Hb contains O or not.

(2) It is also asserted that hæmoglobin acts as an *ozone-producer*, *i.e.*, that it can convert the ordinary O of the air into ozone. Hence the reason why red blood corpuscles alone render guaiacum blue. This reaction succeeds best when the guaiacum solution is allowed to dry on blotting-paper, and a few drops of blood (diluted 5 to 10 times) are poured on it. That the Hb forms ozone from the surrounding O, is shown by the fact that red blood corpuscles containing carbonic oxide cause the blue color (*Kühne and Scholz*). According to Pflüger, however, these reactions only occur from decomposition of the Hb, so that on this view the blood corpuscles cannot be regarded as producers of ozone.

Sulphuretted hydrogen is decomposed by blood (as by ozone itself) into sulphur and water.

Hydric peroxide is decomposed by blood into O and water [but this reaction is prevented by the addition of a small amount of hydrocyanic acid (*Schönbein*)]. Crystallized Hb does not do this, and H_2O_2 may be cautiously injected into the blood vessels of animals. This would show that *unchanged* Hb does *not* produce ozone.

Various Forms of Oxygen.—There are three forms of oxygen: (1) The ordinary oxygen(O_2) in the air. (2) Active or nascent oxygen (O), which never can occur in the free state, but the moment it is formed acts as a powerful oxidizing agent and produces chemical compounds. It converts water into hydric peroxide—the N of the air into nitrous and nitric acids, and even CO into CO_2, which ozone does not. It certainly plays an important part in the organism. (3) Ozone (O_3), which is formed by the decomposition of several molecules of ordinary oxygen (O_2) into two atoms of O, and the appropriation of each of these atoms by a molecule of undecomposed oxygen. It is oxygen condensed to $\frac{3}{2}$ of its volume.

38. CO_2 AND N IN BLOOD.—II. **Carbon Dioxide.**—In **arterial** blood there are about 30 volumes per cent. of CO_2 at 0° C. and 1 metre pressure (*Setschenow*); but in **venous** blood the amount is very variable, *e.g.*, in the venous blood of passive muscles there are 35 volumes per cent. (*Sczelkow*), while in the blood of asphyxia there may be 52.6 volumes per cent. The CO_2 in the *lymph* of asphyxia is less than that in the blood (*Buchner, Gaule*). The CO_2 of the blood may be extracted from it or *completely pumped out*, but during the process of evacuation, or removal of the gas, a new property of the red blood corpuscles is produced, whereby they assume the function of an acid, and thus aid in the *chemical* expulsion of the CO_2. This acid-like property of the red corpuscles occurs especially in the presence of O and heat.

(A) **The CO_2 in the Plasma.**—*The largest portion of the CO_2 belongs to the plasma* (or serum), and it all appears to be in a state of **chemical** combination. Serum takes up CO_2 quite independently of pressure, hence it cannot be merely absorbed. A certain part of the CO_2 can be removed from the serum (plasma) by the Torricellian vacuum, while another part is obtained only after the addition of an acid. [The latter is called the "fixed" CO_2, while the former is known as the "loose" CO_2.] The CO_2 in the serum exists in the following conditions:—

(1) CO_2 is united to the soda of the plasma in the form of "*neutral sodic carbonate.*" This portion of the CO_2 can only be displaced from its combination by the addition of an acid, (In depriving blood of its gases the red corpuscles play the rôle of an acid.)

(2) A portion of the CO_2 is *loosely* united to sodic carbonate in the form of *sodic bicarbonate;* the carbonate takes up 1 equivalent of CO_2; $Na_2CO_3 + CO_2 + H_2O = 2NaHCO_3$. This CO_2 may be pumped out, as in the process the bicarbonate splits up again into the neutral carbonate and CO_2.

Preyer has objected to this view on the ground that blood is alkaline in reaction, while all solutions that contain CO_2 in a state of absorption, or loose chemical combinations, are always acid. Pflüger and Zuntz showed that blood, after being completely saturated with CO_2, still remains alkaline.

As the bicarbonate only gives up its CO_2 very slowly *in vacuo*, while blood gives off its CO_2 very energetically, perhaps the soda, united with an albuminous body, combines with the CO_2 and forms a complex compound, from which the CO_2 is rapidly given off *in vacuo*.

(3) A minimal portion of the CO_2 may be chemically united with *neutral sodic phosphate* in the plasma (*Fernet*). One equivalent of this salt can fix one equivalent of CO_2, so *acid* sodium phosphate and *acid* sodium carbonate are formed, $Na_2HPO_4 + CO_2 + H_2O = NaH_2PO_4 + NaH, CO_3$ (*Hermannn*). When the gases are removed the CO_2 escapes, and *neutral* sodic phosphate remains.

It is probable, however, that *almost all* the sodic phosphate found in the blood-ash arises from the burning of lecithin; we have, therefore, to consider only the very small amount of this salt which occurs in the plasma (*Hoppe-Seyler and Sertoli*).

(B) **The CO_2 in the Blood Corpuscles.**—The red corpuscles contain CO_2 in loose chemical combination; for (1) a volume of blood can fix nearly as much CO_2 as an equal volume of serum (*Ludwig, Al. Schmidt*); and (2) with increasing

pressure the absorption of CO_2 by blood takes place in a different ratio from what occurs with serum (*Pflüger, Zuntz*). The red corpuscles can fix more CO_2 than their own volume, and the union of the CO_2 seems to depend upon the Hb, for Setschenow found that, when Hb was acted on by CO_2, its power of fixing the latter was increased, which is perhaps due to the formation of some substance more suited for fixing CO_2. The colorless corpuscles, after the manner of the serum constituents, also fix CO_2 to the extent of $\frac{1}{8}$ to $\frac{1}{12}$ of the absorbing power of serum.

After the use of I, Hg, sodic oxalate, and nitrite, there is a diminution of CO_2 in arterial blood (*Feitelberg*), and also in fever (*Geppert, Minkowski*). [In the last case it is perhaps due to the diminished alkalinity, and this is in part owing to the acid products formed during the decomposition of the tissues.]

III. **Nitrogen** exists in the blood to the extent of 1.4 to 1.6 vol. per cent., and it appears to be simply *absorbed*.

It is doubtful if any part of the N exists chemically united in the red corpuscles. Blood warmed outside the body, and with a free supply of oxygen, gives off a minute quantity of ammonia, which is perhaps derived from the decomposition of some salt of ammonia as yet unknown (*Kühne and Strauch*).

39. ARTERIAL AND VENOUS BLOOD.—Arterial blood contains in solution all those substances which are necessary for the nutrition of the tissues, those which are employed in secretion, and it also contains a rich supply of O. **Venous blood** must contain less of all these, but in addition it holds the used-up or effete substances derived from the tissues, and the products of their retrogressive metabolism are more numerous; there is in venous blood a larger amount of CO_2. It is evident, also, that the blood of certain veins, the portal and hepatic, must have special characters.

The following are the most important points of difference between arterial blood and venous blood:—

Arterial Blood contains—

more O,	more extractives,	less urea.
less CO_2,	more salts,	It is bright red and not dichroic.
more water,	more sugar,	
more fibrin,	fewer blood corpuscles,	As a rule it is 1° C. warmer.

The **bright-red** color of arterial blood depends on the presence of oxyhæmoglobin, while the dark color of venous blood is due to its smaller proportion of oxyhæmoglobin, and the quantity of reduced hæmoglobin which it contains. The dark change of color is not to be attributed to the larger quantity of CO_2 in venous blood (*Marchand*); for if equal quantities of O be added to two portions of blood, and if CO_2 be added to one of them, the color is not changed (*Pflüger*).

[According to C. Schmidt, the blood of the **portal vein** contains more water, plasma, salts, and fats, but less extractives and corpuscles than the blood of the hepatic vein; while (when an animal is not digesting) sugar is absent or at least only in traces in the portal vein, and in considerable amount in the hepatic vein (§ 175)]

40. QUANTITY OF BLOOD.—In the adult the quantity of blood is equal to $\frac{1}{18}$ part of the body weight (*Bischoff*), in newly-born children $\frac{1}{19}$ (*Welcker*).

According to Schücking, the amount of blood in a newly-born child depends to some extent upon the time at which the umbilical cord is ligatured. The amount = $\frac{1}{15}$ of the body weight when the cord is tied at once, while if it is tied somewhat later it may be $\frac{1}{9}$. Immediate ligature of the cord may, therefore, deprive a newly-born child of 100 grams of blood. Further, the number of corpuscles is less in a child after immediate ligature of the umbilical cord than when it is tied somewhat later (*Helot*).

The methods of Valentin (1838), and Ed. Weber (1850), are not now used, as the results obtained are not sufficiently accurate.

Method of Welcker (1854).—Begin by taking the weight of the animal to be experimented on; place a cannula in the carotid, and allow the blood to run into a flask previously weighed, and in which small pebbles (or Hg) have been placed in order to defibrinate the blood by shaking.

Take a part of this defibrinated blood, and make it cherry-red in color by passing through it a stream of CO (because ordinary blood varies in color according to the amount of O contained in it—*Gscheidlen, Heidenhain*). Tie a ⊢ shaped cannula in the two cut ends of the carotid, and allow a 0.6 per cent. solution of common salt to flow into the vessel from a pressure bottle; collect the colored fluid issuing from the jugular veins and inferior vena cava until the fluid is quite clear. The entire body is then chopped up (with the exception of the contents of the stomach and intestines, which are weighed, and their weight deducted from the body weight), and extracted with water, and after twenty-four hours the fluid is expressed. This water, as well as the washings with salt solution, are collected and weighed, and part of the mixture is saturated with CO. A sample of this dilute blood is placed in a vessel with parallel sides (1 cm. apart) opposite the light (the so-called hæmatinometer), and in a second vessel of the same dimensions a sample of the undiluted CO blood is diluted with water from a burette, until both fluids give the *same intensity of color*. From the quantity of water required to dilute the blood to the tint of the washings of the blood vessels, the quantity of blood in the washings is calculated. On chopping up the muscles alone, we obtain the amount of Hb present in them, which is not taken into calculation.

Quantity of Blood in Various Animals.—The quantity of blood in the mouse $= \frac{1}{12}$ to $\frac{1}{18}$; guinea-pig $= \frac{1}{19.7}$ ($\frac{1}{17}$ to $\frac{1}{22}$); rabbit $= \frac{1}{20.1}$ ($\frac{1}{15}$ to $\frac{1}{27}$); dog $= \frac{1}{18}$ ($\frac{1}{11}$ to $\frac{1}{18}$); cat $= \frac{1}{21.5}$; birds $= \frac{1}{10}$ to $\frac{1}{18}$; frog $= \frac{1}{15}$ to $\frac{1}{20}$; fishes $= \frac{1}{14}$ to $\frac{1}{19}$ of the body weight (without the contents of the stomach and intestines).

The specific gravity of the blood ought always to be taken when estimating the amount of blood. The amount of blood is diminished during inanition; fat persons have relatively less blood; after hemorrhage the loss is at first replaced by a watery fluid, while the blood corpuscles are gradually regenerated.

Blood in Organs.—The estimation of the *quantity of blood in different organs* is done by suddenly ligaturing their blood vessels *intra vitam*. A watery extract of the chopped-up organ is prepared, and the quantity of blood estimated as described above. [Roughly it may be said that the lungs, heart, large arteries, and veins contain ¼; the muscles of the skeleton, ¼; the liver, ¼; and other organs, ¼ (*Ranke*).]

41. **ABNORMAL CONDITIONS OF THE BLOOD.**—(A) 1 **Polyæmia.**—(1) An increase in the entire mass of the blood, *uniformly in all organs*, constitutes *polyæmia* or *plethora*, and in over-nourished individuals it may approach a pathological condition. A bluish-red color of the skin, swollen veins, large arteries, hard, full pulse, injection of the capillaries and smaller vessels of the visible mucous membranes are signs of this state, and, when accompanied by congestion of the brain, there is vertigo, congestion of the lungs, and breathlessness. After major amputations with little loss of blood a relative but transient increase of blood has been found (?) (*plethora apocoptica*).

Transfusion.—Polyæmia may be produced artificially by the *injection of blood* of the same species. If the normal quantity of blood be increased 83 per cent. no abnormal condition occurs, because the blood pressure is not permanently raised. The excess of blood is accommodated in the greatly distended capillaries, which may be stretched beyond their normal elasticity. If it be increased to 150 per cent. there are variations in the blood pressure, life is endangered, and there may be sudden rupture of blood vessels (*Worm Müller*).

Fate of Transfused Blood.—After the transfusion of blood the formation of lymph is greatly increased; but in one or two days the serum is used up, the water is excreted chiefly by the urine, and the albumin is partly changed into urea. Hence, the blood at this time appears to be relatively richer in blood corpuscles (*Panum, Lesser, Worm Müller*). The red corpuscles break up much more slowly, and the products thereof are partly excreted as urea and partly (but not constantly) as bile pigments. Even after a month an increase of colored blood corpuscles has been observed (*Tschirjew*). That the blood corpuscles are broken up *slowly* in the economy is proved by the fact, that the amount of urea is much larger when the same quantity of blood is swallowed by the animal than when an equal amount is transfused (*Tschirjew, Landois*). In the latter case there is a moderate increase of the urea, lasting for days, a proof of the slow decomposition of the red corpuscles. Pronounced over-filling of the vessels causes loss of appetite and a tendency to hemorrhage of the mucous membranes.

(2) **Polyæmia serosa** is that condition in which the amount of serum, *i.e.*, the amount of water in the blood, is increased. This may be produced artificially by the transfusion of blood serum from the same species. The water is soon given off in the urine, and the albumin is decomposed into urea, without, however, passing into the urine. An animal forms more urea in a short time from a quantity of transfused serum than from the same quantity of blood, a proof that the blood corpuscles remain longer undecomposed than the serum (*Forster, Landois*). If serum from another species of animal be used (*e.g.*, dog's serum transfused into a rabbit), the blood corpuscles of the

recipient are dissolved; hæmoglobinuria is produced (*Ponfick*); and if there be general dissolution of the corpuscles, death may occur (*Landois*).

(3) **Polyæmia aquosa** is a simple increase of the water of the blood, and occurs temporarily after copious drinking, but increased diuresis soon restores the normal condition. Diseases of the kidneys, which destroy their secreting parenchyma, produces this condition, and often general dropsy, owing to the passage of water into the tissues. Ligature of the ureter produces a watery condition of the blood.

(4) **Plethora polycythæmica, Hyperglobulie.**—An increase of the red corpuscles has been assumed to occur when periodically recurring hemorrhages are interrupted, *e.g.*, menstruation, bleeding from the nose, etc.; but the increase of corpuscles has not been definitely proved. There is a proved case of temporary polycythæmia, viz., when similar blood is transfused, a part of the fluid being used up, while the corpuscles remain unchanged for a considerable time. There is a remakable increase in the number of blood corpuscles (to 8.82 millions per cubic millimetre) in certain severe cardiac affections where there is great congestion, and much water transudes through the vessels. In cases of hemiplegia, for the same reason, the number of corpuscles is greater on the paralyzed congested side (*Pensoldt*). After diarrhœa, which diminishes the water of the blood, there is also an increase (*Brouardel*), and the same is the case after profuse sweating and polyuria. Drugs (alcohol, chloral, amyl nitrite) which act on the blood vessels affect the number of corpuscles; during contraction of the blood vessels their number increases, during dilatation they diminish in number (*Andreesen*). There is a temporary increase in the hæmatoblasts as a reparative process after severe hemorrhage (§ 7), or after acute diseases. In cachectic conditions this increase continues, owing to the diminished non-conversion of these corpuscles into red corpuscles. In the last stages of cachexia the number diminishes more and more until the formation of hæmatoblasts ceases (*Hayen*).

(5) **Plethora hyperalbuminosa** is a term applied to the increase of albumins in the plasma, such as occurs after taking a large amount of food. A similar condition is produced by transfusing the serum of the same species, whereby, at the same time, the urea is increased. Injection of egg-albumin produces albuminuria (*Stokvis, Lehmann*).

[The **subcutaneous injection** of human blood has been practiced with good results in anæmia (*v. Ziemssen*). When defibrinated *human* blood is injected subcutaneously, while its passage into the circulation is aided by massage, it causes neither pain nor inflammation, but the blood of *animals*, and a solution of hæmoglobin, always induce abscess (*Benczur*). Blood is also rapidly absorbed when injected in small amount into the respiratory passages.]

Mellitæmia.—The sugar in the blood is partly given off by the *urine*, and in "**diabetes mellitus**" 1 kilo. (2.2 lbs.) may be given off daily, when the quantity of urine may rise to 25 kilos. To replace this loss of grape sugar a large amount of food and drink is required, whereby the urea may be increased threefold. The increased production of sugar causes an increased decomposition of albuminous tissues; hence the urea is always increased, even though the supply of albumin be insufficient. The patient loses flesh; all the glands, and even the testicles, atrophy or degenerate (pulmonary phthisis is common); the skin and bones become thinner; the nervous system holds out longest. The teeth become carious on account of the acid saliva, the crystalline lens becomes turbid from the amount of sugar in the fluid of the eye which extracts water from the lens, and wounds heal badly because of the abnormal condition of the blood. Absence of all carbohydrates in the food causes a diminution of the sugar in the blood, but does not cause it to disappear entirely. [The sugar in the blood is also increased after the inhalation of chloroform or amyl nitrite, and after the use of curara, nitro-benzole, and chloral (§ 175).] An excessive amount of inosite has been found in the blood and urine (§ 267), constituting **mellituria inosita** (*Vohl*).

Lipæmia, or an Increase of the Fat in the Blood, occurs after every meal rich in fat (*e.g.*, in sucking kittens), so that the serum may become turbid like milk. Pathologically, this occurs in a high degree in drunkards and in corpulent individuals. When there is great decomposition of albumin in the body (and therefore in very severe diseases), the fat in the blood increases, and this also takes place after a liberal supply of easily decomposable carbohydrates and much fat.

After injuries to bones affecting the marrow, not unfrequently fatty granules pass from the marrow through the imperfect walls of the blood vessels into the blood stream. These fatty particles may form fat emboli, *e.g.*, in the liver or lungs, or they may appear in the urine.

If granules of cinnabar or indigo are injected into the blood, they are taken up by the leucocytes, and by them are carried outside the blood stream. The cells of the splenic pulp, marrow of bone, and the liver also take up these particles (*Siebel*).

The **salts** remain very persistently in the blood. The withdrawal of common salt produces albuminuria, and, if all salts be withheld, paralytic phenomena occur (*Forster*). Over-feeding with salted food, such as salt meat, has caused death through fatty degeneration of the tissues, especially of the glands. Withdrawal of lime and phosphoric acid produces atrophy and softening of the bones. In infectious diseases and dropsies the salts of the blood are often increased, and diminished in inflammation and cholera. [Na Cl is absent from the urine in certain stages of pneumonia, and it is a good sign when the chlorides begin to return to the urine.] [In **scurvy** the

corpuscular elements are diminished in amount, but we have not precise information as to the salts, although this disease is prevented, in persons forced to live upon preserved and salted food, by a liberal use of the salts—especially potash salts—of the organic acids, as contained in lime-juice. In **gout** the blood, during an acute attack, and also in chronic gout, contains an excess of uric acid (*Garrod*).]

The **amount of fibrin** is increased in inflammations of the lung and pleura [croupous pneumonia, erysipelas], hence such blood forms a *crusta phlogistica* (§ 27). In other diseases, where decomposition of the blood corpuscles occurs, the fibrin is increased, perhaps because the dissolved red corpuscles yield material for the formation of fibrin. After repeated hemorrhages, Sigm. Mayer found an increase of fibrin. Blood rich in fibrin is said to coagulate *more slowly* than when less fibrin is present—still there are many exceptions.

(B) (I.) Diminution of the Quantity of Blood, or its Individual Constituents.—(1) **Oligæmia vera, Anæmia,** or diminution of the quantity of blood as a whole, occurs whenever there is hemorrhage. Life is endangered in newly-born children when they lose a few ounces of blood; in children a year old, on losing half a pound; and in adults, when one-half of the total blood is lost. Women bear loss of blood much better than men. The periodical formation of blood after each menstruation seems to enable blood to be renewed more rapidly in their case. Stout persons, old people, and children do not bear the loss of blood well. The more rapidly blood is lost, the more dangerous it is. [A moderate loss of blood is soon made up, but the fluid part is more quickly restored than are the corpuscles.]

Symptoms of Loss of Blood.—Great loss of blood is accompanied by general paleness and coldness of the cutaneous surface, increased oppression, twitching of the eyeballs, noises in the ears and vertigo, loss of voice, great breathlessness, stoppage of secretions, coma; dilatation of the pupils, involuntary evacuations of urine and fæces, and lastly, general convulsions, are sure signs of **death by hemorrhage.** In the gravest cases recovery is only possible by means of transfusion. Animals can bear the loss of one-fourth of their entire blood without the blood pressure in the arteries permanently falling, because the blood vessels contract and accommodate themselves to the smaller quantity of blood (in consequence of the stimulation of the vasomotor centre in the medulla). The loss of one-third of the total blood diminishes the blood pressure considerably (one-fourth in the carotid of the dog). If the hemorrhage is not such as to cause death, the fluid part of the blood and the dissolved salts are restored by absorption from the tissues, the blood pressure gradually rises, and then the albumin is restored, though a longer time is required for the formation of red corpuscles. At first, therefore, the blood is abnormally rich in water (**hydræmia**), and at last abnormally poor in corpuscles (**oligocythæmia, hypoglobulie**). With the increased lymph stream which pours into the blood, the colorless corpuscles are considerably increased above normal, and during the period of restitution fewer red corpuscles seem to be used up (*e.g.*, for bile).

After moderate bleeding from an artery in animals, Buntzen observed that the *volume* of the blood was restored in several hours; after more severe hemorrhage in 24 to 48 hours. The red blood corpuscles, after a loss of blood equal to 1.1 to 4.4 per cent. of the body weight, are restored only after 7 to 34 days. The regeneration *begins* after 24 hours. During the period of regeneration the number of the blood corpuscles in an early stage of development is increased. The newly-formed corpuscles contain less Hb than normal (*Jac. G. Ott*). Even in man the duration of the period of regeneration depends upon the amount of blood lost (*Lyon*). The amount of hæmoglobin is diminished nearly in proportion to the amount of the hemorrhage (*Bizzozero and Salvioli*).

Metabolism in Anæmia.—The *condition of the metabolism* within the bodies of anæmic persons is important. The decomposition of proteids is increased (the same is the case in hunger), hence the excretion of urea is increased (*Bauer*). The decomposition of fats, on the contrary, is diminished, which stands in relation with the diminution of CO_2 given off. Anæmic and chlorotic persons put on fat easily. The fattening of cattle is aided by occasional bleedings and by intercurrent periods of hunger (*Aristotle*).

(2) An excessive thickening of the blood through loss of water is called **Oligæmia sicca.** This occurs in man after copious watery evacuations, as in cholera, so that the thick tarry blood stagnates in the vessels. Perhaps a similar condition—though to a less degree—may exist after very copious perspiration.

(3) If the proteids in blood be abnormally diminished the condition is called **Oligæmia hypalbuminosa;** they may be diminished about one-half. They are usually replaced by an excess of water in the blood [so that the blood is watery, constituting **hydræmia**]. Loss of albumin from the blood is caused directly by albuminuria (25 grams of albumin may be given off by the urine daily), persistent suppuration, great loss of milk, extensive cutaneous ulceration, albuminous diarrhœa (dysentery). Frequent and copious hemorrhages, however, by increasing the absorption of water into the vessels, at first produce oligæmia hypalbuminosa.

For the **abnormal changes** of the red and white blood corpuscles, see § 10; for **Hæmophilia,** § 28.

[**Organisms in the Blood.**—The presence of animal and vegetable parasites in the blood gives rise to certain diseases. Some of these, and especially the vegetable organisms, have the power of multiplying in the blood. The vegetable forms belonging to the **schizomycetes** are frequently spoken of collectively under the title **bacteria.** They are classified by Cohn into

I. Sphærobacteria.
II. Microbacteria, exhibit movements.
III. Desmobacteria } exhibit movements.
IV. Spirobacteria }

These forms are shown in Fig. 23. The micrococci (A) are examples of I; while Bacterium termo (B) is an example of II. In III the members are short cylindrical rods, straight (Bacillus,

FIG. 23.

A, micrococcus; B, bacterium; C, vibrios; D, bacilli; E, spirillum.

FIG. 24.

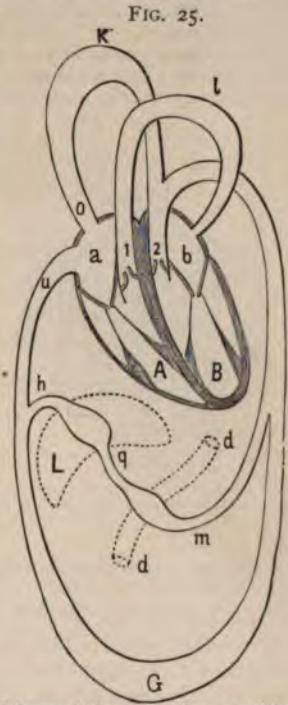
Bacillus anthracis from the blood (ox) in splenic fever.

D) or wavy (Vibrio, C). Splenic fever of cattle is due to the presence of Bacillus anthracis (Fig. 24). These rod-shaped bodies under proper conditions divide transversely and elongate, but they also form spores in their interior, which in turn under appropriate conditions may germinate (Fig. 24). Class IV is represented by two genera, Spirochæta and Spirillum (Fig. 23), the former with close, and the later with open spirals. The Spirochæta Obermeieri (often spoken of as "Spirillum") is present in the blood during the paroxysms in persons suffering from relapsing fever. Among animal parasites are Filaria sanguinis, and Bilharzia Hæmatobia, which occurs in the portal vein and in the veins of the urinary apparatus.]

PHYSIOLOGY OF THE CIRCULATION.

42. GENERAL VIEW.—The blood within the vessels is in a state of continual motion, being carried *from* the ventricles by the large arteries (aorta and pulmonary) and their branches *to* the system of *capillary* vessels, *from* which again it passes into the *veins* that end in the atria of the auricles (*W. Harvey*, 1628).

FIG. 25.



Scheme of the circulation.—*a*, right, *b*, left auricle; A, right, B, left ventricle; 1, pulmonary artery; 2, aorta; *l*, area of pulmonary, K, area of systemic circulation; *o*, the superior vena cava; G, area supplying the inferior vena cava, *u*; *d*, *d*, intestine; *m*, mesenteric artery; *q*, portal vein; L, liver; *h*, hepatic vein.

The **cause of the circulation** is the *difference of pressure* which exists between the blood in the aorta and pulmonary artery on the one hand, and the two venæ cavæ and the four pulmonary veins on the other. The blood, of course, moves continually in its closed tubular system in the direction of least resistance. The greater the difference of pressure, the more rapid the movement will be. The cessation of the difference of pressure (as after death) naturally brings the movement to a standstill (§ 81). The circulation is usually divided into—

(1) **The greater, or systemic circulation,** which includes the course of the blood from the left auricle and left ventricle, through the aorta and all its branches, the capillaries of the body and the veins, until the two venæ cavæ terminate in the right auricle.

(2) **The lesser, or pulmonic circulation,** which includes the course from the right auricle and right ventricle, the pulmonary artery, the pulmonary capillaries, and the four pulmonary veins springing from them, until these open into the left auricle.

(3) **The portal circulation** is sometimes spoken of as a special circulatory system, although it represents only a second set of capillaries (within the liver) introduced into the course of a venous trunk. It consists of the vena portarum—formed by the union of the intestinal or mesenteric and splenic veins, and it passes into the liver, where it divides into capillaries, from which the hepatic veins arise. The hepatic vein joins the inferior vena cava.

Strictly speaking, however, there is no special portal circulation. Similar arrangements occur in other animals in different organs, *e. g.*, snakes have such a system in their supra-renal capsules, and the frog in its kidneys. When an *artery* splits up into fine branches during its course, and these branches do not form capillaries, but reunite into an arterial trunk, a **rete mirabile** is formed, such as occurs in apes and the edentata. Microscopic retia mirabilia exist in the human mesentery (*Schöbl*). Similar arrangements may exist in connection with veins, giving rise to *venous retia mirabilia*.

43. **THE HEART.—The muscular fibres** of the mammalian heart consist of short (50 to 70 μ in man), very fine, transversely striated fibres, which are actual unicellular elements, devoid of a sarcolemma (15 to 25 μ broad), and usually divided at their blunt ends, by which means they anastomose and form a network (Fig. 26, A, B). The individual muscle cells contain in their centre an oval nucleus, and are held together by a cement which is blackened by silver nitrate, and dissolved by a 33 per cent. solution of caustic potash. This cement is also dissolved by a 40 per cent. solution of nitric acid. The transverse striæ are not very distinct, and not unfrequently there is an appearance of longitudinal striation, produced by a number of very small granules arranged in rows within the fibres. The fibres are gathered lengthwise in bundles, or fasciculi, surrounded and separated from each other by delicate processes of the **perimysium.** When the connective tissue is dissolved by prolonged boiling, these bundles can be isolated, and constitute the so-called "fibres" of the heart. The transverse sections of the bundles in the auricles are polygonal or rounded, while in the ventricles they are somewhat flattened. [The muscular mass of the heart is called the **myocardium,** and is invested by fibrous tissue. It is important to notice that the connective tissue of the visceral pericardium (**epicardium**) is continuous with that of the endocardium by means of the perimysium surrounding the bundles of muscular fibres.] The fine spaces which exist between these bundles form narrow lacunæ, lined with epithelium, and constituting part of the lymphatic system of the heart.

[The cardiac muscular fibres occupy an intermediate position between striped and plain muscular fibres. Although they are striped, they are involuntary, not being directly under the influence of the will, while they contract more slowly than a voluntary muscle of the skeleton.] In the **frog's** heart

FIG. 26.

A, muscular fibres from the heart of a mammal, and C from a frog; B, transverse section of the cardiac fibres; *b*, connective-tissue corpuscles; *c*, capillaries.

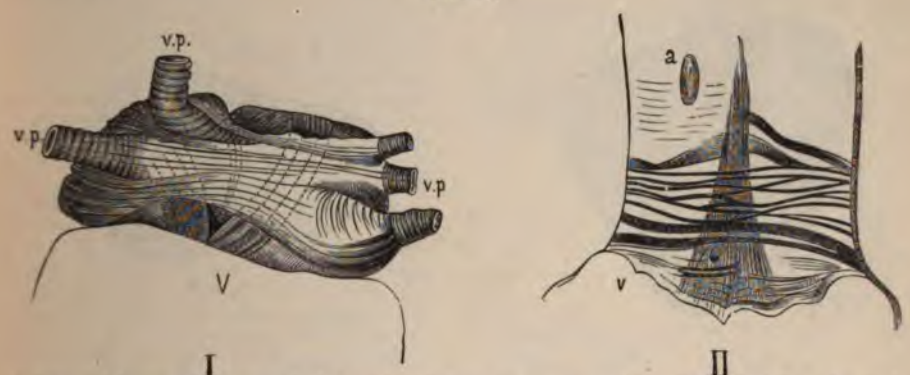
the muscular fibres are in shape elongated spindles, or fusiform, in this respect resembling the plain muscle cells, but they are transversely striped (Fig. 26, C). They are easily isolated by means of a 33 per cent. solution of potash or dilute alcohol.

44. **ARRANGEMENT OF THE CARDIAC MUSCULAR FIBRES.**—The study of the embryonic heart is the key to a proper understanding of the complicated arrangement of the fibres in the adult heart. The simple tubular heart of the embryo has an *outer circular* and an *inner longitudinal* layer of fibres. The septum is formed later; hence, it is clear that a part, at least, of the fibres must be common to the two auricles, and a part also to the two ventricles, since there is, originally, but one chamber in the heart. The muscular fibres of the auricles are, however, *completely separated* from those of the ventricles by the fibro-cartilaginous rings. In the auricles the fundamental arrangement of the embryonic fibres partly remains, while in the ventricles it becomes obscured as the cavities undergo a sac-like dilatation, and also become twisted in a spiral manner.

(1) **The muscular fibres in the auricles** are completely separated from the fibres of the ventricles by the *fibrous* rings which surround the auriculo-ventricular orifices, and which serve as an attachment for the auriculo-ventricular valves (Fig. 27, I). The auricles are much thinner than the ventricles, and their fibres are generally arranged in two layers; the outer *transverse* layer is continuous over

both auricles, while the inner one is directed *longitudinally*. The outer transverse fibres may be traced from the openings of the venous trunks anteriorly and posteriorly over the auricular walls. The longitudinal fibres are specially well marked where they are inserted into the fibro-cartilaginous rings, while in some parts of the anterior auricular wall they are not continuous. In the *auricular septum*, some fibres, circularly disposed around the *fossa ovalis* (formerly the embryonic opening of the foramen ovale), are well marked. *Circular bands* of striped muscle exist around the *veins* where they open into the heart; these are least marked on the inferior vena cava, and are stronger and reach higher (2.5 cm.) on the superior vena cava (Fig. 27, II). Similar fibres exist around the pulmonary veins, where they join the left auricle, and these fibres (which are arranged as an inner circular and an outer longitudinal layer) can be traced to the hilus of the lung in man and some mammals; in the ape and rat they extend on the pulmonary veins right into the lung. In the mouse and bat, again, the striped muscular fibres pass so far into the lungs that the walls of the smaller veins are largely composed of striped muscle (*Stieda*).

FIG. 27.



I. Course of the muscular fibres on the left auricle with the outer transverse and inner longitudinal fibres, the circular fibres on the pulmonary veins (*v. p.*); V, the left ventricle (*John Reid*). II. Arrangement of the striped muscular fibres on the superior vena cava (*Elischer*)—*a*, opening of vena azygos; *v*, auricle.

Circular muscular fibres are found where the vena magna cordis enters the heart, and in the *Valvula Thebesii* which guards it.

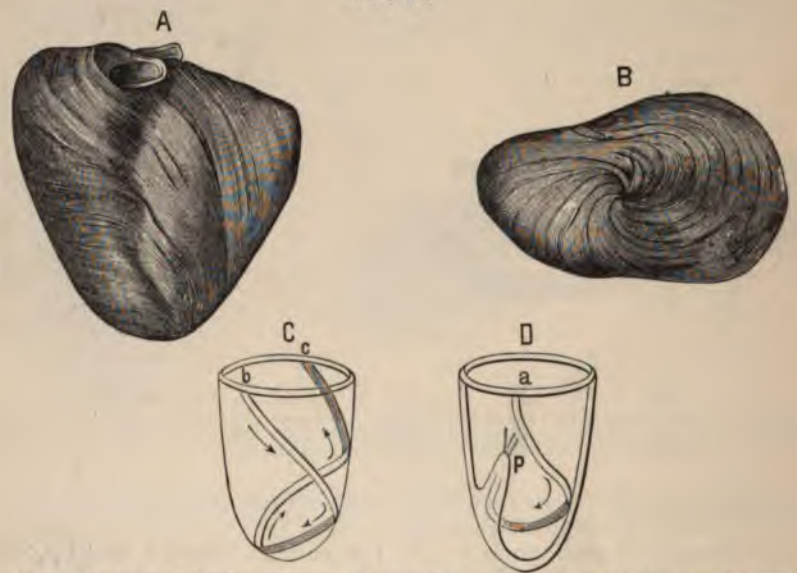
Physiological Significance. — (1) The auricles contract *independently* of the ventricles. This is seen when the heart is about to die; when there may be several auricular contractions for one ventricular, and at last only the auricles pulsate. The auricular portion of the right auricle beats longest; hence it is called the "ultimum moriens." Independent rhythmical contractions of the venæ cavæ and pulmonary veins are often noticed after the heart has ceased to beat. [This beating can also be observed in those veins in a rabbit after the heart is cut out of the body.]

(2) The double arrangement of the fibres (transverse and longitudinal) produces a simultaneous and uniform diminution of the auricular cavity (such as occurs in most of the hollow viscera).

(3) The contraction of the circular muscular fibres around the venous orifices, and the subsequent contraction of the auricle, cause these veins to empty themselves into the auricle; and by their presence and action they prevent any large quantity of blood from passing backward into the veins when the auricle contracts. [No valves are present in the superior and inferior vena cava in the adult heart, or in the pulmonary veins; hence the contraction of these circular muscular fibres plays an important part in preventing any reflux of blood during the contraction of the auricles.]

45. ARRANGEMENT OF THE VENTRICULAR FIBRES.—(2) **The muscular fibres** in the thick wall of the **ventricles** are arranged in several layers (Fig. 28, A) under the pericardium. First, there is an *outer longitudinal* layer (A) which is in the form of single bundles on the right ventricle, but forms a complete layer on the left ventricle, where it measures about one-eighth of the thickness of the ventricular wall. A *second longitudinal* layer of fibres lies on the *inner surface* of the ventricles, distinctly visible at the orifices, and within the vertically placed papillary muscles, while elsewhere it is replaced by the irregularly arranged trabeculæ carneæ. Between these two layers there lies the thickest layer, consisting of *more or less transversely* arranged bundles, which may be broken up into single layers more or less circularly disposed. The deep *lymphatic vessels* run between the layers, while the *blood vessels* lie within the substance of the layers, and are surrounded by the primitive bundles of muscular fibres. All three layers are not completely independent of each other; on

FIG. 28.



Course of the ventricular muscular fibres. A, on the anterior surface; B, view of the apex with the vortex; C, course of the fibres within the ventricular wall; D, fibres passing into a papillary muscle.

the contrary, the fibres which run *obliquely* form a gradual *transition* between the transverse layers and the inner and outer longitudinal layers. It is not, however, quite correct to assume that the outer longitudinal layer gradually passes into the transverse, and this again into the inner longitudinal layer (as is shown schematically in C); because, as Henle pointed out, the transverse fibres are relatively far greater in amount. In general, the *outer* longitudinal fibres are so arranged as to cross the *inner* longitudinal layer at an acute angle. The transverse layers lying between these two form gradual transitions between these directions. At the apex of the left ventricle, the outer longitudinal fibres bend or curve so as to meet at the so-called vortex B, where they enter the muscular substance, and, taking an upward and inward direction, reach the papillary muscles, P, D; although it is a mistake to say that all the bundles which ascend to the papillary muscles arise from the vertical fibres of the outer surface: many seem to arise independently within the ventricular wall. According to Henle, all the external longitudinal

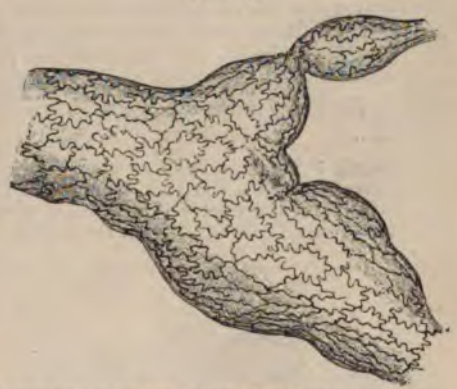
fibres do not arise from the fibrous rings or the roots of the arteries. The mitral orifice is surrounded by circular fibres which act like a sphincter (*Henle*).

[The assumption that the muscles of the ventricle are arranged so as to form a figure of 8, or in loops, seems to be incorrect; thus, fibres are said to arise at the base of the ventricle, to pass over it, and to reach the vortex, where they pass into the interior of the muscular substance, to end either in the papillary muscles or high up on the inner surface of the heart at its base. Figs. C and D give a schematic representation of this view.]

Only the general arrangement of the ventricular muscular fibres has been indicated. According to Pettigrew, there are seven layers in the ventricle, viz., three external, a fourth or central layer, and three internal. These internal layers are continuous with the corresponding external layers at the apex, thus—one and seven, two and six.

46. PERICARDIUM, ENDOCARDIUM, VALVES.—The **pericardium** encloses within its two layers [visceral and parietal] a lymph space—the pericardial space—which contains a small quantity of lymph—the **pericardial fluid**. It has the structure of a serous membrane, *i. e.*, it consists of *connective tissue* mixed with *fine elastic fibres* arranged in the form of a thin delicate membrane, and covered on its free surfaces with a single layer of epithelium or *endothelium*, composed of irregular, polygonal, flat cells. A rich *lymphatic network* lies under the pericardium (Fig. 29) and endocardium; also in the deeper layers of the visceral pericardium next the heart and between muscular bundles (*Salvioli*). No stomata exist either on its visceral or parietal layers. Around the coronary arteries of the heart exist lymph vessels and deposits of fat, which lie in the furrows and grooves in the *tuberosa* of the *epicardium* (visceral layer).

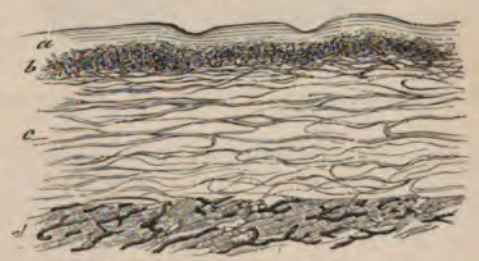
FIG. 29.



Lymphatic of the pericardium, epithelium stained with nitrate of silver.

The **endocardium**, next the cavity of the heart, consists of a *single* layer of polygonal, flat, nucleated *endothelial* cells. [Under this there is a nearly homogeneous hyaline layer (Fig. 30, *a*), slightly thicker on the left side, which gives the endocardium its polished appearance.] Then follows, as the *basis of the membrane*, a layer of *fine elastic fibres*—stronger in the auricles, and in some places thereof assuming the characters of a fenestrated membrane. Between these fibres a small quantity of connective tissue exists, which is in larger amount and more areolar in its characters next the myocardium. Bundles of *non-striped muscular* fibres (few in the auricles) are scattered and arranged for the most part longitudinally between the elastic fibres. These seem evidently meant to resist the distention which is apt to occur when the heart contracts and great pressure is put upon the endocardium. In all cases where high pressure is put upon walls composed of soft parts, we always find muscular fibres present, and never elastic fibres alone. No *blood vessels* occur in the endocardium (*Langer*).

FIG. 30.



Section of the endocardium. *a*, hyaline layer; *b*, network of fine elastic fibres; *c*, network of stronger elastic fibres; *d*, myocardium with blood vessels, which do not pass into the endocardium.

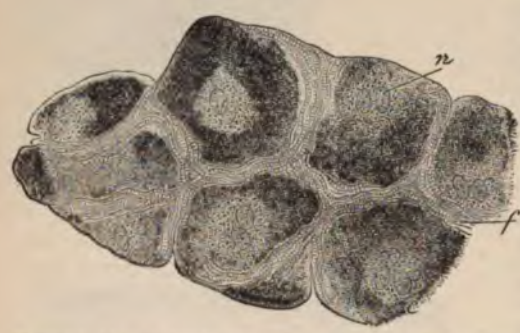
The **valves** also belong to the endocardium—both the *semilunar valves* of the aorta and pulmonary artery, which prevent the blood from passing back into the ventricles, and the tricuspid (*right* auriculo-ventricular) and mitral (*left* auriculo-ventricular), which protect the auricles from the same result. The lower vertebrata have valves in the orifices of the venæ cavæ, which prevent regurgitation into them; while in birds and some mammals these valves exist in a rudimentary condition. The valves are fixed by their base to resistant *fibrous*

rings, consisting of elastic and fibrous tissue. They are formed of two layers—(1) the *fibrous*, which is a direct continuation of the fibrous rings, and (2) a layer of *elastic* elements. The elastic layer of the auriculo-ventricular valves is an immediate prolongation of the endocardium of the auricles, and is directed toward the auricles. The semilunar valves have a thin elastic layer directed toward the arteries, which is thickest at their base. The connective-tissue layer directed toward the ventricle is about half the thickness of the valve itself.

The auriculo-ventricular valves also contain **striped muscular fibres.** Radiating fibres proceed from the auricles and pass into the valves, which, when the atria contract, retract the valves toward their base, and thus make a larger opening for the passage of the blood into the ventricles; according to Paladino, they raise the valves after they have been pressed down by the blood current. This observer also described some longitudinal fibres which proceed from the ventricles to enter these valves. There is also a concentric layer of fibres arranged near their point of attachment, and directed more toward their ventricular surface. These fibres seem to contract sphincter-like when the ventricle contracts, and thus approximate the base of the valves, and so prevent too great tension being put upon them. The larger chordæ tendineæ also contain striped muscle, while a delicate muscular network exists in the valvula Thebesii and valvula Eustachii.

Purkinje's Fibres consist of an anastomosing system of grayish fibres which exist in the subendocardial tissue of the ventricles, especially in the heart of the sheep and ox. The fibres are made up of polyhedral clear cells, containing some granular protoplasm, and usually two nuclei (Fig. 31). The margins of the cells are striated. Transition forms are found between these cells and the ordinary cardiac fibres; in fact, these cells become continuous with the true fully developed cardiac fibres. They represent cells which have been arrested in their development. They are absent in man and the lower vertebrates, but in birds and some mammals they are well marked (*Schweigger-Seidel, Ranvier*).

FIG. 31.



Purkinje's fibres isolated with dilute alcohol. *c*, cell; *f*, striated substance; *n*, nucleus. × 300.

Blood Vessels occur in the auriculo-ventricular valves only where muscular fibres are present, while the semilunar valves are usually devoid of vessels except at their base. The best figures of the blood vessels of the valves are given by Langer. The network of **lymphatics** in the endocardium reaches toward the middle of the valves.

Weight of the Heart.—According to W. Müller the proportion between the weight of the body and the heart in the child, and until the body reaches 40 kilos., is 5 grms. of heart substance to 1 kilo. of body weight; when the body weight is from 50 to 90 kilos. the ratio is 1 kilo. to 4 grms. of heart substance; at 100 kilos. 3.5 grms. As age advances, the auricles become stronger. The right ventricle is half the weight of the left. The weight of the heart of an adult man is about 309 grms.; female, 274 grms. [According to Laennec the heart is about the size of the closed fist of the individual.] Blosfeld and Dieberg give 346 grms. for the male, and 310 to 340 grms. for the female heart. The *specific gravity* of the heart muscle is 1.069. The thickness of the left ventricle in the middle in man is 11.4 mm., and in woman 11.15; that of the right is 4.1 and 3.6 mm. respectively.

47. AUTOMATIC REGULATION OF THE HEART.—Anatomical Investigations.—The two coronary arteries arise from the first part of the aorta *in the region* of the sinus of Valsalva. The position of origin varies—(1) either the orifices lie within the sinus, or (2) their openings are only partially reached by the margins of the semilunar valves (which is *usually* the case in the *left* coronary artery of man and the ox), or (3) their orifices lie clear above the margins of the valves. Post-mortem observations seem to show that during contraction of the ventricle it is very improbable that the semilunar valves constantly cover the origin of the coronary arteries.

Automatic Regulation of the Heart.—Brücke attempted to show that during the systole, or contraction of the ventricle, the semilunar valves covered the openings of the coronary arteries, so that these vessels could be filled with blood only during the diastole or relaxation of the ventricle. To him it seemed that (*a*) the diastolic filling of the coronary arteries would help to dilate the ventricles; (*b*) on the contrary, a systolic filling of these arteries would oppose the contraction, because the systolic filling and expulsion of the blood from the coronary arteries would diminish the force of the ventricular contraction. [To this supposed arrangement Brücke gave the name "Selbststeuerung," which may be rendered as above, or as "self-controlling" action of the heart by the aortic valves.]

Arguments against Brücke's View.—The following considerations militate against this theory: (1) Filling the coronary vessels under a high pressure in a dead heart causes a *diminution* of the ventricular cavity (*v. Wittich*). (2) The chief trunks of the coronary arteries lie in loose sub-pericardial fatty tissue in the cardiac sulci, hence a dilatation of the ventricle through this agency is most unlikely (*Landois*). (3) Experiments on animals have shown that a coronary artery spouts, like all arteries, during the systole of the ventricle. Von Ziemssen found that in the case of a woman who had a large part of the anterior wall of the thorax removed by an operation, the heart being covered only by a thin membrane, the pulse in the coronary arteries was synchronous with the pulse in the pulmonary artery. H. N. Martin and Sedgwick placed a manometer in connection with the coronary artery, and another with the carotid in a large dog, and they found that the pulsations occurred *simultaneously*. When a coronary artery is divided, the blood flows out continuously, but undergoes acceleration during the systole of the ventricles (*Endemann, Perls*). (4) If a strong intermittent current of water be allowed to flow through a sufficiently wide tube into the left auricle of a fresh pig's heart, so that the water passes into the aorta, and if the aorta be provided with a vertical tube, the water flows continuously from the coronary arteries, and is accelerated during the systole. (5) It is exceedingly improbable that the coronary arteries should be filled during the diastole, while all the other arteries are filled during systole of the ventricle. (6) There is always a sufficient quantity of blood in the sinus of Valsalva to fill the arteries during the first part of the systole. (7) The valves, when raised, are not applied directly to the aortic wall (*Hamberger, Rüdinger*) even by the most energetic pressure from the ventricle (*Sandborg and Worm Müller*). (8) Observations on voluntary muscles have shown that the small arteries dilate during contraction of the muscle, and the blood stream is accelerated. (9) By the systolic filling of the aorta the arterial path is elongated—this elastic distention is compensated before the diastole occurs. By the recoil of the aortic walls the layer of blood in them is driven backward and closes the valves (*Ceradini*). According to Sandborg and Worm Müller, the semilunar valves close just after the ventricles have begun to relax, which agrees with the curve obtained from the cardiac impulse (Fig. 39, A).

During the systole, the small arterial trunks lying next the ventricular cavities have to bear a higher pressure than that borne by the aorta, and their lumen must be compressed during the systole so that their contents are propelled toward the veins.

Peculiarities of the Cardiac Blood Vessels.—The *capillary vessels* of the myocardium are very numerous, corresponding to the energetic activity of the heart. Where they pass into veins, several unite at once to form a wide venous trunk, whereby an easy passage is offered to the blood. The *veins* are provided with valves so that (1) during systole of the right auricle the venous stream is interrupted; (2) during contraction of the ventricles, the blood in the coronary veins is similarly accelerated as in the veins of muscles. The coronary arteries are characterized by their very thick connective tissue and elastic intima, which perhaps accounts for the frequent occurrence of atheroma of these vessels (*Henle*). Some observers maintain that the coronary arteries do not anastomose, but this is denied by Langer and Krause. [West has injected the one artery from the other.] Many of the small lower vertebrates have no blood vessels in their heart muscle, *e. g.*, frog (*Hyrtl*).

Ligature of the Coronary Arteries.—The phenomena produced by partial obliteration or ligature of the coronary arteries are most important. In man analogous conditions occur, as in atheroma or calcification of these arteries. Sée and others have ligatured the coronary arteries in dogs, and found that after two minutes the cardiac contractions gave place to twitchings of the muscular fibres, and ultimately the heart ceased to beat. Ligature of the anterior coronary artery alone, or of both its branches, is sufficient to produce this result. If the coro-

nary arteries be compressed or tied in a rabbit in the angle between the bulbus aortæ and the ventricle, the heart's action is soon weakened, owing to the sudden anæmia and to the retention of the decomposition products of the metabolism in the heart muscle. Ligature of one artery first affects the corresponding ventricle, then the other ventricle, and, last of all, the auricles. Hence, compression of the *left* coronary artery (with simultaneous artificial respiration in a curarized animal) causes slowing of the contractions, especially of the left ventricle, while the right one at first contracts more quickly, and then, gradually, its rhythm is slowed. The contractions of the left ventricle are not only slowed but also weakened, while the right pulsates with undiminished force. Hence it follows that, as the left half of the heart cannot expel the blood in sufficient quantity, the left auricle becomes filled, while the right ventricle, not being affected, pumps blood into the lungs. Œdema of the lungs is produced by the high pressure in the pulmonary circulation, which is propagated from the right heart through the pulmonary vessels into the left auricle (*Samuelson and Grünhagen*). According to Sig. Mayer, protracted dyspnœa causes the left ventricle to beat more feebly sooner than the right, so that the left side of the heart becomes congested. Perhaps this may explain the occurrence of pulmonary œdema during the death agony.

Cohnheim and v. Schulthess-Rechberg found, after ligature of one of the large branches of a coronary artery in a dog, that at the end of a minute the pulsations become intermittent. This intermittence becomes more pronounced, the two sides of the heart do not contract simultaneously (**arhythmia**), the heart beats more slowly, and the blood pressure falls. Suddenly, about 105 seconds after the ligature is applied, both ventricles cease to beat, and there is a great fall of the blood pressure. After an arrest lasting for 10 to 20 seconds, twitching movements occur in the ventricles, while the auricles pulsate regularly, and may continue to do so for many minutes, but the ventricles cease to beat altogether after 50 seconds. According to Lukjanow, there is a peristaltic condition which operates upward and downward, and occurs in the period between the regular contraction and the twitching vibratory movement. Stimulation of the vagus does not arrest these peristaltic movements.

Pathological.—In so-called sclerosis of the coronary arteries in old age, there are attacks of diminished cardiac activity, weakness of the heart, an altered rhythm and frequency, with consequent breathlessness; there may also be loss of consciousness, congestions, and attacks of pulmonary œdema. Death may take place unexpectedly from sudden arrest of the heart's action.

48. MOVEMENTS OF THE HEART.—Cardiac Revolution.—The movement of the heart is characterized by an alternate contraction and relaxation of its walls. The total cardiac movement is called a "**cardiac revolution**" or a "**cardiac cycle,**" and consists of three acts—the contraction or *systole of the auricles*, the contraction or *systole of the ventricles*, and the *pause* (Fig. 50). During the pause, the auricles and ventricles are relaxed; during the contraction of the auricles the ventricles are at rest; while during the contraction of the ventricles the auricles are relaxed. The rest during the phase of relaxation is called the *diastole*. The following is the sequence of events in the heart during a cardiac revolution:—

(**A**) **The blood flows into the auricles,** and thus distends them and the auricular appendices. This is caused by—

(1) The *pressure* of the blood in the venæ cavæ (right side) and the pulmonary veins (left side) being greater than the pressure in the auricles. (2) The *elastic traction of the lungs* (§ 68), which, after complete systole of the auricles, pulls asunder the now relaxed and yielding auricular walls. The auricular appendages are also filled at the same time, and they act to a certain extent as accessory reservoirs for the large supply of blood streaming into the auricles.

(**B**) **The auricles contract,** and we observe in rapid succession—

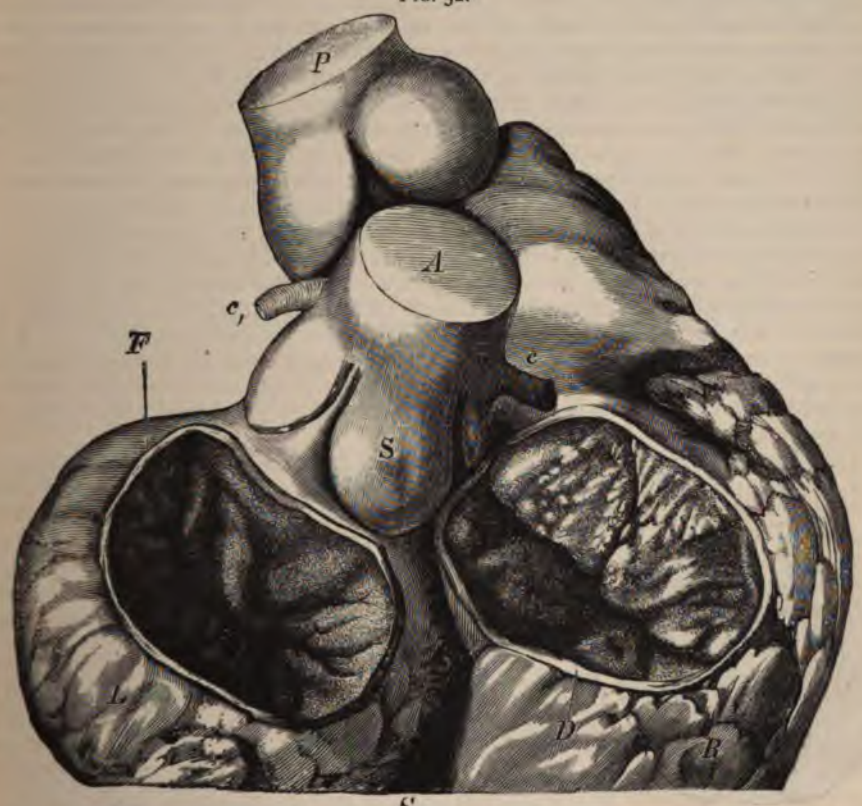
(1) The contraction and emptying of the auricular appendix toward the atrium. Simultaneously the mouths of the veins become narrowed, owing to the contraction of their circular muscular fibres (more especially the superior vena cava and the pulmonary veins); (2) the auricular walls contract simultaneously toward the

auriculo-ventricular valves and the venous orifices, whereby (3) the blood is driven into the relaxed ventricles, which are considerably distended thereby.

The contraction of the auricles is followed by

(*a*) A slight stagnation of the blood in the large venous trunks, as can be observed in a rabbit after division of the pectoral muscles so as to expose the junction of the jugular with the subclavian vein. There is no actual regurgitation of the blood, but only a partial interruption of the inflow into the auricles, because the mouths of the veins are contracted, and the pressure in the superior vena cava and pulmonary veins soon holds in equilibrium any reflux of blood; and lastly,

FIG. 32.



Cast of the ventricles of the human heart viewed from *behind* and above; the walls have been removed, and only the fibrous rings and the auriculo-ventricular valves are retained. L, left, R, right ventricle; S, septum; F, left fibrous ring, with mitral valve closed; D, right fibrous ring, with tricuspid closed; A, aorta, with the left (C_1) and right (C) coronary arteries; S, sinus of Valsalva; P, pulmonary artery.

because any reflux into the cardiac veins is prevented by valves. The movement of the heart causes a regular pulsatile phenomenon in the blood of the venæ cavæ, which under abnormal circumstances may produce a venous pulse (see § 99).

(*b*) The chief motor effect of the contraction of the auricles is the *dilatation of the relaxed ventricle*, which has already been dilated to a slight extent by the *elastic traction* of the lungs.

Aspiration of the Ventricles.—The dilatation of the ventricles has been ascribed to the elasticity of the muscular walls—the strongly contracted ventricular walls (like a compressed india-rubber bag), in virtue of their elasticity, are supposed, in returning to their normal resting form, to

suck in or aspirate the blood under a negative pressure; this power on the part of the ventricle is not great (see below).

(*c*) When the ventricles are distended by the inflowing blood, the auriculo-ventricular valves are floated up, partly by the recoil or reflexion of the blood from the ventricular wall, and partly owing to their lighter specific gravity, whereby they easily float into a more or less horizontal position. The valves are also raised to a slight extent by the longitudinal muscular fibres, which pass from the auricles into the cusps of the valve.

(**C**) **The ventricles now contract,** and simultaneously the auricles relax, whereby—

(1) The muscular walls contract forcibly from all sides, and thus diminish the ventricular cavity. (2) The blood is at once pressed against the under surface of the auriculo-ventricular valves, whose curved margins are opposed to each other like teeth, and are pressed hermetically against each other (Fig. 32). It is impossible for the blood to push the cusps backward into the auricle, as the **chordæ tendineæ** hold fast their margins and surfaces like a taut sail. The margins of the neighboring cusps are also kept in apposition, as the chordæ tendineæ from one papillary muscle always pass to the adjoining edges of two cusps. The extent to which the ventricular wall is shortened is compensated by the contraction of the papillary muscle, and also of the large muscular chordæ, so that the cusps cannot be pushed into the auricle. When the valves are closed, their surfaces are horizontal, so that, even when the ventricles are contracted to their greatest extent, there remains in the *supra-papillary space* a small amount of blood which is not expelled (*Sandborg and Worm Müller*). (3) When the pressure within the ventricles exceeds that in the arteries, the semilunar valves are forced open and stretched like a sail across the pocket-like sinus, without, however, being directly applied to the wall of the arteries (pulmonary and aorta), and thus the blood enters the arteries.

(**D**) **Pause.**—As soon as the ventricular contraction ends, and the ventricles begin to relax, the *semilunar valves close* (Fig. 33). The diastole of the ventricles is followed by the **pause.** Under normal circumstances, the right and left halves of the heart always contract or relax uniformly and simultaneously.

FIG. 33.

The closed semilunar valve of the pulmonary artery seen from below.

Negative Pressure in the Ventricle.—Goltz and Gaule found that there was a *negative pressure* of 23.5 mm. Hg (dog) in the interior of the ventricle during a certain phase of the heart's action. This they determined by a maximal and minimal manometer. They surmised that this phase coincided with the *diastolic dilatation*, for which they assumed a considerable power of aspiration. Moens is of opinion that this negative pressure within the ventricle obtains *shortly before the systole has reached its height, i. e.*, just before the inner surface of the ventricles and the valves, after the blood is expelled, are nearly in apposition. He explains this aspiration as being due to the formation of an empty space in the ventricle caused by the energetic expulsion of the blood through the aorta and pulmonary artery.

FIG. 34.

FIG. 35.

Gaule's maximum and minimum manometer.

[**Maximum and Minimum Manometer.**—Into the tube connecting the interior of the ventricle of the heart with the ordinary **U**-shaped mercury manometer, is introduced the maximum manome-

ter, which is constructed on the principle of a ball and cup valve (Fig. 34), the ball A being kept closed in B by a spring C. To make it a maximum manometer, the end A is connected with the heart, and B with the mercurial manometer (Fig. 35). When a clamp is placed on the upper limb the valve is acted on only at each systole of the heart, blood is driven beyond it, but during diastole it closes and no blood can return. This goes on until the pressure beyond the valve in the mercury manometer is the same as in the heart. If the valve be reversed, it is converted into a minimum manometer.]

49. **PATHOLOGICAL CARDIAC ACTION.—Cardiac Hypertrophy.**—All resistances to the movement of the blood through the various chambers of the heart, and through the vessels communicating with it, cause a greater amount of work to be thrown upon the portion of the heart specially related to this part of the circulatory system; consequently, there is produced an increase in the thickness of the muscular walls and dilatation of the heart. If the resistance or obstacle does not act upon *one* part of the heart alone, but on parts lying in the *onward* direction of the blood stream, these parts also subsequently undergo hypertrophy. If, in addition to the muscular thickening of a part of the heart, the cavity is simultaneously dilated, it is spoken of as **eccentric hypertrophy** or **hypertrophy with dilatation.** The obstacles most likely to occur in the *blood vessels* are narrowing of the lumen or want of elasticity in their walls; in the *heart*, narrowing of the arterial or venous orifices or insufficiency or incompetency of the valves. Incompetency of the valves forms an obstruction to the movement of the blood, by allowing part of the blood to flow back or regurgitate, thus throwing extra work upon the heart.

Thus arise—(1) **Hypertrophy of the left ventricle,** owing to resistance in the area of the systemic circulation, especially in the arteries and capillaries—not in the veins. Among the causes are—constriction of the orifice or other parts of the aorta, calcification, atheroma, and want of elasticity of the large arteries and irregular dilatations or aneurisms in their course; insufficiency of the aortic valves, in which case the same pressure always obtains within the ventricle and in the aorta; and, lastly, cirrhosis of the kidneys, whereby the excretion of water by these organs is diminished. Even in mitral insufficiency, compensatory hypertrophy of the left ventricle must occur, owing to the hypertrophy of the left atrium in consequence of the increased blood pressure in the pulmonary circuit.

(2) **Hypertrophy of the left auricle** occurs in stenosis or constriction of the left auriculo-ventricular orifice, or in insufficiency of the mitral valve, and it occurs also as a result of aortic insufficiency, because the auricle has to overcome the continual aortic pressure within the ventricle.

(3) **Hypertrophy of the right ventricle** occurs (*a*) when there is resistance to the blood stream through the pulmonary circuit. The resistance may be due to (*α*) obliteration of large vascular areas in consequence of destruction, shrinking or compression of the lungs, and the disappearance of numerous capillaries in emphysematous lungs; (*β*) overfilling of the pulmonary circuit with blood in consequence of stenosis of the left auriculo-ventricular orifice, or mitral insufficiency—consequent upon hypertrophy of the left auricle resulting from aortic insufficiency. (*b*) When the valves of the pulmonary artery are insufficient, thus permitting the blood to flow back into the ventricle, so that the pressure within the pulmonary artery prevails within the right ventricle (very rare).

(4) **Hypertrophy of the right auricle** occurs in consequence of the last-named condition, and also from stenosis of the tricuspid orifice, or insufficiency of the tricuspid valve (rare).

Artificial Injury to the Valves.—If the aortic valves are perforated, with or without simultaneous injury to the mitral or tricuspid valves, the heart does more work; thus the physical defect is overcome for a time, so that the blood pressure does not fall. The heart seems to have a store of reserve energy which is called into play. Soon, however, dilatation takes place, on account of the regurgitation of the blood into the heart. Hypertrophy then occurs, but the compensation meanwhile must be obtained through the reserve energy of the heart (*O. Rosenbach*).

Impeded Diastole.—Among causes which hinder the diastole of the heart are—copious effusion into the pericardium, or the pressure of tumors upon the heart. The systole is greatly interfered with when the heart is united to the pericardium and to the connective tissue in the mediastinum. As a consequence the connective tissue, and even the thoracic wall, are drawn in during contraction of the heart, so that there is a retraction of the region of the apex beat during systole, and a protrusion of this part during the diastole.

[**Palpitation** is a symptom indicating generally very rapid and quick action of the heart, the pulsations often being unequal in time and intensity, while the person is generally conscious of the irregularity of the cardiac action. It may be due to some *organic* condition of the heart itself, especially where the cardiac muscles are weak, in cases of dilatation and hypertrophy of the left ventricle, where the heart is gradually becoming unable to overcome the resistances offered to its work, and especially during exertion when the heart is taxed above its strength. It may also occur where the blood pressure is low, as in anæmia, so that the heart contracts quickly, there being little resistance opposed to its action. The excitability of the cardiac muscle may be increased, as in fatty heart,

when very slight exertion may excite it often in a paroxysmal way. In other cases, it is *nervous* in its origin, being either diect or reflex. In very emotional and excitable people (especially in women) it is easily set up, and in some people it may be produced reflexly by gastric or intestinal irritation or dyspepsia. It also frequently results from excesses of all kinds and the over-use of tobacco. The **remedies** to be used obviously depend on the cause. Where the blood pressure is low, as in anæmia, digitalis and iron will do good; the former by increasing the blood pressure, and the latter by improving the general nutrition of the body and the blood in particular. In neurotic cases cardiac sedatives are indicated, while in cases due to indigestion hydrocyanic acid is useful (*Brunton*).]

[**Fainting or Syncope.**—In fainting, the person loses consciousness, owing to a sudden arrest of the blood supply to the brain, the face is pallid, the respiration is feeble or ceases, while the heart beats but feebly or not at all. The defective supply of blood to the brain may depend upon sudden arrest of the heart's action, caused, it may be, by a fright, or the heart's action may be arrested reflexly. Any cause which suddenly diminishes the blood pressure may produce it, or when pressure is suddenly removed from the large vessels, as in tapping the abdomen in ascites, without at the same time giving sufficient support to the abdominal viscera. When a person has been long in the recumbent position, on being rapidly set up in bed he may faint. In some forms of heart disease, sudden exertion or change of posture may produce it.]

[**Treatment.**—The object is to restore consciousness and the action of the heart. Place the person in the horizontal position, keep the head low, even lower than the body, and do not support it with pillows. Dashing cold water on the face, so as to stimulate the fifth nerve, usually succeeds in causing the person to take a deep inspiration. In other cases a sniff of smelling salts or ammonia, acting through the nasal branch of the fifth nerve, will excite the cardiac and respiratory functions (§ 368).]

50. **THE APEX BEAT, CARDIOGRAM.—Cardiac Impulse.**—By the term "**apex beat**" or "**cardiac impulse**" is understood, under normal circumstances, an elevation (perceptible to touch and sight) in a circumscribed area of the *fifth left* intercostal space, and caused by the movement of the heart. [The apex beat is felt in the fifth left intercostal space, 2 inches below the nipple, and 1 inch to its sternal side, or at a point 2 inches to the left of the sternum.] The impulse is more rarely felt in the fourth intercostal space, and it is much less distinct when the heart beats against the fifth rib itself. The position and force of the cardiac impulse vary with changes in the position of the body.

[The cardiac impulse is synchronous with the systole of the heart, but although this name and apex beat are frequently used as synonymous terms, it is to be remembered that the impulse may be caused by different parts of the heart being in contact with the chest wall. The cardiac impulse is usually higher than normal in children, while it is lower during inspiration than expiration.]

[**Methods.**—To obtain a curve of the apex beat or a **cardiogram**, we may use one or other of the following cardiographs (Fig. 36). Fig. 36, A, is the first form used by Marey, and it consists of an oval wooden capsule applied in an air-tight manner over the apex beat. The disk, *p*, capable of being regulated by the screw, *s*, presses upon the region of the apex beat, while *t* is a tube which may be connected with a recording tambour (Fig. 47). B is an improved form of the instrument, consisting essentially of a tambour, while attached to the membrane is a button, *p*, to be applied over the apex beat. The movements of the air within the capsule are communicated by the tube, *t*, to a recording tambour. Fig. 36, C, is the **pansphygmograph** of Brondgeest, which consists of a Marey's tambour, in an iron horse-shoe frame, and adjustable by means of a screw, *s*. Burdon-Sanderson's cardiograph is shown in D. The button, *p*, carried by the spring, *e*, does not rest upon the caoutchouc membrane, but on an aluminium plate attached to it. The apparatus is adjusted to the chest by three supports. Fig. 36, E, shows a modified instrument on the same principle, by Grummach and v. Knoll. In all these figures the *t* indicates the exit tube communicating with a recording tambour (Fig. 47). D and E may be used for other purposes, *e. g.*, for the pulse, so that they are **polygraphs**. See also Fig. 76.]

Fig. 39, A, shows the **cardiogram** or the impulse curve of the heart of a healthy man; B, that of a dog, obtained by means of a sphygmograph. In both the following points are to be noticed: *ab*, corresponds to the time of the pause and *the contraction of the auricles*. As the atria contract in the direction of the axis of the heart from the right and above toward the left and below, the apex of the heart moves toward the intercostal space. The two or three smaller elevations are perhaps caused by the contractions of the ends of the veins, the auricular appendices, and the atria themselves.

The portion *bc*, which communicates the greatest impulse to the instrument, and also to one's hand when it is placed on the apex beat, is caused by *the contraction of the ventricles*, and during it the first sound of the heart occurs. Fre-

quently, but erroneously, the cardiac impulse has been ascribed to the contraction of the ventricles alone. It, however, is due to all those conditions which cause an elevation in the region of the cardiac impulse.

[Edgren recorded a human cardiogram, and listened at the same time to the heart sounds, recording the latter by means of an electric signal. The curve rises at *a*, with the beginning of

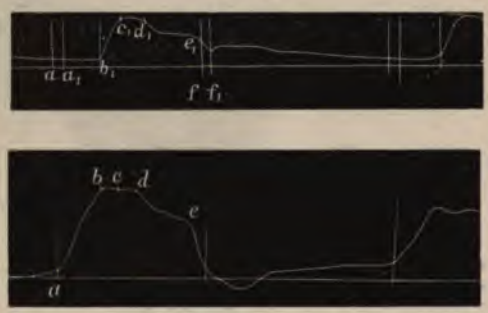
FIG. 37.

Cardiogram. *a-f*: 1, beginning of 1st, and 2, 2d sound.

the first sound, *i. e.*, with the contraction of the ventricles, and reaches the abscissa at *f* with the beginning of the second sound, *i.e.*, when the semilunar valves are closed. The relation between *a* and the points intermediate between it and *f*, and to the pulse curve of the carotid, is shown in Fig. 38. The letters with the dash correspond to the unmarked letters in the cardiogram.]

The **cause of the ventricular impulse** has been much discussed. It depends upon the following:—

FIG. 38.

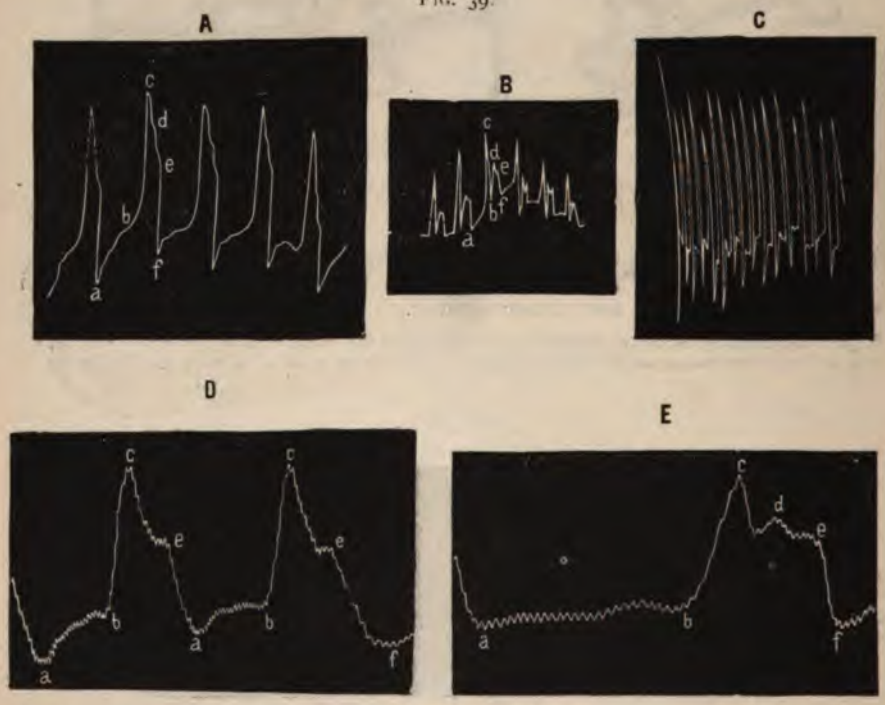


The upper curve from the human carotid; the lower a cardiogram taken simultaneously.

(1) The base of the heart (auriculo-ventricular groove) represents during diastole a *transversely-placed ellipse* (Fig. 40, I, FG), while during contraction it has a more *circular* figure, *ab*. Thus, the long diameter of the ellipse (FG) is diminished, the small diameter *dc* is increased, while the base is brought nearer to the chest wall *e*. This alone does not cause the impulse, but the basis of the heart, being hardened during the systole and brought nearer to the chest wall, allows the apex to execute the movement which causes the impulse (p. 102).

(2) During relaxation, the ventricle lies with its apex (Fig. 40, II, *i*) obliquely

FIG. 39.



Curves from the apex beat. A, normal curve (man); B, from a dog; C, very rapid curve (dog); D and E, normal curves (man) registered on a vibrating glass plate where each indentation = 0.01613 sec. In all the curves *ab* means contraction of the auricles, and *bc* of the ventricles; *d*, closure of the aortic, and *e*, of the pulmonary valves; *ef*, diastole of the ventricle.

downward, and with its long axis in an oblique direction—so that the angles (*bci*, *aci*) formed by the axis of the ventricles with the diameter of the base are unequal

—during systole it represents a regular cone, with its axis at right angles to its base. Hence, the apex (*i*) must be erected from below and behind (*p*), forward and upward (*Harvey*—"cor sese erigere"), and when hardened during systole presses itself into the intercostal space (Fig. 40, II).

(3) The ventricles undergo during systole a slight spiral twisting on their long axis ("lateralem inclinationem"—*Harvey*), so that the apex is brought from behind more forward, and thus a greater portion of the left ventricle is turned to the front. This rotation is caused by the muscular fibres of the ventricles, which proceed from that part of the fibrous rings between the auricles and ventricles which lies next the anterior thoracic wall. The fibres pass from above obliquely downward, and to the left, and also run in part upon the posterior surface of the ventricles. When they contract in the axis of their direction, they tend to

FIG. 40.

raise the apex, and also to bring more of the posterior surface of the heart in relation with the anterior thoracic wall. It is favored by the slightly spiral arrangement of the aorta and pulmonary artery.

These are the most important causes, but the minor causes are—

(4) The "*reaction impulse*" or "*recoil*," or that movement which the ventricles are said to undergo (like an exploded gun or rocket), at the moment when the blood is discharged into the aorta and pulmonary artery, whereby the apex goes in the opposite direction, *i. e.*, downward and slightly outward. Landois, however, has shown that the mass of blood is discharged into the vessels 0.08 of a second after the beginning of the systole, while the cardiac impulse occurs with the first sound.

(5) When the blood is discharged into the aorta and pulmonary artery, these

vessels are slightly *elongated*, owing to the increased blood pressure. As the heart is suspended from above by these vessels, the apex is pressed slightly downward and forward toward the intercostal space (?).

As the cardiac impulse is observed in the empty hearts of dead animals, (4) and (5) are certainly of only second-rate importance. Filehne and Pentzoldt maintain that the apex during systole does not move to the left and downward, as must be the case in (4) and (5), but that it moves upward and to the right—a result corroborated by v. Ziemssen. [Barr attributes the cause of the impulse to the rigidity or hardening of the ventricle during systole, to the rotatory movement and lengthening downward of the blood column in the aorta and pulmonary artery, while toward the end of the systole the maximum of recoil takes place and also contributes to cause it.]

It is to be remembered that as the apex is *always* applied to the chest wall, separated from it merely by the thin margin of the lung, it only presses against the intercostal space during systole (*Kiwisch*).

After the apex of the curve, *c*, has been reached at the end of the systole, the curve falls rapidly, as the ventricles quickly become relaxed. In the descending part of the curve, at *d* and *e*, are two elevations, which occur *simultaneously with the second sound.* These are caused by the sudden closure of the semilunar valves, whereby an impulse is propagated through the axis of the ventricle to its apex, and thus causes a vibration of the intercostal space; *d* corresponds to the closure of the aortic valves, and *e* to the closure of the pulmonary valves. The closure of the valves in these two vessels is not simultaneous, but is separated by an interval of 0.05 to 0.09 sec. The aortic valves close sooner on account of the greater blood pressure there. Complete diastolic relaxation of the ventricle occurs from *e* to *f* in the curve.

It is clear, then, that the cardiac impulse is caused chiefly by the contraction of the ventricles, while the auricular systole and the vibration caused by the closure of the semilunar valves are also concerned in its production.

[**Change in Shape of Heart.**—The experiments of Ludwig and Hesse on the heart of the dog show that the shape of the ventricles varies remarkably in systole and diastole, and that the shape of the heart as found post-mortem is not its natural shape.]

[**Method.**—Bleed a dog rapidly from the carotids, defibrinate the blood, expose the heart, tie graduated straight tubes into the pulmonary artery and aorta, and ligature the auricular vessels. Pour the blood into the heart until it is dilated under a pressure equal to the mean arterial pressure

FIG. 41. FIG. 42. FIG. 43.

Projection of a dog's heart. Posterior surface. Anterior surface. Left lateral surface.

(150 mm.). The ventricles are in the diastolic phase, the auricles still pulsate. A plaster cast is now rapidly made of the ventricles. This represents the diastolic phase. To obtain what may be regarded as the systolic phase, a heart, similarly prepared but emptied of blood, is suddenly plunged into a hot (50° C.) saturated solution of potassic bichromate, when the heart gives one rapid and final contraction and remains permanently contracted, owing to the heat rigor, its proteids being coagulated (§ 295). This is the systolic phase. Little pins with twisted points are previously inserted in the organ to mark certain parts of both hearts for comparison.]

[In diastole, the shape of the ventricle is hemispheroidal, the apex being rounded, while the posterior surface is flatter than the anterior (Fig. 41). In the plane of

the ventricular base, the greatest diameter is from right to left, and the shortest from base to apex. The conus arteriosus is above the plane of the base. During *systole*, the apex is more pointed, the ventricle more conical, while all the diameters in the plane of the base are equally diminished, hence the vertical measurement from base to apex is longer now than either of the diameters at the base (Fig. 43). The conus arteriosus sinks toward the plane of the base, while the base of the ventricle becomes more circular, so that the difference of the curvatures of the anterior and posterior surfaces vanishes (Fig. 42). In all these figures the shaded part represents diastole and the clear part systole. The most remarkable point is that the vertical measurement remains unchanged. This refers to the left ventricle, which of course forms the apex; the right is shortened. The plane of the ventricular base in systole is about one-half of what it is in diastole, as is shown in Fig. 44. Thus the heart is diminished in all its diameters except one, the arterial orifices are scarcely affected, while the area of the auriculo-ventricular orifices (M, T) is diminished about one-half (Fig. 45). This is most important in connection with the closure of the auriculo-ventricular valves; as it shows that the muscular fibres of the heart, by diminishing these orifices during systole, greatly aid in the perfect closure of these valves. Thus we explain why defective nutrition of the cardiac muscle may give rise to incompetency of these valves, without the valves themselves being diseased (*Macalister*).]

FIG. 44.

Projection of the base in systole and diastole. RV, right, and LV, left ventricle.

FIG. 45.

A, aorta; PA, pulmonary artery; M, mitral, and T, tricuspid orifice.

[In order to account for the vertical diameter remaining unchanged, we may represent the ventricular fibres as consisting of three layers, viz., an inner and outer set, more or less longitudinal, and a middle set, circular. Both sets will tend, when they contract, to diminish the cavity, but the shortening of the longitudinal layers is compensated for by the contraction, *i. e.*, the elongation produced by the circular set.]

[In order to obtain the **shape of the cavities**, dogs were taken of the same litter and as nearly alike as possible. One heart was filled with blood, as already described, and placed in a cool solution of potassic bichromate, whereby it was slowly hardened in the diastolic form, while the other was plunged, as before, into a hot solution. Casts were then made of the cavities.]

51. THE TIME OF THE CARDIAC MOVEMENTS.—Methods.—The time occupied by the various *phases of the movements* of the heart may be determined by studying the apex beat curve.

(1) If we know at what rate the plate on which the curve was obtained moved during the experiment, of course all that is necessary is to measure the distance, and so calculate the time occupied by any event (see Pulse, § 67).

(2) It is preferable, however, to cause a tuning fork, whose rate of vibration is known, to write its vibrations under the curve of the apex beat, or the curve may be written upon a plate attached to a vibrating tuning fork (Fig. 39, D, E). Such a curve contains fine teeth caused by the vibrations of the tuning fork. D and E are curves obtained from the cardiac impulse in this way from healthy students. In D the notch *d* is not indicated. Each complete vibration of the tuning fork, reckoned from apex to apex of the teeth = 0.01613 second, so that it is simply necessary to count the number of teeth and multiply to obtain the time. The values obtained vary within certain limits even in health.

The value of *a b* = **pause + contraction of the auricles,** is subject to the greatest variation, and depends chiefly upon the number of heart beats per minute. The more quickly the heart beats, the shorter is the pause, and conversely. In some curves, even when the heart beats slowly, it is scarcely possible to distinguish

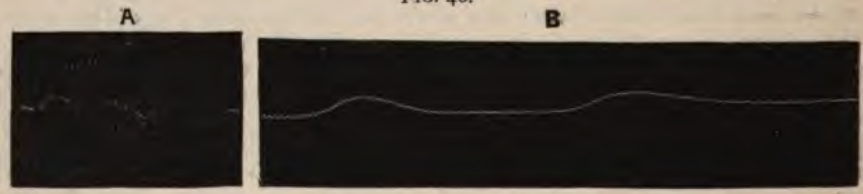
the auricular contraction (indicated by a rise) from the part of the curve corresponding to the pause (indicated by a horizontal line). In one case (heart beats 55 per minute) the pause = 0.4 second, the auricular contraction = 0.177 second. In Fig. 39, A, the time occupied by the pause + the auricular contraction (74 beats per minute) = 0.5 second. In D, *a b* = 19 to 20 vibrations = 0.32 second; in E = 26 vibrations = 0.42 second.

The **ventricular systole** is calculated from the beginning of the contraction *b*, to *e* when the semilunar valves are closed; it lasts from the first to the second sound. It also varies somewhat, but is more constant. When the heart beats rapidly, it is somewhat shorter—during slow action longer. In E = 0.32 second; in D = 0.29 second; with 55 beats per minute Landois found it = 0.34, with a very high rate of beating = 0.199 second.

When the ventricles beat feebly, they contract more slowly, as can be shown by applying the registering apparatus to the heart of an animal just killed. In Fig. 46, from the ventricle of a rabbit just killed, the slow heart beats, B, are seen to last longest. In cases of enormous hypertrophy and dilatation of the left ventricle, the duration of the ventricular systole is not longer than normal (*Landois*).

In calculating the time occupied by the ventricular systole we must remember—(1) *The time between the two sounds* of the heart, *i. e.*, from the beginning of the first to the end of the second sound (*b* to *e*). (2) *The time the blood flows into the aorta*, which comes to an end at the depression between *c* and *d* (in Fig. 39, E). Its commencement, however, does not coincide with *b*, as the aortic valves open 0.085 to 0.073 second after the beginning of the ventricular systole. Hence the aortic current lasts 0.08 to 0.09 second. This is calculated in the following way: The time between

FIG. 46.



Curves recorded by the ventricle of a rabbit, upon a vibrating plate attached to a tuning fork (vibration = 0.01613 sec.). A, soon after death; B, from the dying ventricle.

the first sound of the heart and the pulse in the axillary artery is 0.137 second, and of this time 0.052 second is occupied in the propagation of the pulse wave along the 30 cm. of artery lying between the root of the aorta and the axilla. Thus the pulse wave in the aorta occurs 0.137 minus 0.052 = 0.085 second after the beginning of the first sound. The current in the pulmonary artery is interrupted in the depression between *d* and *e*. (3) *Lastly, the time occupied by the muscular contraction of the ventricle*, which begins at *b*, reaches its greatest extent at *c*, and is completely relaxed at *f*. The apex of the curve, *c*, may be higher or lower according to the flexibility of the intercostal space, hence the position of *c* varies. In hypertrophy with dilatation of the left ventricle, the duration of the ventricular contraction does not greatly exceed the normal.

The time which elapses between *d* and *e*, *i.e.*, between the complete closure of the aortic and pulmonary valves, is greater the more the pressure in the aorta exceeds that in the pulmonary artery, as the valves are closed by the pressure from above, and the difference in time may be 0.05 second, or even double that time, in which case the second sound appears double (compare § 54). If the aortic pressure diminishes while that in the pulmonary artery rises, *d* and *e* may be so near each other that they are no longer marked as distinct elements in the curve.

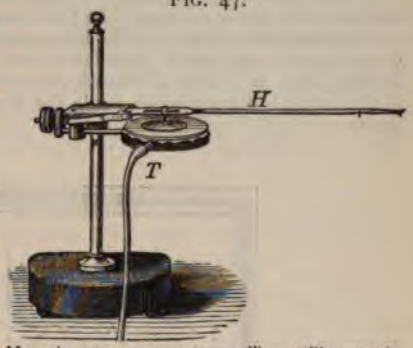
The time, *ef*, during which the ventricles relax varies somewhat: 0.1 second may be taken as a mean.

Accelerated Cardiac Action.—When the action of the heart is greatly accelerated, the pause is considerably shortened in the first instance (*Donders*), and to a less extent the time of contraction of the auricles and ventricles. When the pulse rate is very rapid, the systole of the atria coincides with the closure of the arterial valves of the preceding contraction, as is shown in Fig. 39, C (dog).

In registering the cardiac impulse, the apparatus is separated by a greater or less depth of soft parts from the heart itself, so that in all cases the intercostal tissues do not follow exactly the movements of the heart, and thus the curve obtained may not coincide mathematically with the movements of the heart. It is desirable that curves be obtained from persons whose hearts are exposed, *i.e.*, in cases of **ectopia cordis.**

Cleft Sternum.—Gibson inscribed cardiograms from the heart of a man with cleft sternum. The following were the results obtained: Auricular contraction = 0.115; ventricular contraction $(b, d) = 0.28$; difference between closure of valves $(d, e) = 0.09$; ventricular diastole $(e, f) = 0.11$; pause = 0.45 second.

FIG. 47.



Marey's registering tambour. T, metallic capsule, with thin india-rubber stretched over it, and bearing an aluminium disk, which acts upon the writing lever, H. By means of a thick-walled caoutchouc tube, it may be connected with any system containing air, so as to record variations of pressure.

Endocardial Pressure.—In large mammals, such as the horse, Chauveau and Marey (1861) determined the duration of the events that occur within the heart, and also the endocardial pressure by means of a **cardiac sound.** Small elastic bags attached to tubes were introduced through the jugular vein into the right auricle and ventricle. Each of these tubes was connected with a registering tambour (Fig. 47), and simultaneous tracings of the variations of pressure within the cavities of the heart were obtained by causing the writing points of the levers of the tambours to write upon a revolving cylinder.

Fig. 48, A, gives the result obtained when one elastic bag was placed in the right auricle, being introduced through the jugular vein and superior vena cava; B, when the other bag pushed through the tricuspid orifice was in the right ventricle; D, in the root of the aorta, pushed in through the carotid; C, pushed past the semilunar valves into the left ventricle; while at E a similar bag has been placed externally between the heart's apex and the inner wall of the chest. In all cases v = auricular contraction; V, that of the ventricle; s, closure of semilunar valves, sooner in C than B; P = pause.

Methods.—(1) The **cardiac sound** consists of a tube containing two separate air passages, and in connection with each of these there is a small elastic bag or ampulla. One of the bags is fixed to the free end of the sound, and communicates with one of the air passages. The other bag is placed in connection with the second air passage in the sound, and at such a distance that, when the former bag lies within the ventricle, the latter is in the auricle. Each bag and air tube communicating with it is connected with a Marey's tambour (Fig. 47), provided with a lever which inscribes its movements upon a revolving cylinder. Any variation of pressure within the auricle or ventricle will affect the elastic ampullæ, and thus raise or depress the lever. Care must be taken that the writing points of the levers are placed exactly above each other. A tracing of the cardiac impulse is taken simultaneously by means of a cardiograph attached to a separate tambour.

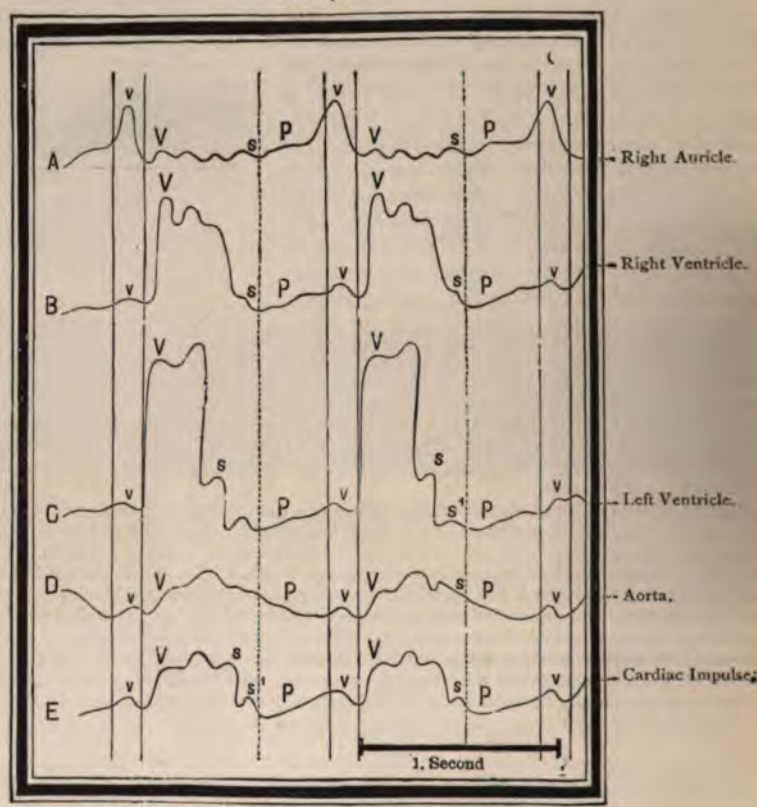
It has still to be determined whether the auricles and ventricles act alternately, so that at the moment of the beginning of the ventricular contraction the auricles relax, or whether the ventricles are contracted while the auricles still remain slightly contracted, so that the whole heart is contracted for a short time at least. The latter view was supported by Harvey, Donders, and others, while Haller and many of the more recent observers support the view that the action of the auricles and ventricles alternates. In the case of Frau Serafin, whose heart was exposed, v. Ziemssen obtained curves from the auricles, which showed that the contraction of the auricles continued even after the commencement of the ventricular systole. In Marey's curve the contraction of the ventricle is represented as following that of the auricle (Fig. 48).

[(2) Rolleston used a special apparatus which was connected with the interior of the heart, and he finds that there is no distinct rise of pressure in the dog within the ventricles corresponding to the auricular systole such as was obtained by Marey in the horse. During the ventricular diastole in certain cases the pressure falls below the atmospheric pressure, and may be equal to —20 mm. mercury or more in the left ventricle (*cf.* 48). It is probably caused by the elastic expansion of the

ventricle continuing after the blood in the auricle at the moment of the cessation of the ventricular systole has entered the ventricle, *i.e.*, the quantity of blood in the auricle is not sufficient in all cases to distend the left ventricle to the point at which its suction action ceases. Magini, operating on dogs with a trocar which perforated the cavities of the heart, found none of the secondary elevations obtained by Marey with his sound.]

A. Fick regards the alternating contraction as a means whereby the pressure in the large venous trunks is kept nearly constant. At the moment of ventricular systole the auricles relax, and the venous blood flows freely into the latter, while if the auricles remained contracted, the blood in the veins would be kept back. Further, at the moment of ventricular diastole the auricles contract, so that there is not an abnormal diminution of the pressure in the veins. Thus the pressure in the auricle is more equable, while the current in the terminal parts of the veins is kept more constant.

FIG. 48.



Curves obtained from the heart of a horse by the cardiac sound.

52. **PATHOLOGICAL CARDIAC IMPULSES.—Change in the Position of the Apex Beat.**—The position of the cardiac impulse is changed—(1) by the accumulation of fluids (serum, pus, blood) or gas in one pleural cavity. A copious effusion into the left pleural cavity compresses the lung, and may displace the heart toward the right side, while effusion on the right side may push the heart more to the left. As the right heart must make a greater effort to propel the blood through the compressed lung, the cardiac impulse is usually increased. Advanced emphysema of the lung, causing the diaphragm to be pressed downward, displaces the heart downward and inward, while pushing or pulling up of the diaphragm (by contraction of the lung, or through pressure from below) causes the apex beat to be displaced upward, and also slightly to the left. Thickening of the muscular walls with dilatation of the cavities of the left ventricle makes that ventricle longer and broader, while the increased cardiac impulse may be felt in the axillary line in the sixth, seventh, or even eighth intercostal space to the left of the mammary line. Hyper-

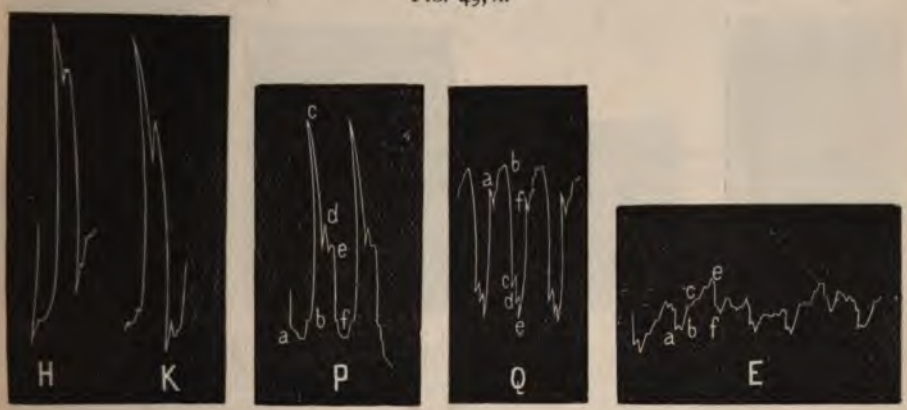
trophy, with dilatation of the right side, increases the breadth of the heart, so that the cardiac impulse is felt more to the right, even to the right of the sternum. In the rare cases where the heart is transposed, the apex beat is felt on the right side. When the cardiac impulse goes to the left of the left mammary line, or to the right of the parasternal line, the heart is increased in breadth, and there is hypertrophy of the heart. A greatly increased cardiac impulse may extend to several intercostal spaces.

The cardiac impulse is abnormally **weakened** in cases of atrophy and degeneration of the cardiac muscle, or by weakening of the innervation of the cardiac ganglia. It is also weakened when the heart is separated from the chest wall owing to the collection of fluids or air in the pericardium, or by a greatly distended left lung; and, indeed, when the left side of the chest is filled with fluid, the cardiac impulse may be extinguished. The same occurs when the left ventricle is very imperfectly filled during its contraction (in consequence of marked narrowing of the mitral orifice), or when it can only empty itself very slowly and gradually, as during marked narrowing of the aortic orifice.

An **increase** of the cardiac impulse occurs during hypertrophy of the walls, as well as under the influence of various stimuli (psychical, inflammatory, febrile, toxic) which affect the cardiac ganglia. Great hypertrophy of the left ventricle causes the heart to *heave*, so that a part of the chest wall may be raised and also vibrate during systole.

A **pulling in** of the anterior wall of the chest during the cardiac systole occurs in the third and fourth interspaces, not unfrequently under normal circumstances, sometimes during increased cardiac action, and in eccentric hypertrophy of the ventricles. As the heart's apex is slightly displaced, and the ventricle becomes slightly smaller during its systole, the empty space is filled by the

FIG. 49, A.



yielding soft parts of the intercostal space. When the heart is united with the pericardium and the surrounding connective tissue, which renders systolic locomotion of the heart impossible, retraction of the chest wall during systole takes the place of the cardiac impulse (*Skoda*). During the diastole, a diastolic cardiac impulse of the corresponding part of the chest wall may be said to occur.

Clinically, changes in the cardiac impulse are best ascertained by taking graphic representations of the cardiac impulse, and studying the curves so obtained (Figs. 49 A and 49 B).

In curve P (much reduced), from a case of marked **hypertrophy with dilatation,** the ventricular contraction, *bc*, is usually very great, while the time occupied by the contraction is not much increased. P and Q were obtained from a case of marked eccentric hypertrophy of the left ventricle, due to insufficiency of the aortic valves. Curve Q was taken intentionally over the auriculo-ventricular groove, where retraction of the chest wall occurred during systole; nevertheless the individual events occurring in the heart are indicated.

Fig. E is from a case of **aortic stenosis.** The auricular contraction (*ab*) lasts only a short time; the ventricular systole is obviously lengthened, and after a short elevation (*bc*) shows a series of fine indentations (*c*, *e*) caused by the blood being pressed through the narrow and roughened aorta.

Fig. F, from a case of **insufficiency of the mitral valve,** shows (*ab*) well marked on account of the increased activity of the left auricle, while the shock (*d*) from the closure of the aortic valves is small, on account of the diminished arterial tension. On the other hand, the shock from the accentuated pulmonary sound (*e*) is very great, and is in the apex of the curve. On account of the great tension in the pulmonary artery, the second pulmonary tone may be so strong, and

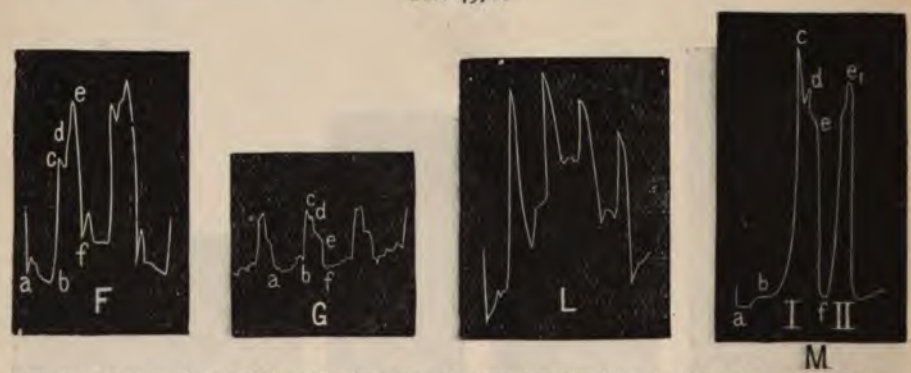
succeed the second aortic sound (*d*) so rapidly, that both almost merge completely into each other (H and K).

The curve of **stenosis of the mitral orifice** (G) shows a long, irregular, notched, auricular contraction (*ab*), caused by the blood being forced through an irregular narrow orifice. The ventricular contraction (*bc*) is feeble because the ventricle is imperfectly filled. The closures of the two valves, *d* and *e*, are relatively far apart, and one can hear distinctly a reduplicated second sound. The aortic valves close rapidly, because the aorta is imperfectly supplied with blood, while the more copious inflow of blood into the pulmonary artery causes its valves to close later.

If the heart beats rapidly and feebly—if the blood pressure in the aorta and pulmonary artery be low, the signs of closure of the pulmonary valves may be absent—as in curve L—taken from a girl suffering from nervous palpitation and morbus Basedowii.

In very rare cases of insufficiency of the mitral valve, it has been observed that at certain times both ventricles contract simultaneously, as in a normal heart, but that this alternates with a condition where the right ventricle alone seems to contract. Curve M is such a curve obtained by Malbranc, who called this condition **intermittent hemisystole.** The first curve (I) is like a normal curve, during which the whole heart acted as usual. The curve II, however, is caused by the right side of the heart alone; it wants the closure of the aortic valves, *d*, and there was no pulse in the arteries. Owing to insufficiency of the tricuspid valve, the same person had a venous pulse with every cardiac impulse, so that the arterial and venous pulses first occurred together, and then the venous pulse alone occurred. In these cases the mitral insufficiency leads to the right ventricle

FIG. 49, B.



FIGS. 49 A AND 49 B.—Curves of the cardiac impulses. *ab*, contraction of auricles; *bc*, ventricular systole: *d*, closure of aortic, and *e*, of pulmonary valves; *ef*, diastole of ventricle: P, Q, hypertrophy and dilatation of the left ventricle; E, stenosis of the aortic orifice; F, mitral insufficiency; G, mitral stenosis; L, nervous palpitation in Basedow's disease; M, so-called hemisystole.

being overdistended, while the left is nearly empty, so that the right side requires to contract more energetically than the left. It does not seem that the right ventricle alone contracts in these cases, but rather that the action of the left side is very feeble.

53. THE HEART SOUNDS.—On listening over the region of the heart in a healthy man, either with the ear applied directly to the chest wall (*Harvey*), or by means of a stethoscope (*Laennec*, 1819), we hear two characteristic sounds, the so-called "**heart sounds.**" The two sounds are called first and second, and together they correspond to a single cardiac cycle. These sounds are separated by silences. [Fig. 50 shows the relation of the events occurring in the heart during a cardiac cycle to the sounds and silences.]

FIG. 50.

Scheme of a cardiac cycle. The inner circle shows what events occur in the heart, and the outer, the relation of the sounds and silences to these events.

1. The first sound.
2. The first or short silence.
3. The second sound.
4. The second or long silence.

[**Relative Duration.**—There is no absolute duration of each phase of a cardiac cycle, but we may take the aver-

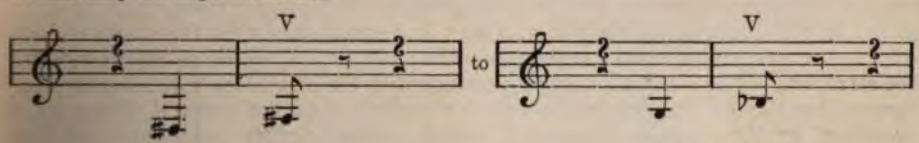
age duration calculated from the measurements of Gibson, in a case of fissure of the sternum, to be as follows:—

Auricular systole,	.112 sec.
Ventricular systole,	.368 "
Ventricular diastole,	.578 "
Cardiac cycle,	1.058 sec.

Suppose we divide the cycle into tenths (*Walshe*), then the first sound will last $\frac{4}{10}$, the first silence $\frac{1}{10}$, the second sound $\frac{2}{10}$, and the long silence $\frac{3}{10}$ of the entire period.]

The **first sound** [long or systolic] is twice as long as, somewhat duller, and one-third or one-fourth deeper than, the second sound; it is less sharply defined at first, and is *synchronous with the systole of the ventricles.*

The **second sound** [short or diastolic] is clearer, sharper, shorter, more sudden, and is one-third to one-fourth higher; it is sharply defined and *synchronous with the closure of the semilunar valves.* The sounds emitted during each cardiac cycle have been compared to the pronunciation of the syllables *lŭbb, dŭp.* Or the result may be expressed thus—



[It is to be remembered that in reality *four* sounds are produced in the heart, but the two first sounds occur together and the two second, so that only a single first and a single second sound are heard.]

The **causes of the first sound** are due to two conditions. As the sound is heard, although enfeebled, in an excised heart in which the movements of the valves are arrested, and also when the finger is introduced into the auriculo-ventricular orifices so as to prevent the closure of the valves (*C. Ludwig and Dogiel*), one of the chief factors lies in the "*muscle sound*" produced by the contracting muscular fibres of the ventricles. This sound is supported and increased by the sound produced by the tension and vibration of the auriculo-ventricular valves and their chordæ tendineæ, at the moment of the ventricular systole. Wintrich, by means of proper resonators, has analyzed the first sound and distinguished the clear, short, valvular part from the deep, long, muscular sound.

The muscle sound produced by *transversly striped muscle* does not occur with a *simple* contraction (p. 127), but only when several contractions are superposed to produce tetanus (§ 303). The ventricular contraction is only a *simple* contraction, but it lasts considerably longer than the contraction of other muscles, and herein lies the cause of the occurrence of the muscle sound during the ventricular contraction.

Defective Heart Sounds.—In certain conditions (typhus, fatty degeneration of the heart), where the muscular substance of the heart is much weakened, the first sound may be completely inaudible. In aortic insufficiency, in consequence of the reflux of blood from the aorta into the ventricle, the mitral valve is gradually stretched, and sometimes even before the beginning of the ventricular systole, the first sound may be absent. Such pathological conditions seem to show that, for the production of the first sound, muscle sound and valve sound must eventually work together, and that the tone is altered, or may even disappear, when one of these causes is absent. [Yeo and Barrett state that the sound is purely muscular (?).]

The cause of the second sound is undoubtedly due to the prompt closure, and therefore sudden stretching or tension, of the semilunar valves of the aorta and pulmonary artery, so that it is purely a valvular sound. Perhaps it is augmented by the sudden vibration of the fluid particles in the large arterial trunks. [The second sound has all the characters of a valvular sound. That the aortic

valves are concerned in its production, is proved by introducing a curved wire through the left carotid artery and hooking up one or more segments of the valve, when the sound is modified, and it may disappear or be replaced by an abnormal sound or "murmur." Again, when these valves are diseased, the sound is altered, and it may be accompanied or even displaced by murmurs.] Although the aortic and pulmonary valves do not close simultaneously, usually the difference in time is so small that *both* valves make *one* sound, but the second sound may be double or divided when, through increase of the difference of pressure in the aorta and pulmonary artery, the interval becomes longer. Even in health this may be the case, as occurs at the end of inspiration or the beginning of expiration (*v. Dusch*).

Where the Sounds are Heard Loudest.—The sound produced by the *tricuspid valve* is heard loudest at the junction of the lower right costal cartilages with the sternum; as the *mitral valve* lies more to the left and deeper in the chest, and is covered in front by the arterial orifice, the mitral sound is best heard at the apex beat, or immediately above it, where a strip of the left ventricle lies next the chest wall. [The sound is conducted to the part nearest the ear of the listener by the muscular substance of the heart.] The aortic and pulmonary orifices lie so close together that it is convenient to listen for the second (*aortic*) sound in the direction of the aorta, where it comes nearest to the surface, *i. e.*, over the second right costal cartilage or aortic cartilage close to its junction with the sternum. The sound, although produced at the semilunar valves, is carried upward by the column of blood and by the walls of the aorta. The sound produced by the *pulmonary artery* is heard most distinctly over the third left costal cartilage, somewhat to the left and external to the margin of the sternum (Fig. 51).

54. **VARIATIONS OF THE HEART SOUNDS.**—**Increase** of the first sound of both ventricles indicates a more energetic contraction of the ventricles and a simultaneously greater and more sudden tension of the auriculo-ventricular valves. Increase of the second sound is a sign of increased tension in the interior of the corresponding large arteries. Hence increase of the second (pulmonary) sound indicates overfilling and excessive tension in the pulmonary circuit. *A feeble* action of the heart, as well as abnormal want of blood in the heart, causes weak heart sounds, which is the case in degenerations of the heart muscle.

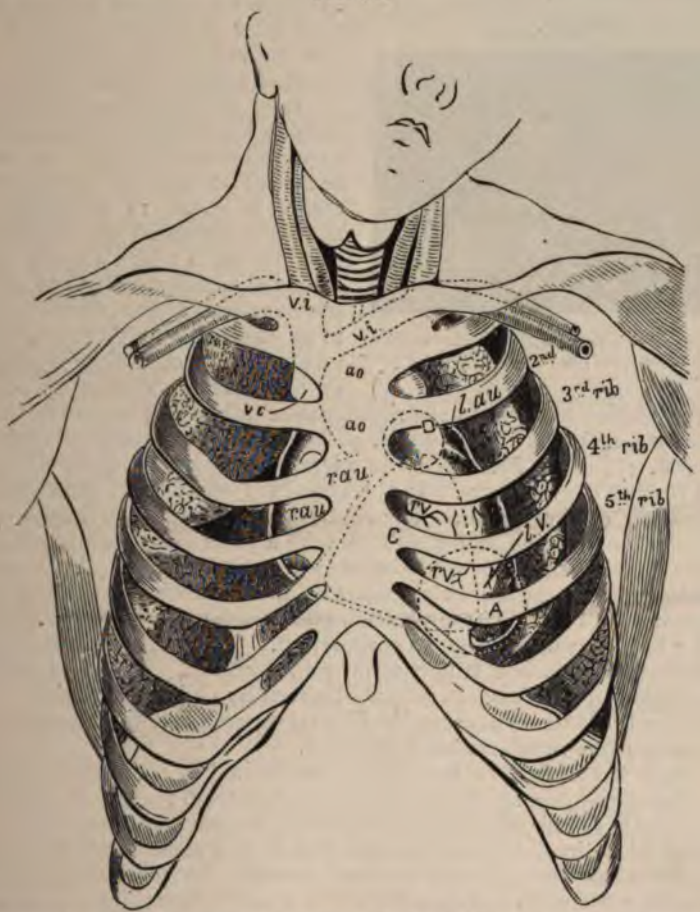
Irregularities in structure of the individual valves may cause the heart sounds to become "**impure.**" If a pathological cavity, filled with air, be so placed, and of such a form as to act as a resonator to the heart sounds, they may assume a "metallic" character. The first and second sounds may be "**reduplicated**" or [although "duplication" is a more accurate term (*Barr*)] doubled. The reduplication of the first sound is explained by the tension of the tricuspid and that of the mitral valves not occurring simultaneously. Sometimes in disease a sound is produced by a hypertrophied auricle producing an audible **presystolic sound**, *i. e.*, a sound or "murmur" preceding the first sound. [This has been questioned quite recently.] As the aortic and pulmonary valves do not close quite simultaneously, a *reduplicated second sound* is only an increase of a physiological condition. All conditions which cause the aortic valves to close rapidly (diminished amount of blood in the left ventricle) and the pulmonary valves to close later (congestion of the right ventricle—both conditions together in mitral stenosis), favor the production of a reduplicated second sound.

Cardiac Murmurs.—If irregularities occur in the valves, either in cases of stenosis or in insufficiency, so that the blood is subjected to vibratory oscillations and friction, then, instead of the heart sounds, other sounds—**murmurs** or **bruits**—arise or accompany these. A combination of these sounds is always accompanied by disturbances of the circulation. [These murmurs may be produced within the heart, when they are termed **endocardial**; or outside it, when they are called **exocardial** murmurs. But other murmurs are due to changes in the quality or amount of the blood, when they are spoken of as **hæmic** murmurs. In the study of all murmurs, note their *rhythm* or exact relation to the normal sounds, their *point of maximum intensity*, and the *direction in which the murmur is propagated.*] It is rare that tumors or other deposits projecting into the ventricles cause murmurs, unless there be present at the same time lesions of the valves and disturbances of the circulation. The cardiac murmurs are always related to the systole or diastole, and usually the systolic are more accentuated and louder. Sometimes they are so loud that the thorax trembles under their irregular oscillations (*fremitus*, frémissement cataire).

In cases where **diastolic murmurs** are heard, there are always anatomical changes in the car-

diac mechanism. These are insufficiency of the arterial valves, or stenosis of the auriculo-ventricular orifice (usually the left). **Systolic murmurs** do not always necessitate a disturbance in the cardiac mechanism. They may occur on the left side, owing to insufficiency of the mitral valve, stenosis of the aorta, and in the calcification and dilatation of the ascending part of the aorta. These murmurs occur very much less frequently on the right side, and are due to insufficiency of the tricuspid and stenosis of the pulmonary orifice.

FIG. 51.



The heart—its several parts and great vessels in relation to the front of the thorax. The lungs are collapsed to their normal extent, as after death, exposing the heart. The outlines of the several parts of the heart are indicated by very fine dotted lines. The area of propagation of valvular murmurs is marked out by more visible dotted lines. A, the circle of mitral murmur, corresponds to the left apex. The broad and somewhat *diffused area*, roughly triangular, is the region of tricuspid murmurs, and corresponds generally with the right ventricle, where it is least covered by lung. The letter C is in its centre. The circumscribed *circular area*, D, is the part over which the pulmonic arterial murmurs are commonly heard loudest. In many cases it is an inch, or even more, lower down, corresponding to the *conus arteriosus* of the right ventricle, where it touches the wall of the thorax. The internal organs and parts of organs are indicated by letters as follows:—*r. au*, right auricle, traced in fine dotting; *ao*, arch of aorta, seen in the first intercostal space, and traced in fine dotting on the sternum; *v. i.*, the two innominate veins; *r. v.*, right ventricle; *l. v.*, left ventricle.

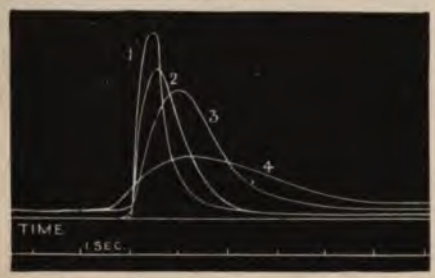
Functional Murmurs.—Systolic murmurs often occur without any valvular lesion, although they are always less loud, and are caused by abnormal vibrations of the valves or arterial walls. They occur most frequently at the orifice of the pulmonary artery [and are generally heard at the base], less frequently at the mitral, and still less frequently at the aortic or the tricuspid orifice. Anæmia, general malnutrition, acute febrile affections, are the causes of these murmurs. [Some of

these are due to an altered condition of the blood, and are called **hæmic**, and others to defective cardiac muscular nutrition, and are called **dynamic** (*Walshe*).]

Sounds may also occur during a certain stage of inflammation of the pericardium (pericarditis) from the roughened surfaces of this membrane rubbing upon each other. Audible friction sounds are thus produced, and the vibration may even be perceptible to touch. [These are "**friction sounds**," and quite distinct from sounds produced within the heart itself.]

55. DURATION OF THE MOVEMENTS OF THE HEART.—

FIG. 52.



Curves of excised rabbit's heart. 1, 6 mins. after excision; 2, 10 mins.; 3, 20 mins.; 4, 70 mins. (After *Waller and Reid.*)

The heart continues to beat for some time after it is cut out of the body. The movement lasts longer in cold-blooded animals (frog, turtle)—extending even to days—than in mammals. A rabbit's heart beats from 3 minutes up to 36 minutes after it is cut out of the body. The average of many experiments is about 11 minutes. [Waller and Reid recorded the ventricular contractions of a rabbit's heart 72 minutes after its excision. Fig. 52 shows the prolongation of the ventricular systole in an excised rabbit's heart, the movements being recorded by a lever resting on the heart.] Panum found the last trace of contraction to occur in the right auricle (rabbit) 15 hours after death; in a mouse's heart, 46 hours; in a dog's, 96 hours. An excised frog's heart beats, at the longest, 2½ days (*Valentin*). In a human embryo (third month) the heart was found beating after 4 hours. In this condition stimulation causes an increase and acceleration of the action. The ventricular contraction weakens, and soon each auricular contraction is not followed by a ventricular contraction, two or more of the former being succeeded by only one of the latter. At the same time the ventricles contract more slowly (Fig. 46), and soon stop altogether, while the auricles continue to beat. If the ventricles be stimulated directly, as by pricking them with a pin, they may execute a contraction. The left auricle soon ceases to beat, while the right auricle still continues to contract. The right auricular appendix continues to beat longest, as was observed by Galen and Cardanus (1550), and it is termed "ultimum moriens." Similar observations have been made upon the hearts of persons who have been executed.

If the heart has ceased to beat, it may be excited to contract for a short time by direct stimulation, more especially by heat (*Harvey*); even under these circumstances the auricles and their appendices are the last parts to cease contracting. As a general rule, direct stimulation, although it may cause the heart to act more vigorously for a short time, brings it to rest sooner. In such cases, therefore, the regular sequence of events ceases, and there is usually a twitching movement of the muscular fibres of the heart. C. Ludwig found that, even after the excitability is extinguished in the mammalian heart, it may be restored by injecting arterial blood into the coronary arteries; conversely lesion of these vessels is followed by enfeebled action of the heart (§ 47). Hammer found that in a man whose left coronary artery was plugged the pulse fell from 80 to 8 beats per minute.

[The beats of the excised heart of a rabbit gradually decline in force and frequency, the latent period and contraction become longer and the excitability more obtuse. The duration of a contraction may be 6 sec., the normal being .3 sec. The beats have often a bigeminal character. An excised heart may be frozen quite hard, yet on being thawed it contracts spontaneously. The contraction proceeds in a wave from the spot stimulated in the frog's heart at 8° to 12° C. at 30 to 90 mm. per sec.; in the mammalian excised heart about 8 metres per sec. (*Waller and Reid*).]

Action of Gases on the Heart.—During its activity the heart uses O, and produces CO_2, so that it beats longest in pure O (12 hours), and not so long in N,—H (1 hour)—CO_2 (10 minutes)

—CO (42 minutes)—Cl (2 minutes), or in a vacuum (20 to 30 minutes), even when there is watery vapor present to prevent evaporation. If the heart be reintroduced into O it begins to beat again. [A frog's heart ceases to beat in compressed O (10 to 12 atmospheres) in about one-third of the time it would do were it simply excised and left to itself. An excised heart suspended in ordinary air beats three to four times as long as a heart which is placed upon a glass plate.]

[56. **PHYSICAL EXAMINATION OF THE HEART.**—The **physical methods** of diagnosis enable us to obtain precise knowledge regarding the actual state of the heart. The methods available are:—

1. Inspection.
2. Palpation.
3. Percussion.
4. Auscultation.

To arrive at a correct diagnosis all the methods must be employed.]

[**Inspection.**—The person is supposed to have his chest exposed and to be in the recumbent position. It is important to remember the **limits of the heart.** The *base* corresponds to a line joining the upper margins of the third costal cartilages, the apex to the fifth interspace, while transversely it extends from a little to the right of the sternum to within a little of the left nipple; this area occupied by the heart being called the **deep cardiac region.** By the eye we can detect any alteration in the configuration of the præcordia, bulging or retraction of the region as a whole or of the intercostal spaces, and we may detect variations in the position, character, extent of the cardiac impulse, or the presence of other visible pulsations.]

[**Palpation.**—By placing the whole hand flat upon the præcordia, we can ascertain the presence or absence, the situation and extent, and any alterations in the characters of the apex beat; or we may detect the existence of abnormal pulsations, vibrations, thrills, or friction in this region. In feeling for the apex beat, if it be at all feeble, it is well to make the patient lean forward. Of course, it must be remembered that the whole heart may be displaced by tumors or accumulations of fluids pressing upon it, *i. e.*, conditions external to itself, or the apex beat may be displaced from causes within the heart itself, as in hypertrophy of the left ventricle.]

[**Percussion.**—As the heart is a solid organ, and is surrounded by the lungs which contain air, it is evident that the sound emitted by striking the chest over the region of the former must be different from that produced over the latter. Not only is there a difference in the sound or note emitted, but the "sensation of resistance" which one feels on percussing the two organs is different. We may ascertain—

1. The superficial or absolute cardiac dullness.
2. The deep or relative dullness.

[**Superficial Cardiac Dullness.**—This theoretically is the part of the heart in direct contact with the chest wall and uncovered by lung, but obviously as the lungs vary in size during respiration, it must be smaller during inspiration and larger during expiration. It forms a roughly triangular space, whose base cannot be accurately determined, as the heart dullness merges into that of the liver, situate below it, but it corresponds to a horizontal line 2½ inches long, extending from the apex beat to the middle of the sternum. The internal side corresponding to the left edge of the sternum is 2 inches long, and reaches from the junction of the fourth costal cartilage with the sternum—apex of the triangle—to the sternal end of the base line. The superior, outer, or oblique line, 3 inches in length, is somewhat curved, and passes downward and outward from the apex of the triangle to the apex of the heart.]

[**Deep Cardiac Dullness.**—By this method theoretically we seek to define the exact limits of the heart as a whole, and thus to ascertain its absolute size, and of course percussion has to be done through a certain thickness of lung tissue, and hence one must strike the pleximeter forcibly. It extends vertically from the third rib and ends at the sixth, but owing to the cardiac merging in the hepatic dullness, this lower limit cannot be accurately ascertained; while *transversely* at the fourth rib it extends from just within the nipple line to slightly beyond the right of the sternum. By these means we may detect increase in the size of the heart or alterations in the relation of the lungs to the heart, fluid in pericardium, etc.]

[**Auscultation.**—This is one of the most valuable methods, for by it we can detect variations and modifications in the healthy sounds of the heart, the rhythm and frequency of the heart beat, the existence of abnormal sounds, and their exact relation to the normal sounds, also their characters and relation to the cardiac cycle, and the direction in which these sounds are propagated (§ 54).]

57. **INNERVATION OF THE HEART.**—[**Intra- and Extra-Cardiac Nervous Mechanism.**—When the heart is removed from the body, or when all the nerves which pass to it are divided, it still beats for some time, so that its movements must depend upon some mechanism situated within itself. The ordinary rhythmical movements of the heart are undoubtedly *associated with* the presence of nerve ganglia, which exist in the substance of the heart—the

intra-cardiac ganglia. But the movements of the heart are influenced by nervous impulses which reach it from without, so that there falls to be studied an *intra-cardiac* and an *extra-cardiac* nervous mechanism.]

The **cardiac plexus** is composed of the following nerves: (1) The cardiac branches of the vagus, the branch of the same name from the external branch of the superior laryngeal, a branch from the inferior laryngeal, and sometimes branches from the pulmonary plexus of the vagus (more numerous on the right side); (2) the superior, middle, inferior, and lowest cardiac branches of the three cervical ganglia and the first thoracic ganglia of the sympathetic; (3) the inconstant twig of the descending branch of the hypoglossal nerve, which, according to Luschka, arises from the upper cervical ganglion. From the plexus there proceed—the *deep* and the *superficial* nerves (the latter usually at the division of the pulmonary artery under the arch of the aorta, and containing the ganglion of Wrisberg) (§ 370). The following nerves may be separately traced from the plexus:—

(*a*) The **plexus coronarius dexter and sinister,** which contains the *vaso-motor nerves* for the coronary vessels (physiological proof still wanting) as well as the nerves (sensory?) proceeding from them (to the pericardium?).

(*b*) **Intra-cardiac nerves and ganglia.**—The nerves lying in the *grooves of the heart* and in *its substance* contain numerous ganglia (*Remak*), and are regarded as the automatic motor centres of the heart. A nervous ring containing numerous ganglia corresponds to the margin of the septum atriorum; there is another in the auriculo-ventricular groove. Where the two meet, they exchange fibres. The ganglia usually lie near the pericardium. In *mammals*, the two largest ganglia lie near the orifice of the superior vena cava—in *birds*, the largest ganglion (containing thousands of ganglionic cells) lies posteriorly where the longitudinal and transverse sulci cross each other. Fine branches, also provided with small ganglia, proceed from these ganglia, and penetrate the muscular walls of the auricles and ventricles.

[**Frog's Heart.**—The frog's heart consists of the *sinus venosus*, into which open the single inferior and the two superior venæ cavæ (Fig. 54). There are *two auricles;* the right one communicates with the sinus venosus, and opens into the single ventricle; the left auricle also

FIG. 53.

opens into the *single ventricle* (Fig. 53, *v*), and in the latter are mixed the venous blood returned by the right auricle and the arterial blood from the left auricle. The aorta with its *bulbus arteriosus* conducts the blood from the ventricle. The various orifices are guarded by projections of tissue, which act like valves. The two auricles are completely separated by a septum. This septum ends posteriorly in a free concave margin so as to divide the auriculo-ventricular orifice into a right and a left orifice. Each orifice is guarded by two thick, fleshy valves, which close it.]

[**Nerves.**—The two cardiac branches of the vagi—the **nervi cardiaci**—proceed to the posterior surface of the sinus venosus, and where the latter joins the auricle they interlace, and are mixed with a number of ganglion cells (Fig. 57). This spot is called **Remak's ganglion,** is sometimes single, at others double, and it can be seen as a white "crescent" when the heart is lifted up and looked at from behind (Fig. 54). The cardiac nerves proceed downward on the auricular septum,

FIG. 55.

exchanging fibres in their course to join two ganglia at the auriculo-ventricular groove, and known as **Bidder's ganglia** (Fig. 57). It has been stated by one observer that the bulbus arteriosus contains ganglionic cells, but this is denied by others.]

According to Openchowsky, every part of the heart (frog, triton, tortoise) contains nerve fibres which are connected with every muscular fibre. In the auricles, at the end of the non-medullated fibre, a tri-radiate nucleus exists which gives off fibrils to the muscular bundles. There is a

FIG. 57.

network of fine nerve fibres distributed immediately under the endocardium—these fibres act partly *in a centripetal direction* on the cardiac ganglia, and are partly *motor* for the endocardial muscles. The parietal layer of the pericardium contains (sensory) nerve fibres. The following kinds of nerve cells are found—*unipolar cells*, the single processes of which afterward divide; **bipolar pyriform cells** (Fig. 56), which in the frog possess a straight (*n*) and usually also a spiral process (*o*).

58. THE AUTOMATIC MOTOR CENTRES OF THE HEART.—(1) It is generally assumed that the nervous centres which excite the cardiac movements, and maintain the rhythm of these movements, lie within the heart, and that they are probably represented by the *ganglia*.

(2) There are—not one, but several of these centres in the heart, which are connected with each other by conducting paths. As long as the heart is intact,

all its parts move in rhythmical sequence from a principal central point, an impulse being conducted from this centre through the conducting paths. What the "discharging forces" of these regular progressive movements are, is unknown. If, however, the heart be subjected to the action of diffuse stimuli (*e.g.*, strong electrical currents), all the centres are thrown into action, and a spasm-like action of the heart occurs. The *dominating centre lies in the auricles*, hence the regular progressive movement usually starts from them. If the excitability is diminished, as by touching the septum with opium, other centres seem to undertake this function, in which case the movement may extent from the ventricles to the auricles. According to Kronecker and Schmey, in the *dog's* heart there is a spot above the lower limit of the upper third of the ventricular septum, which, when it is injured, *e.g.*, by destroying it with a stout needle, brings the heart to a standstill; this has been called a coördinating centre.

(3) All stimuli of moderate strength applied directly to the heart cause at first an increase of the rhythmical heart beats; stronger stimuli cause a diminution, and it may be paralysis, which is often preceded by a convulsive movement. Increased activity exhausts the energy of the heart sooner.

(4) Single very weak stimuli, which have no effect on the heart when applied singly, if repeated sufficiently often, may become active, owing to "summation of the stimuli" (*v. Basch*).

(5) Even the weakest stimulus which can excite a contraction always causes an energetic contraction, *i. e.*, "the minimal stimulus causes a maximal effect" (*Bowditch, Kronecker and Stirling*).

(6) After every contraction of the heart there is a short period of "diminished excitability" or Marey's "refractory period," during which the heart is less susceptible to further stimulation.

(7) The non-ganglionic apex of the heart, when it is not stimulated, no longer beats spontaneously, but it responds each time by a single contraction to a single direct stimulus. If, however, a continuous stimulus, *e. g.*, a continuous current of electricity, be applied to it, it executes a series of beats. Such continuous stimuli are obtained through a continuous pressure of fluid, exerted on the interior of the heart or by moistening the heart with chemical substances.

(8) The auricular centres seem to be more excitable than those of the ventricle; hence, in a heart left to itself the auricles pulsate longest.

(9) The heart may be excited (reflexly) from its inner surface. Weak stimuli applied to the inner surface of the heart greatly accelerate the heart's action, the stimulus required being much feebler than that applied to the external surface of the heart. Strong stimuli, which bring the heart to rest, also act more easily when applied to the inner surface than when they are applied to its outer surface. The ventricle is always the first part to be paralyzed.

(10) In order that the heart may continue to contract, it is necessary that it be supplied with a fluid which, in addition to O, must contain the *necessary nutritive materials*. The most perfect fluid, of course, is blood. Hence the heart after a time ceases to beat in an indifferent fluid (0.6 per cent. sodium chloride), but its activity may be revived by supplying it with a proper nutritive fluid.

Cardiac Nutritive Fluids.—These nutritive fluids are such as contain serum-albumin, *e.g.*, blood, serum, or lymph. Serum retains its nutritive properties even after it has been subjected to diffusion (*Martius and Kronecker*). Milk and whey (*v. Ott*), normal saline solution mixed with blood, albumin, or peptone, and 0.3 per cent. solution carbonate (*Kronecker, Merunowicz and Stiénon*), a trace of caustic soda (*Gaule*), or a solution of the salts of serum, are suitable. Alkaline solution of soda revives a feebly beating heart by neutralizing the acid formed in the cardiac muscle, or normal saline containing calcic phosphate and potassic chloride (*S. Ringer*).

(11) The independent pulsations of parts of the heart which are devoid of ganglia, show that the presence of ganglia is not absolutely necessary in order to have

rhythmical pulsation. Direct stimulation of the heart may cause these movements. But the ganglia are more excitable than the heart muscle itself, and they conduct the impulses which lead to the regular alternating action of the various parts of the heart, so that, under normal circumstances, we must assume that the action of the heart is governed by the ganglia.

(12) If a heart be cut into pieces, so that the individual pieces still remain connected with each other, the regular peristaltic or wave-like movements proceeding from the auricles to the ventricle may continue for a long time (*Donders, Engelmann*). If the heart, however, be completely divided into two distinct pieces (auricle and ventricle), the movements of both parts continue, but not in the same sequence—they beat at different rates.

The chief experiments upon which the above statements are based are as follows:—

I. Experiments by **cutting** and **ligaturing** the heart. These experiments have been made chiefly upon the heart of the frog. The **ligature** experiments are performed by tightening and then relaxing a ligature placed around the heart, so that the physiological connection is destroyed, while the anatomical or mechanical connections (continuity of the cardiac wall, intact condition of its cavities) still exist. The most important of these experiments are—

(1) **Stannius's Experiment.**—If the sinus venosus of a frog's heart be separated from the auricles, either by an incision or by a ligature, the auricles and ventricle stand still in diastole, while the veins and the remainder of the sinus continue to beat (Fig. 58, 1). If a second incision be made at the auriculo-ventricular groove, as a rule the ventricle begins at once to beat again, while the auricles remain in the condition of diastolic rest. [Thus the sinus venosus and ventricle continue to beat, while the auricle stands still, but the two former no longer beat with the same rhythm, the ventricle usually beats more slowly, as is shown in Fig. 58, 2, by the large zig-zags.] According to the position of the second ligature or incision, the auricles may also beat along with the ventricles, or the auricles alone may beat, while the ventricles remain at rest.

Theoretical.—Various explanations of these experiments have been given: (*a*) Remak's ganglion in the sinus venosus is distinguished by its great excitability, while Bidder's ganglion in the auriculo-ventricular groove is less excitable; in the normal condition of the heart the motor impulse is carried from the former to the latter. If the sinus venosus be separated from the heart, Remak's ganglion has no action on the heart. The heart stops for two reasons—first, because Bidder's ganglion alone has not sufficient energy to excite it to action, and because the inhibitory fibres of the vagus going to the heart have been stimulated by being divided at this point (*Heidenhain*). [That stimulation of the inhibitory fibres of the vagus is not the cause of the standstill, is proved by the fact that the standstill occurs even after the administration of atropine, which paralyzes the cardiac inhibitory mechanism.] The passive heart, however, may be made to contract by mechanically stimulating Bidder's ganglion, *e. g.*, by a slight prick with a needle in the auriculo-ventricular groove, or by the action of a constant current of moderate strength (*Eckhard*), the ventricular pulsation at the same time preceding the auricular (*v. Bezold, Bernstein*). If the auriculo-ventricular groove be divided, the ventricle pulsates again, because Bidder's ganglion has been stimulated by the act of dividing it; while, at the same time, the ventricle is withdrawn from the inhibitory influence of the vagus produced by the first division at the sinus venosus. If the line of separation is so made that Bidder's ganglion remains attached to the auricles, these pulsate, and the ventricle rests; if it be divided into halves, the auricles and ventricles pulsate, each half being excited by the portion of the ganglion in relation with it. (*b*) According to another view, both Remak's (*a*) and Bidder's ganglia (*b*) are motor centres, but in the auricles there is in addition an *inhibitory ganglionic system* (*c*) (*Bezold, Traube*). Under normal circumstances $a + b$ is stronger than c, while c is stronger than a or b separately. If the sinus venosus be separated, it beats in virtue of a; on the other hand, the heart rests because c is stronger than b. If the section be made at the level of the auriculo-ventricular groove, the auricles stand still, owing to c, while the ventricle beats, owing to b.

(2) If the ventricle of a frog's heart be separated from the rest of the heart by means of a **ligature**, or by an **incision** carried through it at the level of the

auriculo-ventricular groove, the sinus and atria pulsate undisturbed as before (*Descartes*, 1644), but the ventricle stands still in diastole. A single local stimulus applied to the ventricle is responded to by a *single* contraction. If the incision be so made that the lower margin of the auricular septum remains attached to the ventricle, the latter pulsates. Even the ventricles of a rabbit's heart, when separated with a part of the auricles in connection with them, pulsate (*Tigerstedt*).

[**Gaskell's Clamp.**—Gaskell uses a clamp, regulated by a millimetre screw, to compress the heart, and thus to obstruct the passage of impulses from one part of the heart to the other, or to "block" the way, the pulsations of the auricles and ventricles being separately registered. By compressing the heart at the auriculo-ventricular groove, the ratio of auricular and ventricular beats alters, and instead of being 1 : 1, there may be 2, 3, or more auricular beats for each beat of the ventricle, expressed thus: $\frac{A}{V}, \frac{II}{I}, \frac{III}{I}, \frac{IV}{I}$. After the heart is fixed by the clamp, levers are placed horizontally above and below the heart. These levers are fixed to part of the auricles and to the apex by means of threads. Each part of the heart attached to a lever, as it contracts, pulls upon its own lever, so that the extent and duration of each contraction may be registered. This method is applicable for studying the effect of the vagus and other nerves upon the heart.]

(3) **Section.**—A. Fick showed that the process of excitement in the contractile tissue of the frog's heart is propagated in all directions (1874), so that to a certain extent the whole frog's heart behaves like *one* continuous muscular fibre; thus one transverse cut into the ventricle does not prevent contraction from taking place in the separated parts. Engelmann's experiments also show that if the ventricle of a frog's heart be cut up into two or more strips in a zig-zag way, so that the individual parts still remain connected with each other by muscular tissue, the strips still beat in a regularly progressive rhythmical manner, provided one strip is caused to contract. The rapidity of the transmission is about 10 to 15 mm. per sec. Hence, it appears that the conducting paths for the impulse causing the contraction are not nervous, but must be the contractile mass itself. It has not been proved that nerve fibres proceed from the ganglia to all the muscles.

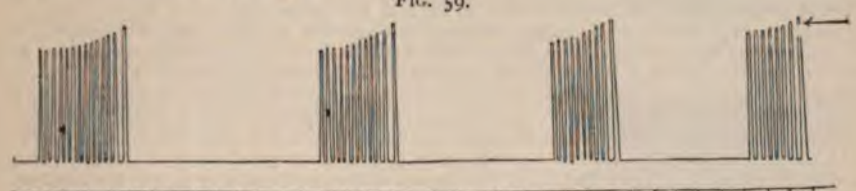
[According to Marchand's experiments, it takes a very long time for the excitement to pass from the auricles to the ventricle—a much longer time, in fact, than it would require to conduct the excitement through muscle—so that it is probable that the propagation of the impulse from the auricles to the ventricle is conducted by nervous channels to the auriculo-ventricular nervous apparatus. In fact, in the mammalian heart the muscular fibres of the auricles are quite distinct from those of the ventricles.]

(4) When the apex of a frog's heart is ligatured off from the rest of the heart, it no longer pulsates (*Heidenhain, Goltz*), but such an apex, if stimulated directly, *e. g.*, by a prick of a pin, responds with a single contraction. If the "heart apex" be filled with normal saline solution under pressure, which acts as a stimulus, the heart begins to pulsate, and the same is the case with a solution of delphinin or quinine. If a cannula be tied into the heart over the auriculo-ventricular groove, the ventricle does not beat, but if the ventricle be filled through the cannula with blood containing oxygen, under a constant and sufficient pressure, it also pulsates (*Ludwig and Merunowicz*).

(5) Luciani found that a heart ligatured above the auriculo-ventricular groove, when filled with pure serum, produced *groups of pulsations* with a long diastolic pause between every two groups (Fig. 59). The successive beats in each group assume a "staircase" character (p. 126). These periodic groups undergo many changes; they occur when the heart is filled with pure serum free from blood corpuscles, and they disappear and give place to regular pulsations when defibrinated blood or serum containing hæmoglobin or normal saline solution is used (*Rossbach*). They also occur when the blood within the heart has become dark-colored, *i, e.*, when it has been deprived of certain of its constituents, and if a trace of *veratrin* be added to bright red blood they occur.]

(6) An apex preparation, when stimulated with even a weak induction shock, always gives its maximal contraction, and when a tetanizing current is applied, tetanus does not occur (*Kronecker and Stirling*). When the opening and closing shocks of a sufficiently strong constant current are applied to the heart apex, it contracts with each closing or opening shock. [When a *constant* current is applied to the lower two-thirds of the ventricle (heart apex), under certain conditions the apex contracts *rhythmically*. This is an important fact in connection with any theory of the cardiac beat.]

FIG. 59.



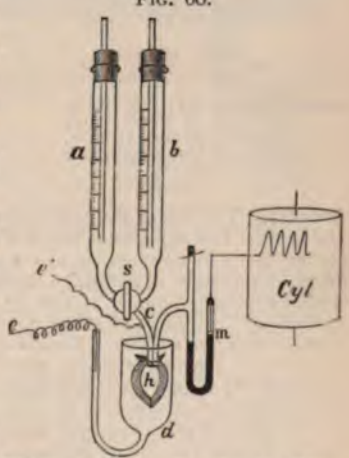
Four groups of pulsations with intervening pauses, with their "staircase" character. The points on the abscissa were marked every 10 seconds.

(7) If the bulbus aortæ (frog) be ligatured, it still pulsates, provided the internal pressure be moderate. Should it cease to beat, a single stimulus makes it respond by a series of contractions. Increase of temperature to 35° C., and raising the pressure within it, increase the number of pulsations (*Engelmann*).

Action of Fluids.—Haller was of opinion that the venous blood was the natural stimulus which caused the heart to contract. That this is not so, is proved at once by the fact that the heart beats rhythmically when it contains no blood. Blood and other fluids which are supplied to an excised heart are not the cause of its rhythmical movements, but only the conditions on which these movements depend.

[**Methods.**—The study of the action of fluids upon the excised frog's heart has been rendered possible by the invention of Ludwig's "**frog manometer.**" The apparatus (Fig. 60) consists of (1) a double-way cannula, *c*, which is tied into the heart, *h*; (2) a manometer, *m*, connected with *c*, and registering the movements of its mercury on a revolving cylinder, *cyl*; (3) two Mariotte's flasks, *a* and *b*, which are connected with the other limb of the cannula. Either *a* or *b* can be placed in communication with the interior of the heart by means of the stop-cock, *s*. The fluid in one graduated tube may be poisoned, and the other not; *d* is a glass vessel for fluid, in which the heart pulsates, *e'* and *e* are electrodes, *e* is inserted into the fluid in *d*, *e'* is attached to the German silver cannula which is shown in Fig. 61.]

FIG. 60.



Scheme of a frog manometer. *a*, *b*, Mariotte's flasks for the nutrient fluids; *s*, stop-cock; *c*, cannula; *m*, manometer; *h*, heart; *d*, glass cup for *h*; *e'*, *e*, electrodes; *cyl*, revolving cylinder.

[In the **tonometer** of Roy (Fig. 62) the ventricle, *h*, or the whole heart, is placed in an air-tight chamber, *o*, filled with oil. As before, a "perfusion" cannula is tied into the heart. A piston, *p*, works up and down in a cylinder, and is adjusted by means of a thin flexible animal membrane, such as is used by perfumers. Attached to the piston by means of a thread is a writing lever, *l*, which records the variations of pressure within the chamber, *o*. When the ventricle contracts, it becomes smaller, diminishes the pressure within *o*, and hence the piston and lever rise; conversely, when the heart dilates, the lever and piston descend. Variations in the volume of the ventricle may be registered, without in any way interfering with the flow of fluids through it.]

[Two preparations of the frog's heart have been used—(1) The "**heart,**" in which case the cannula is introduced into the heart through the sinus venosus, and a ligature is tied over it *around the auricle*, *i. e.*, *above* the auriculo-ventricular groove. Thus the auriculo-ventricular ganglia and other nervous structures remain in the preparation. This was the heart

preparation employed by Luciani and Rossbach. (2) In the "**heart apex,**" or **apex** preparation, the cannula is introduced as before, but the ligature is tied on it over the ventricle, several millimetres *below* the auriculo-ventricular groove, so that this preparation contains none of the auriculo-ventricular ganglia, and, according to the usual statement, this part of the heart is devoid of nerve ganglia. This is the preparation which was used by Bowditch, Kronecker and Stirling, Merunowicz, and others. The first effect of the application of the ligature in both cases is, that both preparations cease to beat, but the "heart" usually resumes its rhythmical contractions within several minutes, while the "heart apex" does not contract spontaneously until after a much longer time (10 to 90 mins.).]

[If the "**heart apex**" be filled with a 0.6 per cent. solution of common salt, the contractions are at first of greater extent, but they afterward cease, and the preparation passes into a condition of "apparent death," lasting 30–90 mins.; while, if the action of the fluid be prolonged, the heart may not contract at all, even when it is stimulated electrically or mechanically. It may be made, however, to pulsate again, if it be supplied with saline solution containing blood (1 to 10 per cent.). If the ventricle be nipped with wire forceps at the junction of the upper with its middle third, so as to separate the lower two-thirds of the ventricle, physiologically but not anatomically, from the rest of the heart, then the apex will cease to contract, although it is still supplied with the frog's own blood (*Bernstein, Bowditch*). The physiologically isolated apex may be made to beat by clamping the aortic branches so as to prevent blood passing out of the heart, and thus raising the intra-cardiac

pressure. The rate of the beat of the apex is independent of and slower than that of the rest of the heart. This experiment proves that the amount of **pressure** within the apex cavity is an important factor in the causation of the spontaneous beats of the apex. If blood serum, to which a trace of delphinin is added, be transfused or "*perfused*" through the heart, it begins to beat within a minute, continues to beat for several seconds, and then stands still in diastole (*Bowditch*). Quinine and a mixture of atropine and muscarin have a similar action. These experiments show that, *provided no nervous apparatus exists within the heart apex*, the cause of the varying contraction is to be sought for in the musculature of the heart, and that the stimulus necessary for the systole of the heart's apex may arise within itself. If there is no nervous apparatus of any kind present, then we must assume that the heart muscle may execute rhythmical movements independently of the presence of any nervous mechanism, although it is usually assumed that the ganglia excite the heart muscle to pulsate rhythmically. It is by no means *definitely proved* that the heart apex is devoid of all nervous structures, which may act as originators of these rhythmical impulses.]

[**Action of Drugs.**—If the heart apex contains no nervous structures, it must form a good object for the study of the action of drugs on the cardiac muscle. Some of these have been mentioned already. Ringer finds that a calcium salt makes the contractions higher and longer. *Dilute acids* added to saline solution, *e.g.*, lactic, cause complete relaxation of the cardiac musculature, while *dilute alkalies* produce an opposite effect or tonic contraction, even though the apex be not pulsating. The action of a dilute acid may be set aside by a dilute alkali, and *vice versâ*. Digitalin, antiarin,

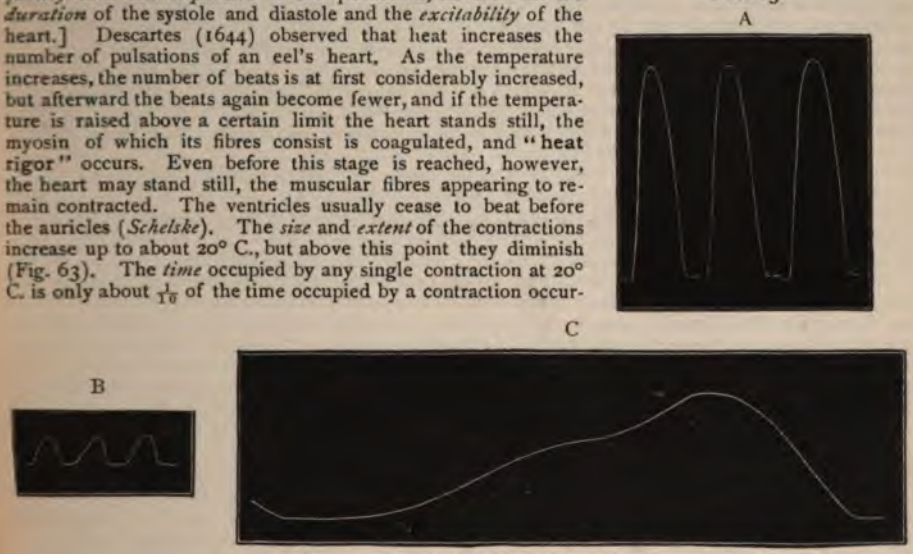
barium, and veratria act like alkalies, while saponin, muscarin, and pilocarpin have the effect of acids (§ 65). An isolated frog's heart, fatigued after being supplied with a solution of blood, is caused to beat more vigorously by a solution of kreatinin, or extract of meat (*Mays*).]

[The "**heart**" preparation in many respects behaves like the foregoing, *i.e.*, it is exhausted after a time by the continued application of normal saline solution (0.6 per cent. NaCl), while its activity may be restored by supplying it with albuminous and other fluids (p. 120).]

II. Direct Stimulation of the Heart.—All direct cardiac stimuli act more energetically on the inner than on the outer surface of the heart. If strong stimuli are applied for too long a time, the ventricle is the part first paralyzed.

(*a*) **Thermal Stimuli.**—[**Heat** affects the *number* or *frequency* and the *amplitude* of the pulsations, as well as the *duration* of the systole and diastole and the *excitability* of the heart.] Descartes (1644) observed that heat increases the number of pulsations of an eel's heart. As the temperature increases, the number of beats is at first considerably increased, but afterward the beats again become fewer, and if the temperature is raised above a certain limit the heart stands still, the myosin of which its fibres consist is coagulated, and "**heat rigor**" occurs. Even before this stage is reached, however, the heart may stand still, the muscular fibres appearing to remain contracted. The ventricles usually cease to beat before the auricles (*Schelske*). The *size* and *extent* of the contractions increase up to about 20° C., but above this point they diminish (Fig. 63). The *time* occupied by any single contraction at 20° C. is only about $\frac{1}{10}$ of the time occupied by a contraction occurring at 5° C. A heart which has been warmed is capable of reacting pretty rapidly to intermittent stimuli, while a heart at a low temperature reacts only to stimuli occurring at a considerable interval (*Gaule*).

FIG. 63.



A, contractions of a frog's heart at 19° C.; B, at 34° C.; C, at 3° C.

Cold.—When the temperature of the blood is diminished, the heart beats more slowly. A frog's heart, placed between two watch glasses and laid on ice, beats very much more slowly. The pulsations of a frog's heart stop when the heart is exposed to a temperature of 4° C. to 0°. If a frog's heart be taken out of warm water, and suddenly placed upon ice, it beats more rapidly, and conversely, if it be taken from ice and placed over warm water, it beats more slowly at first and more rapidly afterward (*Aristow*).

[**Methods.**—The effect of heat on a heart may be studied by the aid of the frog manometer, the fluid in which the heart is placed being raised to any temperature required. For demonstration purposes, the heart of a pithed frog is excised and placed on a glass slide under a light lever, such as a straw. The slide is warmed by means of a spirit lamp. In this way the frequency and amplitude of the contractions are readily made visible at a distance.]

(*b*) **Mechanical Stimuli.**—Pressure applied to the heart from without accelerates its action. In the case of Frau Serafin, v. Ziemssen found that slight pressure on the auriculo-ventricular groove caused a second short contraction of both ventricles after the heart beat. Strong pressure causes a very irregular action of the cardiac muscle. This may readily be produced by compressing the freshly-excised heart of a dog between the fingers. The **intra-cardiac pressure** also affects the heart beat (p. 124). If the pressure within the heart be increased, the heart beats are gradually increased, if it be diminished the number of beats diminishes (*Ludwig and Thiry*). If the intra-cardiac pressure be very greatly increased, the heart's action becomes very irregular and slower. A heart which has ceased to beat may, under certain circumstances, be caused to execute a *single* contraction if it be stimulated mechanically.

(*c*) **Electrical Stimuli.**—A **constant** electrical current of moderate strength increases the number of heart beats. V. Ziemssen found, in the case of Frau Serafin (§ 47, 3), that the number

of beats was doubled when a constant uninterrupted strong current was passed through the ventricles. If the constant current be very strong, or if tetanizing induction currents be used, the cardiac muscle assumes a condition resembling, but not identical with, tetanus (*Ludwig and Hoffa*), and, of course, this results in a fall of the blood pressure. If the auriculo-ventricular groove be compressed so as to cause the ventricle of a frog's heart to cease to beat, on placing one electrode of a constant current on the ventricular wall and the other electrode on an indifferent part of the body, we obtain, on making the current, a systolic contraction of the ventricle only when the cathode touches the ventricle; and conversely on breaking, only when the anode is on the heart (*Biedermann*).

When a **single induction shock** is applied to the ventricle of a frog's heart during systole, it has no apparent effect; but if it is applied during diastole, the succeeding contraction takes place sooner. The auricles and also the apex behave in a similar manner. While they are contracted, an induction shock has no effect; if, however, the stimulus is applied during diastole, it causes a contraction, which is followed by systole of the ventricle. Even when strong tetanizing induction shocks are applied to the heart, they do not produce *tetanus* of the entire cardiac musculature, or as it is said, "the heart knows no tetanus" (*Kronecker and Stirling*). Small, white, local, wheal-like elevations—such as occur when the intestinal musculature is stimulated—appear between the electrodes. They may last several minutes. A frog's heart, which yields weak and irregular contractions, may be made to execute regular rhythmical contractions synchronous with the stimuli, if electrical stimuli are used (*Bowditch*).

[Break induction shocks, if of sufficient strength, cause the heart to contract, while weak stimuli have no effect; on the other hand, moderate stimuli, when they do cause the heart to contract, always cause a maximal contraction, so that a minimal stimulus acts at the same time like a maximal stimulus. The heart either contracts or it does not contract, and when it contracts, the result is always a "maximal" contraction (*Kronecker and Stirling*). Bowditch found that the excitability of the heart was increased by its own movements, so that after a heart had once contracted, the strength of the stimulus required to excite the next contraction may be greatly diminished, and yet the stimulus be effectual. Usually the amplitude of the first beat so produced is not so great as the second beat, and the second is less than the third, so that a "**staircase**" ("Treppe") of beats of successively greater extent was produced (Fig. 59). Under certain circumstances, however, a skeletal muscle gives contractions of a "staircase" character. This staircase arrangement occurs even when the strength of the stimulus is kept constant, so that the production of one contraction facilitates the occurrence of the succeeding one. A staircase arrangement of the pulsations is also seen in Luciani's groups (p. 122). The question, whether a stimulus will cause a contraction, depends upon what particular phase the heart is in when the shock is applied. Even comparatively weak stimuli will cause a heart to contract, provided the stimuli are applied at the proper moment and in the proper tempo, *i.e.*, to say, they become what are called "infallible." If stimuli are applied to the heart, at intervals which are longer than the time the heart takes to execute its contraction, they are effectual or "adequate," but if they are applied before the period of pulsation comes to an end, then they are ineffectual (*Kronecker*). It is quite clear, therefore, that the relation of the strength of the stimulus to the extent of the contraction of the cardiac muscle, is quite different from what occurs in a muscle of the skeleton, where within certain limits the amplitude of the contraction bears a relation to the stimulus, while in the heart the contraction is always *maximal.*]

Human Heart.—V. Ziemssen found that he could not alter the heart beats of the human heart (*Frau Serafin*, § 47, 3), even with strong induction currents. The ventricular diastole seemed to be less complete, and there were irregularities in its contraction. By opening and closing, or by reversing a strong *constant* current applied to the heart, the number of beats was increased, and the increase corresponded with the number of electrical stimuli; thus, when the electrical stimuli were 120, 140, 180, the number of heart beats was the same, the pulse beforehand being 80. The normal pulse rate of 80 was reduced to 60 and 50 when the number of shocks was reduced in the same ratio. [In Frau Serafin's case the electrodes were applied to the heart, separated from it merely by the pericardium. Ziemssen found that the Faradic current did not modify the heart's action when the thorax was intact, but that the constant current did, if of sufficient strength. Herbst and Dixon Mann obtained negative results with both kinds of electricity in the normal thorax.]

(*d*) **Chemical Stimuli.**—Many chemical substances, when applied in a dilute solution to the inner surface of the heart, increase the heart beats, while if they are concentrated, or allowed to act too long, they diminish the heart beats, and paralyze it. Bile and bile salts diminish the heart beats (also when they are absorbed into the blood, as in jaundice); in very dilute solutions both increase the heart beats. A similar result is produced by acetic, tartaric, citric, and phosphoric acids. Chloroform and ether, applied to the inner surface, rapidly diminish the heart beats, and then paralyze it; but very small quantities of ether (1 per cent.) accelerate the heart beat of the frog (*Kronecker and M'Gregor-Robertson*), while a solution of 1½ to 2 per cent, passed through the heart arrests it temporarily or completely. Dilute solutions of opium, strychnia, or alcohol applied to the endocardium, increase the heart beats; if concentrated they rapidly arrest its action. Chloral hydrate paralyzes the heart.

Action of Gases.—When blood containing different gases was passed through a frog's heart, Klug found that blood containing sulphurous acid rapidly and completely killed the heart; chlorine stimulated the heart at first, and ultimately killed it; and laughing gas rapidly killed it also. Blood containing sulphuretted hydrogen paralyzed the heart without stimulating it. Carbonic oxide also paralyzed it, but if fresh blood was transfused the heart recovered. [Blood containing O excites the heart (*Castell*), while the presence of much CO_2 paralyzes it, and the presence of CO_2 is more injurious than the want of O. Blood or serum completely saturated with CO_2 exhausts the heart (*Saltet and Kronecker*), but it recovers itself when the CO_2 is removed. H and N have no effect.]

Cardiac Poisons are those substances whose action is characterized by special effects upon the movements of the heart. Among these are **neutral potash salts**, which cause the heart to stand still in diastole. An excised frog's heart ceases to beat after one-half to one minute when it is placed in a 2 per cent. solution of potassic chloride.] Even a very dilute solution of yellow prussiate of potash injected into the heart of a frog causes the ventricle to stand still in systole. **Antiar** (Java arrow poison) causes the ventricle to stand still in systole and the auricles in diastole. Some heart poisons, in small doses, diminish the heart's action, and in large doses not unfrequently accelerate it, *e. g.*, digitalis, morphia, nicotin. Others, when given in small doses, accelerate its action, and in large doses slow it—veratria, aconitin, camphor.

Special Actions of Cardiac Poisons.—The complicated actions of various poisons upon the heart have led observers to suppose that there are various intra-cardiac mechanisms on which these substances may act. Besides the *muscular fibres* of the heart and its *automatic ganglia*, some toxicologists assume that there are *inhibitory ganglia* into which the inhibitory fibres of the vagus pass, and *accelerator ganglia*, which are connected with the accelerating nerve fibres of the heart. *Both the inhibitory and accelerator ganglia are connected with the automatic ganglia* by conducting channels.

Muscarin and all other trimethylammonium bases stimulate permanently the inhibitory ganglia, so that the heart stands still (*Schmiedeberg and Koppe*). [According to Gaskell, however, when the action of the sinus is arrested by muscarin, there is no deflection of the galvanometer similar to that produced by the excitation of the vagus. He infers that muscarin does not cause arrest of the beat by acting as an excitant of inhibitory mechanisms, but as a depressant to motor activity.] As atropin and daturin paralyze these ganglia, the standstill of the heart brought about by muscarin may be set aside by atropin. [If a frog's heart be excised and placed in a watch glass, and a few drops of a very dilute solution of muscarin be placed on it with a pipette, it ceases to beat within a few minutes, and will not beat again. If, however, the muscarin be removed, and a solution of atropine applied to the heart, it will resume its contractions after a short time.] Physostigmin or Calabar bean excites the energy of the cardiac muscle to such an extent, that stimulation of the vagus no longer causes the heart to stand still. Iodine-aldehyd, chloroform, and chloral hydrate paralyze the automatic ganglia. The heart stands still, and it cannot be made to contract again by atropine. The cardiac muscle itself remains excitable after the action of muscarin and iodine-aldehyd, so that if it be stimulated it contracts. [According to Gaskell, antiarin and digitalin solutions produce an alteration in the condition of the muscular tissue of the apex of the heart of the same nature as that produced by the action of a very dilute alkali solution, while the action of a blood solution containing muscarin closely resembles that of a dilute acid solution (p. 138, § 65).]

[**Nature of a Cardiac Contraction.**—The question as to whether this is a simple contraction or a compound tetanic contraction has been much discussed. So much is certain, that the systolic contraction of the heart is of very much longer duration (8 to 10 times) than the contraction of a skeletal muscle produced by stimulation of its motor nerve. When the sciatic nerve of a nerve-muscle preparation is adjusted upon a contracting heart, a *simple* secondary twitch of the limb, and not a tetanic spasm, is produced when the heart (auricle or ventricle) contracts. This of itself is not sufficient proof that the systole is a simple spasm, for tetanus of a muscle does not in all cases give rise to secondary tetanus in the leg of a rheoscopic limb. Thus, a simple "initial" contraction occurs when the nerve is applied to a muscle tetanized by the action of strychnia, and the contracted diaphragm gives a similar result. The question whether the heart can be tetanized has been answered in the negative, and as yet it has not been shown that the heart can be tetanized in the same way that a skeletal muscle is tetanized.]

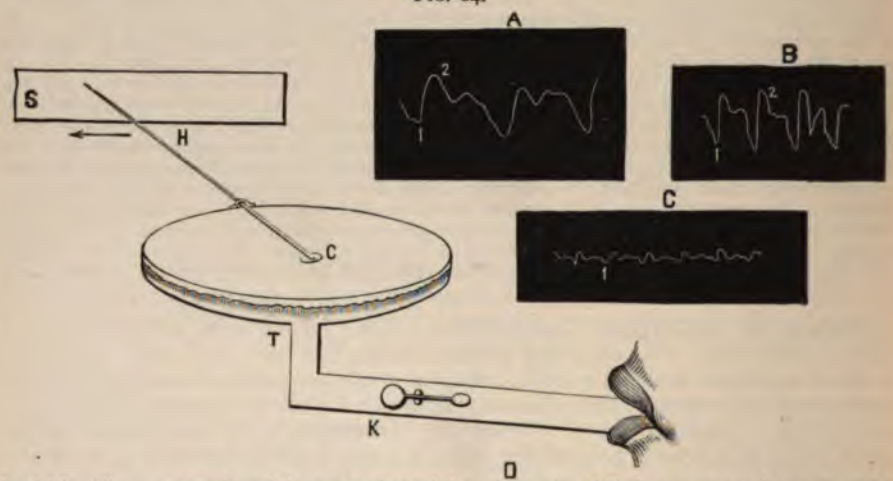
[MacWilliam finds, when the quadriceps extensor cruris contracts to cause the knee jerk, that a sound similar to the first sound of the heart is heard. As the former is regarded as a simple contraction, it is argued that a simple contraction can produce a muscle sound. Frédéricq regards the ventricular systole not as a simple contraction, but as composed of three or more fused contractions corresponding to tetanus. This he concludes from a study of cardiograms as well as from the electro-motive phenomena of the heart.]

The **peripheral** or **extra-cardiac** nerves (§§ 369 and 370).

59. CARDIO-PNEUMATIC MOVEMENT.—As the heart within the thorax occupies a smaller space during the systole than during the diastole, it follows that, when the glottis is open, air must be drawn into the chest when the heart contracts; whenever the heart relaxes, *i. e.*, during diastole, air must be expelled through the open glottis. But we must also take into account the degree to which the larger intra-thoracic vessels are filled with blood. These movements of the air within the lungs, although slight, seem to be of importance in hibernating animals. In animals in this condition, the agitation of the gases in the lungs favors the exchange of CO_2 and O in the lungs, and this slow current of air is sufficient to aerate the blood passing through the lungs. [Ceradini called the diminution of the volume of the entire heart which occurs during systole **meiocardia,** and the subsequent increase of volume, when the heart is distended to its maximum, **auxocardia.**]

Method.—*A manometric flame* may be used. Insert one limb of a Y-tube into the opened trachea of an animal, while the other limb passes to a small gas jet, and connect the other tube with the gas supply. The movements of the heart affect the column of gas, and thus affect the flame. It may also be done in man by inserting the tube into one nostril, while the other nostril and the mouth are closed. [A simpler and less irritating plan is to fill a wide curved glass tube with tobacco smoke, and insert one end of the tube into one nostril while the other nostril and the mouth are closed. If the glottis be kept open, and respiration be stopped, then the movements of the column of smoke within the tube are obvious. Or a manometer containing a drop of a colored fluid may be used under the same conditions.]

FIG. 64.



Landois' cardio-pneumograph, and the curves obtained therewith. A and B, from man, 1 and 2 correspond to the periods of the first and second heart sounds; C, from dog; D, method of using the apparatus.

The cardiac pneumograph (Fig. 64) consists of a tube (D), about 1 inch in diameter and 6 to 8 inches in length; the tube is bent at a right angle, and communicates with a small metal capsule about the size of a saucer (T), over which a membrane composed of collodion and castor oil is loosely stretched. To this membrane is attached a glass rod (H) used as a writing style, which records its movements on a glass plate (S) moved by clock work. A small valve (K) is placed on the side of the tube (D), which enables the experimenter to breathe when necessary. The tube (D) is held in an air-tight manner between the lips, the nostrils being closed, the glottis open, and respiration stopped. In the curves (Fig. 64, A, B) we observe that—

(1) At the moment of the first sound (1) the respiratory gases undergo a sharp *expiratory* movement, because at the moment of the first part of the ventricular systole the blood of the ventricle has not left the thorax, while venous blood is streaming into the right auricle through the venæ cavæ, and because the dilating branches of the pulmonary artery compress the accompanying bronchi. The blood of the right ventricle has not yet left the thorax, it passes merely into the pulmonary circuit. The expiratory movement is diminished somewhat (*a*) by the muscular mass of the ven-

tricle occupying slightly less bulk during the contraction, and (β) owing to the thoracic cavity being slightly increased by the fifth intercostal space being pushed forward by the cardiac impulse.

(2) Immediately after (1) there follows a strong inspiratory current of the respiratory gases. As soon as the blood from the root of the aorta reaches that part of the aorta lying outside the thorax, more blood leaves the chest than passes into it simultaneously through the venæ cavæ.

(3) After the second sound (at 2), indicated sometimes by a slight depression in the apex of the curve, the arterial blood accumulates, and hence there is another expiratory movement in the curve.

(4) The peripheral wave movements of the blood from the thorax cause another inspiratory movement of the gases.

(5) More blood flows into the chest through the veins, and the next heart beat occurs.

60. INFLUENCE OF THE RESPIRATORY PRESSURE ON THE HEART.—The variation in pressure to which all the intra-thoracic organs are subjected, owing to the increase and decrease in the size of the chest caused by the respiratory movements, exerts an influence on the movements of the heart. Examine first the relations in different *passive conditions of the thorax, when the glottis is open.*

The diastolic dilatation of the cavities of the heart, besides the pressure of the venous blood and the elastic stretching of the relaxed muscle wall, is fundamentally due to the **elastic traction of the lungs.** This is stronger the more the lungs are distended (inspiration), and is less active the more the lungs are contracted (expiration). Hence it follows—

(1) When the greatest possible **expiratory effort** is made (of course, with the glottis open, only a small amount of blood flows into the heart; the heart in diastole is small and contains a small amount of blood. Hence the systole must also be small, thus causing a small pulse beat.

(2) On taking the greatest possible **inspiration** (with the glottis open), and therefore causing the greatest stretching of the elastic tissue of the lungs, the elastic traction of the lungs is, of course, greatest = 30 mm. Hg (*Donders*), and may interfere with the contraction of the thin-walled atria and appendices, in consequence of which these cavities do not completely empty themselves into the ventricles. The heart is in a state of great diastolic distention, and filled with blood; nevertheless, in consequence of the limited action of the auricles, only small pulse beats are observed. In several individuals Donders found the pulse to be smaller and slower; afterward it became larger and faster.

(3) When the chest is in a position of **moderate rest,** whereby the elastic traction is moderate = 7.5 mm. Hg, we have the condition most favorable to the action of the heart—sufficient diastolic dilatation of the cavities of the heart, as well as unhindered emptying of them during systole.

Voluntary increase or diminution of the intra-thoracic pressure affects the action of the heart.

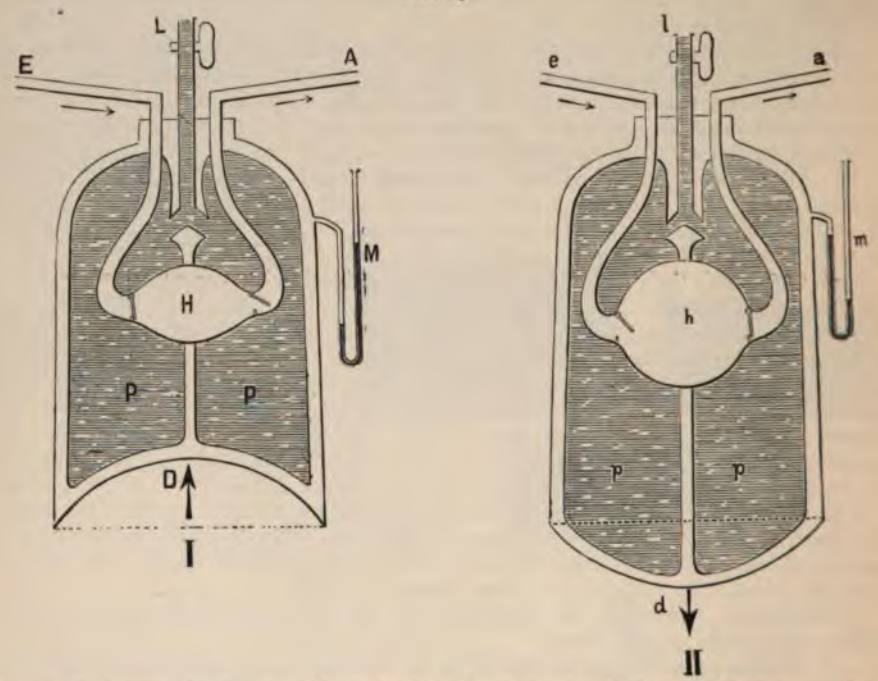
(1) **Valsalva's Experiment** (1740).—If the thorax is fixed in the position of deepest inspiration, and the glottis be then closed, and if a powerful expiratory effort be made by bringing into action all the expiratory muscles, so as to contract the chest, the cavities of the heart are so compressed that the circulation of the blood is temporarily interrupted. In this expiratory phase the elastic traction is very limited, and the air in the lungs being under a high pressure also acts upon the heart and the intra-thoracic great vessels. No blood can pass into the thorax from without; hence the visible veins swell up and become congested, the blood in the lungs is rapidly forced into the left ventricle by the compressed air in the lungs, and the blood soon passes out of the chest, so that the heart and lungs contain little blood, thus leading to a greater supply of blood in the systemic than in the pulmonary circulation and the heart. The heart sounds disappear, and the pulse is absent (*E. H. Weber, Donders*).

(2) **J. Müller's Experiment** (1838).—Conversely, if after the deepest possible expiration the glottis be closed, and the chest be now dilated with a great inspiratory effort, the heart is powerfully dilated, the elastic traction of the lungs,

and the very attenuated air in these organs, act so as to dilate the cavities of the heart. More blood flows into the right heart, and, in proportion as the right auricle and ventricle can overcome the traction outward, the blood vessels of the lungs become filled with blood, and thus partly occupy the lung space. Much less blood is driven out of the left heart, so that the pulse may disappear. Hence the heart is distended with blood and the lungs are congested, while the aortic system contains a small amount of blood, *i. e.*, the systemic circulation is comparatively empty, while the heart and the pulmonary vessels are engorged with blood.

In normal respiration, the air in the lungs during inspiration is under slight pressure, while during expiration the pressure is higher, so that these conditions

FIG. 65.



Apparatus for demonstrating the action of inspiration, II, and expiration, I, on the heart and blood stream. P, *p*, lungs; H, *h*, heart; L, *l*, closed glottis; M, *m*, manometers; E, *e*, ingoing blood stream, vein; A, *a*, outgoing blood stream, artery; D, diaphragm during expiration; *d*, during inspiration.

favor the circulation; inspiration favors the occurrence of diastole, the supply of blood (and lymph) through the venæ cavæ. In operations where the axillary or jugular vein is cut, air may be sucked into the circulation during inspiration, and cause death. Expiration favors the flow of blood in the aorta and its branches, and aids the systolic emptying of the heart.

The elastic traction of the lungs aids the **lesser circulation** through the lungs; the blood of the pulmonary capillaries is exposed to the pressure of the air in the lungs, while the blood in the pulmonary veins is exposed to a less pressure, as the elastic traction of the lungs, by dilating the left auricle, favors the outflow from the capillaries into the left auricle. The elastic traction of the lungs acts slightly as a disturbing agent on the right ventricle, and, therefore, on the movement of

blood through the pulmonary artery, owing to the overpowering force of the blood stream through the pulmonary artery, as against the elastic traction of the lungs (*Donders*).

The above apparatus (Fig. 65) shows the effect of the inspiratory and expiratory movements on the dilatation of the heart, and on the blood stream in the large blood vessels. The large glass vessel represents the thorax; the elastic membrane, D, the diaphragm; P, *p*, the lungs; L, the trachea supplied with a stop-cock to represent the glottis; H, the heart; E, the venæ cavæ; A, the aorta. If the glottis be *closed*, and the expiratory phase imitated by pushing up D as in I, the air in P, P and the heart H are compressed, the venous valve closes, the arterial is opened, and the fluid is driven out through A. The manometer, M, indicates the intra-thoracic pressure. If the glottis be closed, and the inspiratory phase imitated, as in II, *p*, *p* and *h* are dilated, the venous valve opens, the arterial valve closes; hence, venous blood flows from *e* into the heart, Thus, inspiration always favors the venous stream, and hinders the arterial; while expiration hinders the venous, and favors the arterial stream. If the glottis L and *l* be open, the air in P, P, *p*, *p* will be changed during the respiratory movements D and *d*, so that the action on the heart and blood vessels will be diminished, but it will still persist, although to a much less extent.

THE CIRCULATION OF THE BLOOD.

61. FLOW OF FLUIDS THROUGH TUBES.—Toricelli's Theorem states that the velocity of efflux (v) of a fluid—through an opening at the bottom of a cylindrical vessel—is exactly the same as the velocity which a body falling freely would acquire, were it to fall from the surface of the fluid to the base of the orifice of the outflow. If h be the height of the propelling force, the velocity of efflux is given by the formula—

$$v = \sqrt{2gh} \text{ (where } g = 9.8 \text{ metres).}$$

The rapidity of outflow increases with increase in the height of the propelling force, h. The former occurs in the ratio 1, 2, 3, when h increases in the ratio 1, 4, 9, *i.e.*, the velocity of efflux is as the square root of the height of the propelling force. Hence, it follows that the velocity of efflux depends upon the height of the liquid above the orifice of outflow, and not upon the nature of the fluid.

Resistance.—Toricelli's theorem, however, is only valid when all resistance to the outflow is absent; but in every physical experiment such resistance exists. Hence, the propelling force, h, has not only to cause the *efflux* of the fluid, but has also to *overcome resistance.* These two forces may be expressed by the heights of two columns of water placed over each other, viz., by the height of the column of water causing the outflow, F, and the height of the column, D, which overcomes the resistance opposed to the outflow of the fluid. So that

$$h = F + D.$$

62. VELOCITY OF THE CURRENT. RESISTANCE.—In the case of a fluid flowing through a tube, which it fills completely, we have to consider the propelling force, h, causing the fluid to flow through the various sections of the tube. The amount of the propelling force depends upon two factors:—

(1) On the *velocity of the current, v;* (2) on the pressure (amount of *resistance*) to which the fluid is subjected at the various parts of the tube, D.

(1) The **velocity** of the current, v, is estimated—(a) from the lumen, l, of the tube; and (b) from the quantity of fluid, q, which flows through the tube in the unit of time. So that $v = q : l$. Both values, q as well as l, can be accurately measured. (The circumference of a circular tube, whose diameter $= d$ is $3.14.d$. The sectional area (lumen of the tube) is $l = \frac{3.14}{4}.d^2$). Having in this way determined v, from it we may calculate the height of the column of fluid, F, which will give this velocity, *i.e.*, the height from which a body must fall in vacuo, in order to attain the velocity v. In this case $F = \frac{v^2}{4g}$ (where g = the distance traversed by a falling body in 1 sec. = 4.9 metre).

(2) The pressure, D (amount of resistance), is measured directly by placing manometers at different parts of the tube (Fig. 67).

The **propelling force** at any part of the tube is $h = F + D$; or, $h = \frac{v^2}{4g} + D$ (*Donders*). This is proved experimentally by taking a tall cylindrical vessel, A, of sufficient size, which is kept filled with water at a constant level, h. The rigid outflow tube, ab, has in connection with it a number of tubes placed vertically, 1, 2, 3, constituting a **piezometer.** At the end of the tube, b, there is an opening with a short tube fixed in it, from which the water issues to a constant height, provided the level of h is kept constant. The height to which it rises depends on the height of the column of fluid causing the velocity, F. As the pressure in the manometric tubes, D^1, D^2, D^3, can be read off directly, the propelling force of the water at the sections of the tubes, I, II, III, is—

$$h = F + D^1;\ F + D^2;\ F + D^3.$$

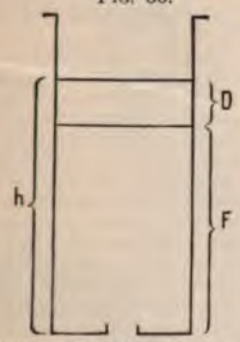
At the end of the tube, b, where $D^4 = O$, $h = F + O$, *i.e.*, $h = F$. In the cylinder itself it is the constant pressure, h, which causes the movement of the fluid. It is clear that the propelling force of the water gradually diminishes as we pass from the inflow toward the outflow of the tube, b. The water in the pressure cylinder, falling from the height, h, only rises as high as F at b. This diminution of the propelling power is due to the presence of **resistances,** which oppose the current in the tube, *i.e.*, part of the energy is transformed into heat. As the propelling force at b is represented only by F, while in the vessel it is h, the difference must be due to the sum of the resistances, $D = h - F$; hence it follows that $h = F + D$.

Estimation of the Resistance.—When a fluid flows through a tube of uniform calibre, the propelling force, *h*, diminishes from point to point on account of the uniformly acting resistance, hence the sum of the resistance in the whole tube is directly proportional to its length. In a uniformly wide tube, fluid flows through each sectional area with equal velocity, hence *v* and also F are equal in all parts of the tube. The diminution which *h* (propelling force) undergoes can only occur from a diminution of pressure D, as F remains the same throughout (and $h = F + D$) Experiment with the pressure cylinder shows that the pressure toward the outflow end of the tube gradually diminishes. *In a uniformly wide tube, the height of the pressure in the manometers expresses the resistances opposed to the current of fluid which it has to overcome in its course from the point investigated to the free orifice of efflux.*

Nature of the Resistance.—The resistance opposed to the flow of a fluid depends upon the *cohesion of the particles* of the fluid among themselves. During the current, the outer layer of fluid which is next the wall of the tube, and which moistens it, is at rest. All the other layers of fluid, which may be represented as so many cylindrical layers, one inside the other, move more rapidly as we proceed toward the axis of the tube, the axial thread or stream being the most rapidly moving part of the liquid. On account of the movement of the cylindrical layers, one within the other, a part of the propelling energy must be used up. The amount of the resistance greatly depends upon the *amount of the cohesive force* which the particles of the fluid have for each other; the more firmly the particles cohere the greater will be the resistance, and *vice versâ*. Hence, the sticky blood current experiences greater resistance than water or ether.

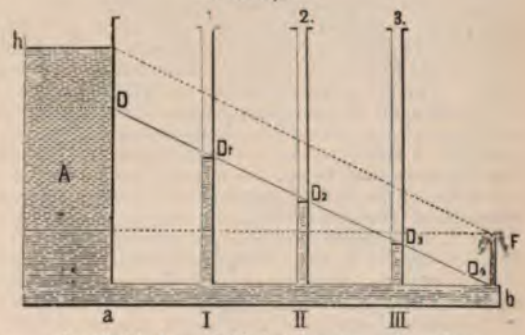
Heat diminishes the cohesion of the particles, hence it also diminishes the resistance to the onflow. These resistances are first developed by, and result from, the movement of the particles

FIG. 66.



Cylindrical vessel filled with water. *h*, height of the column of fluid; D, height required to overcome the resistance; F, height causing the efflux.

FIG. 67.



A, cylindrical vessel filled with water. *ab*, outflow tube, along which are placed at intervals vertical tubes, 1, 2, 3, to estimate the pressure.

of the fluid, they being, as it were, torn from each other. The *more rapid the current*, therefore, *i. e.*, the larger the number of particles of fluid which are pulled asunder in the unit of time, the *greater will be the sum of the resistance.* As the layer of fluid lying next the tube, and moistening it, is at rest, the material which composes the tube exerts no influence on the resistance.

Tubes of Unequal Diameter.—When the velocity of the current is uniform, the resistance depends upon the diameter of the tube—the smaller the diameter the greater the resistance; the greater the diameter the less the resistance. The resistance in narrow tubes, however, increases more rapidly than the diameter of the tube decreases, as has been proved experimentally. In tubes of unequal calibre, at different parts of their course, the velocity of the current varies—it is slower in the wide part of the tube, and more rapid in the narrow parts. As a general rule, in tubes of unequal diameter the velocity of the current is inversely proportional to the diameter of the corresponding section of the tube; *i. e.*, if the tube be cylindrical, it is inversely proportional to the square of the diameter of the circular transverse section. In tubes of uniform diameter, the propelling force of the moving fluid diminishes *uniformly* from point to point, but in tubes of *unequal* calibre it does *not* diminish *uniformly*. As the resistance is greater in narrow tubes, of course the propelling force must diminish more rapidly in them than in wide tubes. Hence, within the wide parts of the tube the pressure is greater than the sum of the resistances still to be overcome, while in the narrow portions it is less than these.

Tortuosities and bending of the vessels add new resistance, and the fluid presses more solely on the convex side than on the concave side of the bend, and there the resistance to the flow than on the convex side.

Division of a tube into two or more branches is a source of resistance, and diminishes the propelling power. When a tube divides into two smaller tubes, of course some of the particles of the fluid are retarded, while others are accelerated on account of the unequal velocities of the different layers of the fluid. Many particles which had the greatest velocity in the axial layer come to lie more toward the side of the tube, where they move more slowly; and conversely many of those lying in the outer layers reach the centre, where they move more rapidly. Hence, some of the propelling force is used up in this process, and the pulling asunder of the particles where the tube divides acts in a similar manner. If two tubes *join* to form *one* tube, new resistance is thereby caused, which must diminish the propelling force. The sum of the mean velocities in both branches is independent of the *angle* at which the division takes place (*Jacobson*). If a branch be opened from a tube, the principal current is accelerated to a considerable extent, no matter at what angle the branch may be given off.

63. FLOW IN CAPILLARY TUBES.—Poiseuille proved experimentally that the flow in the capillaries is subject to special conditions:—

(1) The quantity of fluid which flows out of the *same* capillary tube is proportional to the pressure.

(2) The time necessary for a given quantity of fluid to flow out (with the like pressure, diameter of tube and temperature), is proportional to the length of the tubes.

(3) The product of the outflow (other things being equal) is as the fourth power of the diameter.

(4) The velocity of the current is proportional to the pressure and to the square of the diameter, and inversely proportional to the length of the tube.

(5) The resistance in the capillaries is proportional to the velocity of the current.

64. FLOW IN ELASTIC TUBES.—(1) When an uninterrupted *uniform* current flows through an elastic tube, it follows exactly the *same laws* as if the tube had *rigid walls*. If the propelling power increases or diminishes, the elastic tubes become wider or narrower, and they behave, as far as the movement of the fluid is concerned, as wider or narrower rigid tubes.

(2) **Wave Motion.**—If, however, more fluid be forced *in jerks* into an elastic tube, *i. e.*, *interruptedly*, the first part of the tube dilates suddenly, corresponding to the quantity of fluid propelled into it. The jerk communicates an *oscillatory* movement to the particles of the fluid, which is communicated to all the fluid particles from the beginning to the end of the tube; *a positive wave is thus rapidly propagated throughout the whole length of the tube.* If we imagine the elastic tube to be closed at its peripheral end, the positive wave will be reflected from the point of occlusion, and it may be propagated to and fro through the tube until it finally disappears. In such a closed tube a sudden jet of fluid produces only a *wave movement*, *i. e.*, only a vibratory movement, or an alteration in the shape of the liquid, there being no actual translation of the particles along the tube.

(3) If, however, fluid be pumped interruptedly or by jerks into an elastic tube filled with fluid, in which there is already a continuous current, the movement of the current is combined with the wave movement. We must carefully distinguish the *movement of the current of the fluid*, *i. e.*, the translation of a mass of fluid through the tube, from the *wave movement*, the oscillatory movement, or movement of change of form in the column of fluid. In the former, the particles are actually translated, while in the latter they merely vibrate. The current in elastic tubes is slower than the wave movement, which is propagated with great rapidity. This last case obtains in the arterial system. The blood in the arteries is already in a state of continual movement, directed from the aorta to the capillaries; by means of the systole of the left ventricle a quantity of fluid is suddenly pumped into the aorta, and causes a *positive wave*, the **pulse wave**, which is propagated with great rapidity to the terminations of the arteries, while the current of the blood itself moves much more slowly.

Rigid and Elastic Tubes.—If a quantity of fluid be forced into a *rigid tube* under a certain pressure, the same quantity of fluid will flow out at once at the other end of the tube, provided there be no special resistance. In an *elastic tube*, immediately after the forcing in of a quantity of fluid, at first only a small quantity flows out, and the remainder flows out only after the propelling force has ceased to act. If an equal quantity of fluid be **periodically** injected into a **rigid tube**, with each jerk an equal quantity is forced out at the other end of the tube, and the outflow lasts exactly as long as the jerk or the contraction, and the pause between two periods of outflow is exactly the same as between the two jerks or contractions. In an **elastic tube** it is different, as the outflow continues for a time after the jerk; hence, it follows that a continuous outflow current will be produced in elastic tubes, when the time between two jerks is made shorter than the duration of the outflow after the jerk has been completed. When fluid is pumped periodically into rigid tubes, it causes a sharp abrupt outflow synchronous with the inflow, and the outflow becomes continuous only when the inflow is continuous and uninterrupted. In elastic tubes, an intermittent current under the above conditions causes a continuous outflow, which is increased with the systole or contraction.

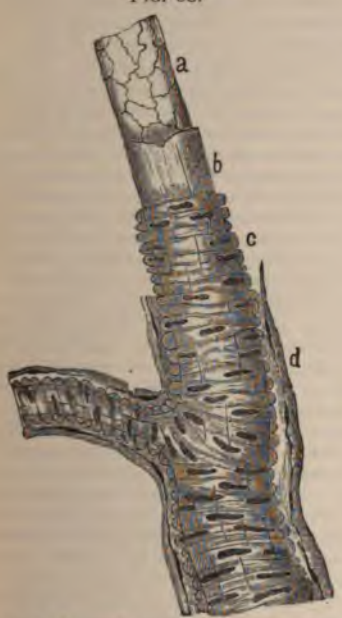
65. STRUCTURE AND PROPERTIES OF THE BLOOD VESSELS.—In the body the large vessels carry the blood to and from the various tissues and organs, while the thin-walled capillaries bring the blood into intimate relation with the tissues. Through the excessively thin walls of the capillaries the fluid part of the blood transudes, to nourish the tissues outside the capillaries.

[At the same time fluids pass from the tissues into the blood. Thus there is an exchange between the blood and the fluids of the tissues. The fluid after it passes into the tissues constitutes the *lymph*, and acts like a stream *irrigating* the tissue elements.]

I. **The arteries** are distinguished from veins by their *thicker walls*, due to the greater development of smooth muscular and elastic tissues—the middle coat (tunica media) of the arteries is specially thick, while the outer coat (t. adventitia) is relatively thin. [The absence of valves is by no means a characteristic feature.]

A **typical artery** consists of *three* coats (Fig. 68). (1) The **tunica intima**, or **inner coat**, consists of a layer of (*a*) irregular, long, fusiform, nucleated, squamous cells forming the excessively thin, transparent endothelium, immediately in contact with the blood stream. [Like other endothelial cells, these cells are held together by a cement substance, which is blackened by the action of silver nitrate.] Outside this lies a very thin, more or less fibrous, layer—*sub-epithelial layer*—in which numerous spindle or branched protoplasmic cells lie embedded within a corresponding system of plasma canals. Outside this is an *elastic lamina* (*b*), which in the *smallest arteries* is a structure-

FIG. 68.



Coats of a small artery. *a*, endothelium; *b*, internal elastic lamina; *c*, circular muscular fibres of the middle coat; *d*, the outer coat.

FIG. 69.

Capillaries. The outlines of the nucleated endothelial cells with the cement blackened by the action of silver nitrate.

less or fibrous elastic membrane—in arteries of *medium size* it is a fenestrated membrane (*Henle*), while in the *largest* arteries there may be several layers of elastic laminæ or fenestrated elastic membrane mixed with connective tissue. [In some arteries the elastic membrane is distinctly fibrous, the fibres being chiefly arranged longitudinally. It can be stripped off, when it forms a brittle elastic membrane, which has a great tendency to curl up at its margins. In a transverse section of a middle-sized artery it appears as a bright wavy line, but the curves are probably produced by the partial collapse of the vessel. It forms an important guide to the pathologist, in enabling him to determine which coat of the artery is diseased.] In middle-sized and large arteries a few non-striped muscular fibres are disposed *longitudinally* between the elastic plates or laminæ. Along with the circular muscular fibres of the middle coat, they may act so as to narrow the artery, and they may also aid in keeping the lumen of the vessel open and of uniform calibre.

(2) The **tunica media**, or **middle coat**, contains much non-striped muscle (*c*), which in the *smallest* arteries consists of transversely disposed non-striped muscular fibres lying between the endothelium and the T. adventitia, while a finely granular tissue with few elastic fibres forms the bond of union between them. As we proceed from the very smallest to the small arteries, the

number of muscular fibres becomes so great as to form a well-marked fibrous *ring of non-striped muscle*, in which there is comparatively little connective tissue. In the *large* arteries the amount of connective tissue is considerably increased, and between the layers of fine connective tissue numerous (as many as fifty) thick, elastic, fibrous or fenestrated laminæ are concentrically arranged. A few non-striped fibres lie scattered among these, and some of them are arranged transversely, while a few have an oblique or longitudinal direction.

The first part of the aorta and pulmonary artery, and the retinal arteries, are devoid of muscle. The descending aorta, common iliac, and popliteal have longitudinal fibres between the transverse ones. Longitudinal bundles lying inside the media occur in the renal, splenic, and internal spermatic arteries. Longitudinal bundles occur both on the outer and inner surfaces of the umbilical arteries, which are very muscular.

(3) The **tunica adventitia**, or **outer coat**, in the *smallest* arteries consists of a structureless membrane with a few connective-tissue corpuscles attached to it; in *somewhat larger* arteries there is a layer of fine fibrous elastic tissue mixed with bundles of fibrillar connective tissue (*a*). In arteries of *middle size*, and in the *largest* arteries, the chief mass consists of bundles of fibrillar connective tissue containing connective-tissue corpuscles. The bundles cross each other in a variety of directions, and fat cells often lie between them. Next the media there are numerous fibrous or fenestrated elastic lamellæ. In medium-sized and small arteries the elastic tissue next the media takes the form of an independent elastic membrane (Henle's external elastic membrane). Bundles of non-striped muscle, arranged longitudinally, occur in the adventitia of the arteries of the penis, and in the renal, splenic, spermatic, iliac, hypogastric, and superior mesenteric arteries.

II. **The capillaries**, while retaining their diameter, divide and reunite so as to form networks, whose shape and arrangement differ considerably in different tissues. The diameter of the capillaries varies considerably, but as a general rule it is such as to admit freely a single row of blood corpuscles. In the retina and the muscles the diameter is 5–6 μ, and in bone marrow, liver, and choroid 10–20 μ. The tubes consist of a single layer of transparent, excessively thin, nucleated, endothelial cells joined to each other by their margins. [The nuclei contain a well marked intra-nuclear plexus of fibrils, like other nuclei.] The cells are more fusiform in the smaller capillaries and more polygonal in the larger. The body of the cells presents the characters of very faintly refractive protoplasm, but it is doubtful whether the body of the cell is endowed with the property of contractility (p. 138).

FIG. 70.

Longitudinal section of a vein at the level of a valve. *a*, hyaline layer of the internal coat; *b*, elastic lamina; *c*, groups of smooth muscular fibres divided transversely; *d*, longitudinal muscular fibres in the adventitia.

If a dilute solution (¼ per cent.) of **silver nitrate** be injected into the blood vessels, the cement substance of the endothelium [and of the muscular fibres as well] is revealed by the presence of the black "**silver lines.**" The blackened cement substance shows little specks and large black slits at different points. It is not certain whether these are actual holes through which colorless corpuscles may pass out of the vessels, or are merely larger accumulations of the cement substance. [If a capillary is examined in a perfectly fresh condition (while living) and without the addition of any reagent, it is impossible to make out any line of demarcation between adjacent cells, owing to the uniform refractive index of the entire wall of the tube.]

[Arnold called these small areas in the black silver lines, when they are large, **stomata**, and when small, **stigmata**. They are most numerous after venous congestion, and after the disturbances which follow inflammation of a part. They are not always present. The existence of cement substance between the cells may also be inferred from the fact that indigo-sulphate of soda is deposited in it (*Thoma*), and particles of cinnabar and China ink are fixed in it, when these substances are injected into the blood (*Foa*).]

Fine anastomosing fibrils derived from non-medullated **nerves** terminate in small end-buds in relation with the capillary wall; ganglia in connection with the nerves of capillaries occur only in the region of the sympathetic.

The small vessels next in size to the capillaries, and continuous with them, have a completely structureless covering in addition to the endothelium.

III. **The veins** are generally distinguished from the arteries by their *lumen* being *wider* than the lumen of the corresponding arteries; their

walls are thinner on account of the smaller amount of non-striped muscle and elastic tissue (the non-striped muscle is not unfrequently arranged longitudinally in veins). They are also more *extensile* (with the same strain). The adventitia is usually the thickest coat. The occurrence of **valves** is limited to the veins of certain areas.

Structure.—(1) The **tunica intima** consists of a layer of *shorter* and broader endothelial cells, under which in the smallest veins there is a structureless elastic membrane, *sub-epithelial layer*, which is fibrous in veins somewhat larger in size, but in all cases is thinner than in the arteries. In large veins it may assume the characters of a fenestrated membrane, which is double in some parts of the crural and iliac veins. Isolated muscular fibres exist in the intima of the femoral and popliteal veins.

(2) The **t. media** of the larger veins consists of alternate layers of elastic and muscular tissue united to each other by a considerable amount of connective tissue, but this coat is always thinner than in the corresponding arteries. This coat diminishes in the following order in the following vessels: popliteal, veins of the lower extremity, veins of the upper extremity, superior mesenteric, other abdominal veins, hepatic, pulmonary, and coronary veins. The following veins contain no muscle: veins of bone, central nervous system and its membranes, retina, the superior cava, with the large trunks that open into it, the upper part of the inferior cava. Of course, in these cases the media is very thin. In the smallest veins the media is formed of fine connective tissue, with very few muscular fibres scattered in the inner part.

(3) The **t. adventitia** is thicker than that of the corresponding arteries; it contains *much connective tissue*, usually arranged longitudinally, and not much elastic tissue. Longitudinally arranged *muscular fibres* occur in some veins (renal, portal, inferior cava near the liver, veins of the lower extremities). The **valves** consist of fine fibrillar connective tissue with branched cells. An elastic network exists on their convex surface, and both surfaces are covered by endothelium. The valves contain many muscular fibres (Fig. 70). [Ranvier has shown that the shape of the epithelial cells on the side over which the blood passes is more elongated than on the cardiac side of the valve, where the long axes of the cells are placed transversely.]

The **sinuses** of the dura mater are spaces covered with endothelium. The spaces are either duplicatures of the membrane, or channels in the substance of the tissue itself.

Cavernous spaces we may imagine to arise by numerous divisions and anastomoses of tolerably large veins of unequal calibre. The vascular wall appears to be much perforated and like a sponge, the internal space being traversed by threads and strands of tissue, which are covered with endothelium on their surfaces, that are in contact with the blood. The surrounding wall consists of connective tissue, which is often very tough, as in the corpus cavernosum, and it not unfrequently contains non-striped muscle.

Cavernous formations of an analogous nature on *arteries* are the *carotid gland* of the frog, and a similar structure on the pulmonary arteries and aorta of the turtle, and the *coccygeal gland* of man. The last structure is richly supplied with sympathetic nerve fibres, and is a convoluted mass of ampullated or fusiform dilatations of the middle sacral artery, surrounded and permeated by non-striped muscle.

Vasa Vasorum.—[These are small vessels which nourish the coats of the arteries and veins. They arise from one part of a vessel and enter the walls of the same, or another vessel at a lower level. They break up chiefly in the outer coat, and none enter the inner coat.] In structure they resemble other small blood vessels. The blood circulating in the arterial or venous wall is returned by small veins.

[**Lymphatics.**—There are no lymphatics on the inner surface of the muscular coat, or under the intima in large arteries. They are numerous in a gelatinous layer immediately outside the muscular coat, and the same relation obtains in large muscular veins and lymphatic trunks (*Heggan*).]

Intercellular Blood Channels.—Intercellular blood channels of narrow calibre, and without walls, occur in the granulation tissue of healing wounds. At first blood plasma alone is found between the formative cells, but afterwards the blood current forces blood corpuscles through the channels. The first blood vessels in the developing chick are formed in a similar way, from the formative cells of the mesoblast.

Properties of the Blood Vessels.—The larger blood vessels are cylindrical tubes composed of several layers of various tissues, more especially *elastic tissue* and *smooth muscular fibres*, and the whole is lined by a smooth polished layer of endothelium. One of the most important properties is the **contractility** of the vascular wall, in virtue of which the calibre of the vessel can be varied, and therefore the supply of blood to a part is altered. The contractility is due to the plain muscular fibres, which are, for the most part, arranged circularly. It is most marked in the small arteries, and of course is absent where no muscular

tissue occurs. The amount and intensity of the contraction depend upon the development of the muscular tissue; in fact, the two go hand in hand. [If an artery be exposed in the living body it soon contracts under the stimulus of the atmosphere acting upon the muscular fibres.]

[**Action of Drugs on the Vascular System.**—Gaskell finds that a very dilute solution of lactic **acid** (1 : 10,000 parts of saline solution), passed through the **blood vessels** of a frog, always enlarges the calibre of the blood vessels, while an **alkaline solution** (1 part sodium hydrate to 10,000 saline solution) always diminishes their size, usually to absolute closure, and indeed the artificial constriction of the blood vessels may be almost complete. These fluids are antagonistic to each other as far as regards their action on the calibre of the arteries. Dilute alkaline solutions act on the **heart** in the same way. After a series of beats the ventricle stops beating, the standstill being in a state of contraction. Very dilute lactic acid causes the ventricle to stand still in the phase of complete relaxation. The acid and alkaline saline solutions are antagonistic in their action on the ventricle. Cash and Brunton find that dilute acids have a tendency to increase the transudation through the vessels and produce *œdema* of the surrounding tissues. They also observed that barium, calcium, strontium, copper, iron, and tin produce contraction of the blood vessels when solutions of their salts are driven through them, while the same effect is produced by very dilute solutions of potassium. Nicotin, atropin, and chloral differ in their action according to the dose. In these experiments the effect was ascertained by the amount of fluid which flowed out of the vessels in a given time.] If blood containing certain drugs be perfused through the blood vessels of a freshly excised organ, the blood vessels are *dilated; e. g.*, by amyl nitrite, chloral hydrate, morphia, CO, paraldehyde, kairin, quinine, atropin, ferricyanide of potassium, (urea and sodic chloride in the renal vessels),—they are contracted by digitalin, veratria, helleborin (*Kobert*). Heat causes contraction of the blood vessels of the frog's mesentery (*Gärtner*). According to Roy the blood vessels shorten when heated.

That the **capillaries** undergo dilatation and contraction, owing to variations in the size of the protoplasmic elements of their walls, must be admitted.

Stricker has described capillaries as "protoplasm in tubes," and observed that in the tadpole they exhibited movements when stimulated. Golubew described an active state of contraction of the capillary wall, but he regarded the nuclei as the parts which underwent change. Rouget observed the same result in the capillaries of new-born mammals. Tarchanoff found that mechanical or electrical stimulation caused a change in the shape and size of the nuclei, so that he regards these as the actively contractile parts. [Severini also attaches great importance to the contractility of the capillaries and especially of their nuclei as influencing the blood stream. Oxygen acts on the nuclei of the capillary wall (membrana nictitans of frog) and causes them to swell, while CO_2 has an opposite effect. The circulation through a lung suddenly filled with O or atmospheric air is at first very rapid, but soon diminishes, while with CO_2 the circulation remains constant.] As the capillaries are excessively thin, soft, and delicate, it is obvious that the form of the individual cells must depend to a considerable extent upon the degree to which the vessels are filled with blood. In vessels which are distended with blood the endothelial cells are flattened, but when the capillaries are collapsed they project more or less into the lumen of the vessel (*Renaut*).

[It is well known that the capillaries present great variations in their diameter at different times. As these variations are usually accompanied by a corresponding contraction or dilatation of the arterioles, it is usually assumed that the variations in the diameter of the capillaries are due to differences of the pressure within the capillaries themselves, viz., to the elasticity of their walls. Every one is agreed that the capillaries are very elastic, but the experiments of Roy and Graham Brown show that they are contractile as well as elastic, and these observers conclude that, under normal conditions, it is by the contractility of the capillary wall as a whole that the diameter of these vessels is changed, and to all appearance their contractility is constantly in action. "The individual capillaries (in all probability) contract or expand in accordance with the requirements of the tissues through which they pass. The regulation of the vascular blood flow is thus more complete than is usually imagined."]

Physical Properties.—Among the physical properties of the blood vessels, **elasticity** is the most important; their elasticity is *small in amount, i. e.*, they offer little resistance to any force applied to them so as to distend or elongate them, but it is *perfect in quality, i.e.*, the blood vessels rapidly regain their original size and form after the force distending them is removed.

[**Uses of Elasticity.**—The elasticity of the arteries is of the utmost importance in aiding the conversion of the unequal movement of the blood in the large arteries into a uniform flow in the capillaries. E. H. Weber compared the elastic wall of the arteries with the air in the air chamber of a fire engine. In both cases an elastic medium is acted upon—the air in the one case and the elastic tissue in the other—which in turn presses upon the fluid, propelling it onward continually,

while the action of the pump or the heart, as the case may be, is intermittent. The ordinary spray producer acts on this principle. A uniform spray or jet is obtained by pumping intermittently, but only when the resistance is such as to bring into action the elasticity of the bag between the pump and the spray orifice.]

According to E. H. Weber, Volkmann, and Wertheim, the elongation of a blood vessel and *moist* tissues generally is not proportional to the weight used to extend it, the elongation being relatively less with a large weight than with a small one, so that the curve of extension is nearly [or, at least bears a certain relation to] a *hyperbola*. According to Wundt, we have not only to consider the extension produced at *first* by the weight, but also the subsequent **"elastic after-effect,"** which occurs gradually. The elongation which takes place during the last few moments occurs so slowly and so gradually that it is well to observe the effect by means of a magnifying lens. Variations from the general law occur to this extent, that if a certain weight is exceeded, less extension, and, it may be, permanent elongation of the artery not unfrequently occur. K. Bardeleben found, especially in veins elongated to 40 or 50 per cent. of their original length, that when the weight employed increased by an equal amount each time, the elongation was proportional to the square root of the weight. This is apart from any elastic after-effect. Veins may be extended to at least 50 per cent. of their length without passing the limit of their elasticity.

[Roy experimented upon the elastic properties of the *arterial wall*. A portion of an artery, so that it could be distended by any desired internal pressure, was enclosed in a small vessel containing olive oil arranged in the same way as in Fig. 62, for the heart. The variations of the contents were recorded by means of a lever writing on a revolving cylinder. The instrument is termed a **sphygmotonometer.** The *aorta and other large arteries* are most elastic and most distensible at pressures corresponding more or less exactly to their normal blood pressure, while in *veins* the relation between internal pressure and the cubic capacity is very different. In them the maximum of distensibility occurs with pressures immediately above zero. Speaking generally, the cubic capacity of an *artery* is greatly increased by raising the intra-arterial tension, say from zero to about the normal internal pressure which the artery sustains during life. Thus in the *rabbit*, the capacity of the aorta was *quadrupled* by raising the intra-arterial pressure from zero to 200 mm. Hg., while that of the carotid was more than *six times* greater at that pressure than it was in the undistended condition. The pulmonary artery is distinguished by its excessive elastic distensibility. Its capacity (rabbit) was increased more than twelve times on raising the internal pressure from zero to about 36 mm. Hg. Veins, on the other hand, are distinguished by the relatively small increase in their cubic capacity produced by greatly raising the internal pressure, so that the enormous changes in the capacity of the veins during life are due less to differences in the pressure than to the great differences in the *quantity* of blood which they contain.]

FIG. 71.

Sphygmometer of Hérisson and Chelius.

Pathological.—Interference with the nutrition of an artery alters its elasticity, [and that in cases where no structural changes can be found]. Marasmus preceding death causes the arteries to become wider than normal. In some old people they become atheromatous and even calcified.

Cohesion.—The cohesion of blood vessels is very great, and in virtue of this they are able to resist even considerable internal pressure without giving way. The carotid of a sheep is ruptured only when fourteen times the usual pressure it is called upon to bear is put upon it (*Volkmann*). Given a vein and an artery of the same thickness, a greater pressure is required to rupture the former than the latter. The human carotid or iliac artery resists a pressure of 8 atmospheres, the veins about the half of this.

66. INVESTIGATION OF THE PULSE.—[The characters of the pulse may be investigated by—(1) the eye (*inspection*); (2) the finger (*palpation*); (3) instruments.

Two or three fingers are placed over the course of the radial artery, and the various phenomena in connection with the pulse are noted. It takes much practice for the physician to acquire the tactus eruditus, and notwithstanding the value of instruments, every physician should make a careful study of the pulse beat with his finger. In order to feel the pulse beat or to take a pulse tracing, there must be some resistant body, *e.g.*, a bone behind the artery, and a certain degree of pressure must be exerted on the artery.]

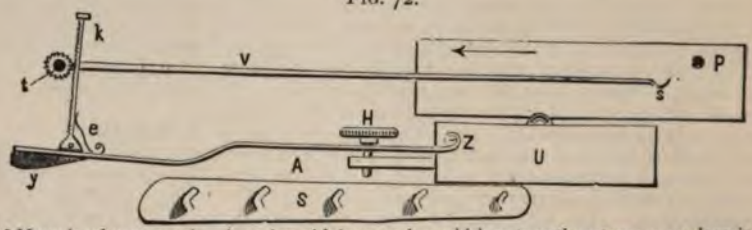
The individual phases of the movement of the pulse can only be accurately investigated by the application of *instruments* to the arteries.

(1) **Poiseuille's Box Pulse Measurer** (1829).—An artery is exposed and placed in an oblong box filled with an indifferent fluid. A vertical tube with a scale attached communicates with the interior of the box. The column of fluid undergoes a variation with every pulse beat.

(2) **Hérisson's Tubular Sphygmometer** consists of a glass tube whose lower end is covered with an elastic membrane (Fig. 71). The tube is partly filled with Hg. The membrane is placed over the position of a pulsating artery, so that its beat causes a movement in the Hg. Chelius used a similar instrument, and he succeeded with this instrument in showing the existence of the double beat (dicrotism) in the normal pulse (1850).

(3) **Vierordt's Sphygmograph** (1855).—In this, one of the earliest sphygmographs, Vierordt departed from the principle of a fluctuating fluid column, and adopted the principle of the *lever*.

FIG. 72.

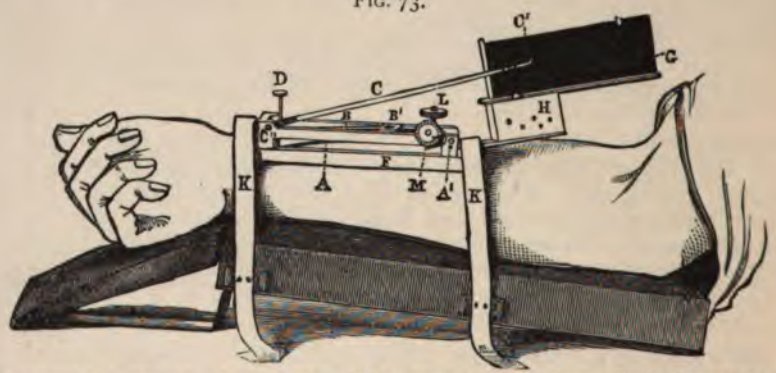


Scheme of Marey's sphygmograph. A, spring with ivory pad, *y*, which rests on the artery; *e*, weak spring pressing *k* into *t*; *v*, writing lever; P, piece of smoked glass or paper moved by clockwork, U; H, screw to limit excursion of A; S, arrangement for fixing the instrument to the arm of the patient.

Upon the artery rested a small pad, which moved a complicated system of levers. At first he used a straw 6 inches long, which rested on the artery. The point of one of the levers inscribed its movements upon a revolving cylinder. This instrument was soon discarded.

(4) **Marey's Sphygmograph** consists of a combination of a lever with an elastic spring. The elastic spring (Fig. 72, A) is fixed at one end, *z*, free at the other end, and provided with an ivory pad, *y*, which is pressed by the spring upon the radial artery. On the upper surface of the pad there is a vertically placed fine-toothed rod, *k*, which is pressed upon by a weak spring, *e*, so that its teeth dovetail with similar teeth in the small wheel, *t*, from whose axis there projects a long, light,

FIG. 73.



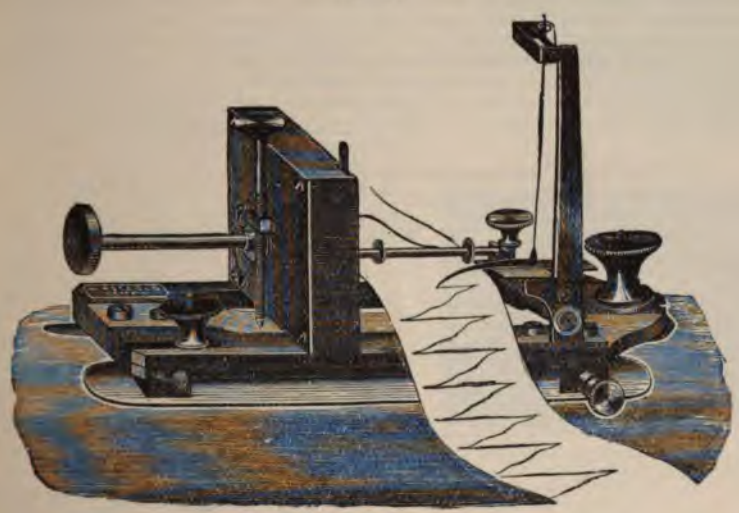
Marey's improved sphygmograph. A, steel spring; B, first lever; C, writing lever; C', its free writing end; D, screw for bringing B in contact with C; G, slide with smoked paper; H, clockwork; L, screw for increasing the pressure; M, dial indicating the pressure; K, K, straps for fixing the instrument to the arm, and the arm to the double inclined plane or support.

wooden lever, *v*, running nearly parallel with the elastic spring. This lever has a fine style at its free end, *s*, which writes upon a smoked plate, P, moved by clockwork, U, in front of the style. Marey's instrument, as improved by Mahomed and others, has been very largely used.

[Its more complete form, as in Fig. 73, where it is shown applied to the arm, consists of (1) a steel spring, A, which is provided with a pad resting on the artery, and moves with each movement of the artery; (2) the lever, C, which records the movement of the artery and spring in a magnified form on the smoked paper, G; (3) an arrangement, L, whereby the exact pressure exerted upon the artery is indicated on the dial, M; (4) the clockwork, H, which moves the smoked paper, G, at a uniform rate; (5) a framework to which the various parts of the instrument are attached, and by means of which the instrument is fastened to the arm by straps K, K (*Byrom Bramwell*).]

[**Application.**—In applying the sphygmograph, cause the patient to seat himself beside a low table, and place his arm on the double inclined plane (Fig. 73). In the newer form of instrument, the lid of the box is so arranged as to unfold to make this support. The fingers ought to be semi-flexed. Mark the position of the radial artery with ink. See that the clockwork is wound up,

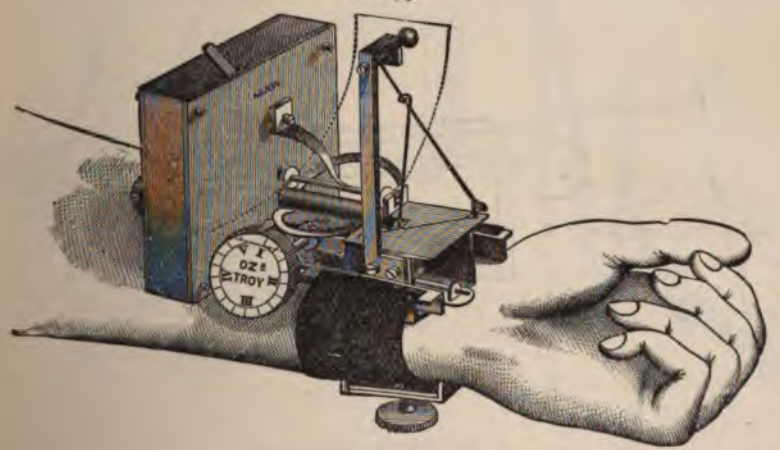
FIG. 74.



Ludwig's Sphygmograph.

and apply the ivory pad exactly over the radial artery where it lies upon the radius, fixing it to the arm by the non-elastic straps, K, K. Fix the slide holding the smoked paper in position. The best paper to use is that with a very smooth surface, or an enameled card smoked over the flame of a turpentine lamp, over a piece of burning camphor, or over a fan-tailed gas burner. The writing

FIG. 75.



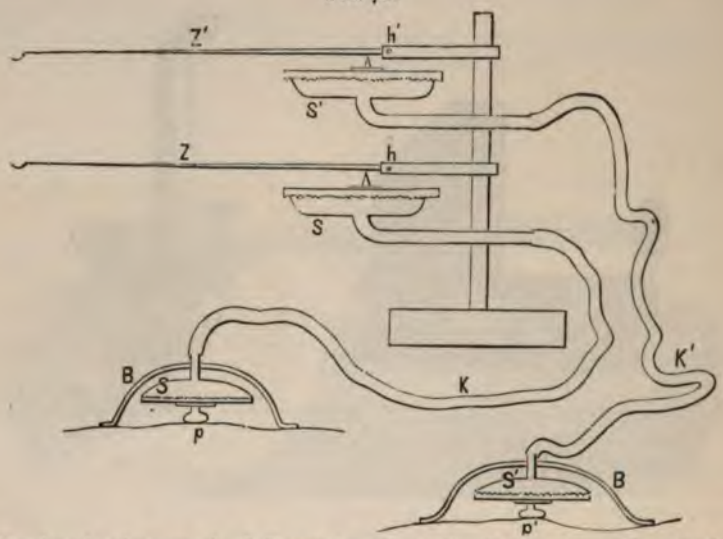
Dudgeon's Sphygmograph.

style is so arranged as to write upon the smoked paper with the least possible friction. It is most important to regulate the pressure exerted upon the artery by means of the milled head, L. This must be determined for each pulse, but the rule is to graduate the pressure until the greatest amplitude of movement of the lever is obtained. Set the clockwork going, and a tracing is obtained,

which must be "fixed" by dipping it in a rapidly drying varnish, *e. g.*, photographic. In every case scratch on the tracing, with a needle, the name, date, and amount of pressure employed.]

[(5) **Dudgeon's Sphygmograph.**—This is a convenient form of sphygmograph, although Broadbent regards its results as untrustworthy. The instrument after being carefully adjusted upon the radial artery is kept in position by an inelastic strap. The pressure of the spring is regulated,

FIG. 76.

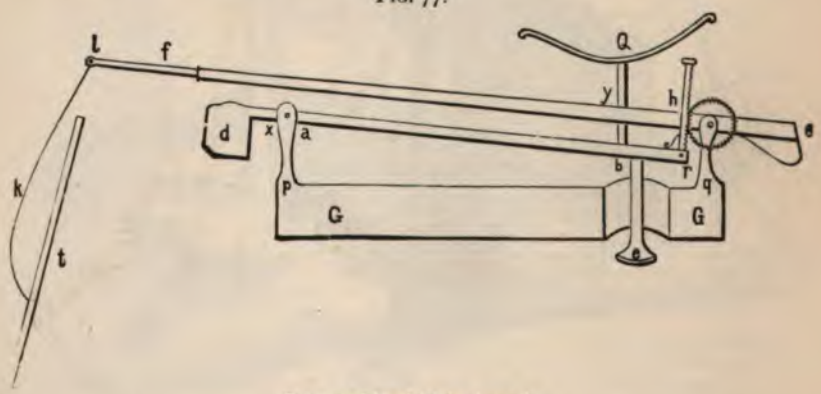


Scheme of Brondgeest's sphygmograph. S, S', receiving and recording (S, S') tambours with writing levers, Z and Z'; K, K', conducting tubes: *p*, over heart, *p'*, over a distant artery.

by the eccentric wheel, to any amount from 1 to 5 ounces. As in other instruments the tracing paper is moved in front of the writing needle by means of clockwork. The writing levers are so adjusted that the movements of the artery are magnified fifty times (Fig. 75).]

(6) [**Ludwig's** improved form is a very serviceable instrument (Fig. 74).]

FIG. 77.



Scheme of Landois' Angiograph.

(7) **Marey's tambours** are also employed for registering the movements of the pulse. They are used in the same way as the **pansphygmograph.** Two pairs of metallic cups (Fig. 76, S, S, and S', S', Upham's capsules) are pierced in the middle by thin metal tubes, whose free ends are connected with caoutchouc tubes, K and K'. All the four metallic vessels are covered with an elastic membrane. On S and S' are fixed two knob-like pads, *p* and *p'*, which are applied to the

pulsating arteries, and the metal arcs, B and B′, retain them in position. On the other tambours are arranged the writing levers, Z and Z′. Pressure on the one tambour necessarily compresses the air, and makes the other, with which it is connected, expand, so as to move the writing lever. This arrangement does not give absolutely exact results; still, it is very easily used, and is convenient. In Fig. 76 a double arrangement is shown, whereby one instrument, B, may be placed over the heart and the other, B′, on a distant artery.

(8) **Landois' Angiograph.**—To a basal plate, G, G, are fixed two upright supports, *p*, which carry between them at their upper part the movable lever, *d*, *r*, carrying a rod bearing a pad, *e*, directed downward, which rests on the pulse. The short arm carries a counterpoise, *d*, so as exactly to balance the long arm. The long arm has fixed to it at *r* a vertical rod provided with teeth, *h*, which is pressed against a toothed wheel firmly fixed on the axis of the very light writing lever, *e*, *f*, which is supported between two uprights, *q*, fixed to the opposite end of the basal plate, G, G. The writing lever is equilibrated by means of a light weight. The writing needle, *k*, is fixed by a joint to *e*, and it writes on the plate, *t*. The first mentioned lever, *d*, *r*, carries a shallow cup, Q, just above the pad, into which weights may be put to press on the pulse. In this instrument the weight can be measured and varied; the writing lever moves vertically, and not in a curve as in Marey's apparatus, which greatly facilitates the measuring of the curves (Fig. 77).

Other sphygmographs are used, both in this country and abroad, including that of Sommerbrodt, which is a complicated form of Marey's sphygmograph, and those of Pond and Mach.

FIG. 78.

Normal pulse curve of the radial artery, obtained by the angiograph writing upon a plate attached to a vibrating tuning-fork. Each double vibration = 0.01613 sec.

In every **pulse curve—sphygmogram** or **arteriogram**—we can distinguish the *ascending part* (ascent) of the curve, the *apex*, and the *descending part* (descent). Secondary elevations scarcely ever occur in the ascent, which is usually represented by a straight line, while they are always present in the descent. Such elevations occurring in the descent are called **catacrotic**, and those in the ascent, **anacrotic**. When the recoil elevation or dicrotic wave occurs in a well-marked form in the descent, the pulse is said to be **dicrotic**, and when it occurs twice, **tricrotic**.

FIG. 79.

Gas Sphygmoscope of S. Mayer.

FIG. 80.

Hæmautographic curve of the posterior tibial artery of a dog. P, primary pulse wave; R, dicrotic wave; *e*, *e*, elevations due to elasticity.

Measuring Pulse Curves.—If the smoked surface on which the tracing is inscribed is moved at a uniform rate by means of the clockwork, then the height and length of the curve are measured by means of an ordinary rule. If we know the rate at which the paper was moved, then it is easy to calculate the duration of any event in the curve.

The curve may be recorded on a plate of glass fixed to a tuning-fork kept in vibration. Every part of the curve shows little elevations (whose rate of vibration is known beforehand). All that is required is to count the number of vibrations in order to ascertain the duration of any part of the curve (Fig. 78).

Gas Sphygmoscope.—A small metallic or glass capsule (Fig. 79), provided with an inlet and an outlet tube, and closed below by a fine membrane, is placed over an artery. The inlet tube is connected to a gas supply, and the outlet to a rat-tail gas burner (*b*). The gas jet responds to every pulse beat. Czermac *photographed* a beam of light set in motion by the movements of the pulse.

Hæmautography.—Expose a large artery of an animal, and divide it so that the stream of blood issuing from it strikes against a piece of paper drawn in front of the blood stream. The curve so obtained (Fig. 80) shows, in addition to the primary wave, P, a distinct dicrotic wave, R, and slight vibrations, *e*, *e*, due to the variations in the elasticity of the arterial wall, which shows that the movements occur in the blood itself, and are communicated as waves to the arterial wall. By estimating the amount of blood in the various parts of the curve, we obtain a knowledge of the amount of blood discharged by the divided artery during the systole and diastole (*i.e.*, the narrowing and dilatation) of the artery—the ratio is 7 : 10. Thus in the *unit of time*, during arterial dilatation, rather more than *twice* as much blood flows out as compared with what occurs during arterial contraction.

67. PULSE TRACING OR SPHYGMOGRAM.—[The Pulse.—With each systole of the heart, a certain quantity of blood is forced into the already filled and partially distended arteries, the resistance in the vessels is lowest between the pulsations, and at this time the arterial tubes are somewhat flattened, but with each systole of the left ventricle the pulse wave, or rather the liquid pressure within the vessel, is increased, thus forcing the artery back into the circular form. "The change of shape, from the flattened condition impressed upon the vessel by the finger or the sphygmograph lever, to the round cylindrical shape which it assumes under the distending force of the blood within it, constitutes the pulse" and it indicates the degree and duration of the increased pressure in the arterial system caused by the ventricular systole (*Broadbent*).]

FIG. 81.

Sphygmogram of radial artery: pressure 2 oz. Each part of the curve between the base of one up-stroke and the base of the next up-stroke corresponds to a beat of the heart, so that this figure shows five heart beats and part of a sixth.

Analysis.—A **sphygmogram** or **pulse tracing** consists of a series of curves (Fig. 81) each of which corresponds with one beat of the heart. Each pulse curve consists of—

1. The line of ascent (*a* to *b* in Fig. 81).
2. The apex (P in Fig. 83, and *b* in Fig. 81).
3. The line of descent (*b* to *h*).

(1) The **line of ascent**, up-stroke, or percussion stroke, is nearly vertical, and occurs during the dilatation of the artery produced by the systole of the left ventricle, when the aortic valves are forced open and the ventricular contents are projected into the arterial system. [The ascent is nearly vertical, but in some cases, where the ventricle contracts very suddenly, as occasionally happens in aortic regurgitation, it is quite vertical (Fig. 85).]

(2) The **apex** or **percussion wave** in a normal pulse is pointed.

(3) The **line of descent** is gradual, and corresponds to the diminution of diameter or contraction of the artery. It is interrupted by *two completely distinct elevations* or secondary waves. Such elevations are called "catacrotic." The more distinct of the two occurs as a well-marked elevation about the middle of the descent (R in Fig. 83 and *f* in Fig. 81); it is called the **dicrotic wave**, or,

with reference to its mode of origin, the "*recoil wave.*" [As the descent corresponds to the time when blood is flowing out of the arteries at the periphery into the capillaries, its direction will depend on the rapidity of the outflow. Thus it will be more rapid in paralysis of the arterioles and very rapid in aortic regurgitation, where, of course, much of the blood flows backward into the left ventricle (Fig. 85). In this case, the artery will recoil suddenly from under the finger or pad of the instrument, and this constitutes the "pulse of empty arteries."]

The **dicrotic wave**, or recoil wave, corresponds to the time following the closure of the aortic valves, and is preceded in the descent by a slight depression, the **aortic notch**.

[The **tidal wave**, or pre-dicrotic, occurs between the apex and the dicrotic wave (Fig. 81, *d'*). It occurs on the descent, and during the contraction of the ventricle. The tidal wave is best marked in a *hard* pulse, *i.e.*, where the blood pressure is high, so that it is usually well marked in cirrhotic disease of the kidney, accompanied by hypertrophy of the left ventricle.]

[In some cases, *e.g.*, **mitral regurgitation**, the pre-dicrotic wave may be present in some pulse beats and absent in others (Fig. 82), where the tidal wave is present in the largest pulse, and absent in the others, while the base line is uneven. In mitral stenosis the amount of blood discharged into the left ventricle frequently varies, hence the variations in the characters of the arterial pulse.]

There may be other **secondary** waves in the lower part of the descent.

[**Respiratory or Base Line.**—If a line be drawn so as to touch the bases of

FIG. 82.

Irregular pulse of mitral regurgitation.

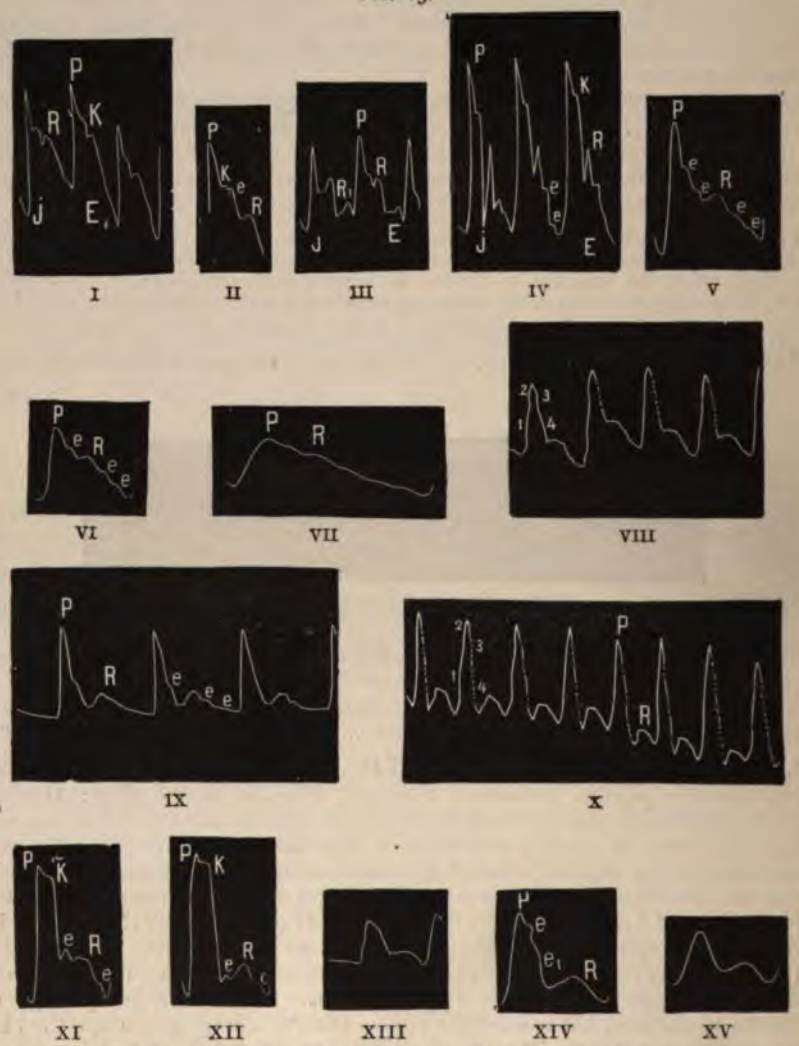
all the up-strokes, we obtain a straight line, hence called by this name. The base line is altered in disease and during forced respiration (§ 74).]

The pulse curve indicates the variations of pressure which the blood exerts on the arterial walls, for the lever rises and falls with the pressure, hence v. Kries calls it the "**pressure pulse.**"

68. **ORIGIN OF THE DICROTIC WAVE.**—The **dicrotic** or **recoil wave**, which is always present in a normal pulse, is caused thus: During the ventricular systole a mass of blood is propelled into the already full aorta, whereby a positive wave is rapidly transmitted from the aorta throughout the arterial system, even to the smallest arterioles, *in which this primary wave is extinguished.* As soon as the semilunar valves are closed, and no more blood flows into the arterial system, the arteries, which were previously distended by the mass of blood suddenly thrown into them, recoil or contract, so that in virtue of the elasticity (and contractility) of their walls, they exert a counter-pressure upon the column of blood, and thus the blood is forced onward. There is a free passage for it toward the periphery, but toward the centre (heart) it impinges upon the already closed semilunar valves. This develops a new positive wave, which is propagated peripherally through the arteries, where it disappears in their finest branches. In those cases where there is sufficient time for the complete development of the pulse curve (as in the short course of the carotids, and in the arteries of the upper arm, but not in those of the lower extremity, on account of their length), a second reflected wave may be caused in exactly the same way as the first. Just as the pulse occurs later in the more peripherally placed arteries than in those near the heart, so the secondary wave reflected from the closed aortic valves

must appear later in the peripheral arteries. Both kinds of waves, the primary pulse wave, the secondary, and eventually even the tertiary reflected wave, arise in the same place, and take the same course, and the longer the course they have to travel to any part of the arterial system, the later they arrive at their destination.

FIG. 83.



I, II, III, sphygmograms of carotid artery; IV, axillary; V to IX, radial; X, dicrotic radial pulse; XI, XII, crural; XIII, posterior tibial; XIV, XV, pedal. In all the curves P indicates apex; R, dicrotic wave; *e*, *e*, elevations due to elasticity; K, elevation caused by the closure of the semilunar valves of the aorta.

[The conditions which favor dicrotism are low blood pressure and a rapid, sharp cardiac contraction. When the blood pressure is low, there is less resistance to the inflow of blood at the aorta from the left ventricle, so that its systole occurs sharply, forcing on the blood and distending the arterial walls. The elastic coats rebound on the contained blood, and thus start a wave from the closed semilunar valves.]

The following points regarding the dicrotic wave have been ascertained experimentally, chiefly by Landois:—

1. The dicrotic wave occurs later in the descending part of the curve, the further the artery experimented upon is distant from the heart. Compare the curves, Fig. 83.

The shortest accessible course is that of the carotid; where the dicrotic wave reaches its maximum 0.35 to 0.37 sec. after the beginning of the pulse. In the upper extremity the apex of the dicrotic wave is 0.36 to 0.38, to 0.40 sec. after the beginning of the pulse beat. The longest course is that of the arteries of the lower extremity. The apex of the dicrotic wave occurs 0.45 to 0.52 to 0.59 sec. after the beginning of the curve. It varies with the height of the individual.

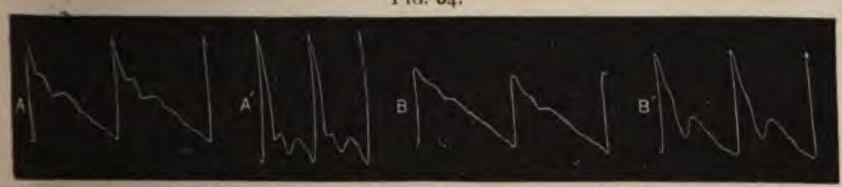
2. The dicrotic elevation in the descent is lower, and is less distinct, the further the artery is situated from the heart, so that the longer the distance which the wave has to travel the less distinct it becomes.

3. It is best marked in a pulse where the primary pulse wave is short and energetic. It is greatest relatively when the systole of the heart is short and energetic.

4. It is better marked *the lower the tension* of the blood within the arteries [and is best developed in a *soft* pulse]. In Fig. 83, IX and X were obtained when the tension of the arterial was *low;* V and VI, *medium;* and VII with *high* tension.

Conditions influencing Arterial Tension.—It is **diminished** at the beginning of inspiration (§ 74), by hemorrhage, stoppage of the heart, heat, an elevated position of parts of the body, **amyl nitrite**, nitro-glycerine, and the **nitrites** generally. [Both drugs accelerate the pulse beats and

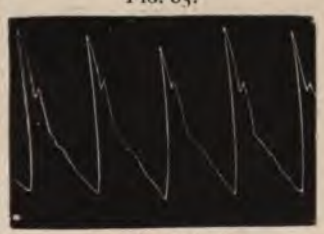
FIG. 84.



Pulse tracings. A, normal; A', one minute after inhalation of amyl nitrite; B, normal; B', after a dose of nitro-glycerine (*Stirling, after Murrell*).

produce marked dicrotism; with amyl nitrite the full effect is obtained in from 15 to 20 sec. after the inhalation of the dose (Fig. 84, A, A'), but with nitro-glycerine not until 6 or 7 min. (Fig. 84, B, B') and in the latter case the effects last longer.] It is **increased** at the beginning of expiration, by accelerated action of the heart, stimulation of vaso-motor nerves, diminished outflow of blood at the periphery, and by inflammatory congestion by certain poisons, as lead; compression of other large arterial trunks, action of cold and electricity on the small cutaneous vessels, and by impeded outflow of venous blood. When a large arterial trunk is exposed, the stimulation of the air causes it to contract, resulting in an increased tension within the vessel. In many diseased conditions the arterial tension is greatly increased—[*e.g.*, in Bright's disease, where the kidney is contracted ("**granular**"), and where the left ventricle is hypertrophied].

FIG. 85.



Aortic Regurgitation.

In all these conditions increased arterial tension is indicated by the dicrotic wave being less high and less distinct, while with diminished arterial tension it is a larger and apparently more independent elevation. Moens has shown that the time between the primary elevation and dicrotic wave increases with increase in the diameter of the tube, with diminution of its thickness, and when its coefficient of elasticity diminishes.

[The dicrotic wave is absent or but slightly marked in cases of atheroma and in aortic regurgitation (Fig. 85). In this figure observe also the vertical character of the up-stroke.]

Elastic Elevations.—Besides the dicrotic wave, a number of small less-marked elevations occur in the course of the descent in a sphygmogram (Fig.

83, *e*, *e*). These elevations are caused by the elastic tube being thrown into vibrations by the rapid, energetic pulse wave, just as an elastic membrane vibrates when it is suddenly stretched. The artery also executes vibratory movements when it passes suddenly from the distended to the relaxed condition. These small elevations in the pulse curve, caused by the elastic vibrations of the arterial wall, are called "**elastic elevations**" by Landois.

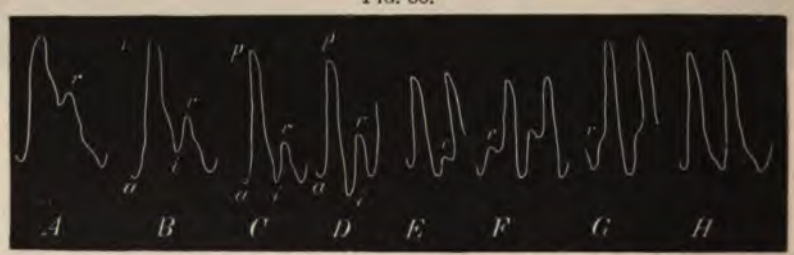
(1) The elastic vibrations increase in number in one and the same artery with the degree of tension of the elastic arterial wall. A very high tension occurs in the cold stage of intermittent fever, in which case these elevations are well marked.

(2) If the tension of the arterial wall be greatly diminished, these elevations may disappear, so that, while diminished tension favors the production of the dicrotic wave, it acts in the opposite way with reference to the "elastic elevations." (3) In diseases of the arterial walls affecting their elasticity, these elevations are either greatly diminished or entirely abolished. (4) The further the arteries are distant from the heart, the higher are the elastic elevations. (5) When the mean pressure within the arteries is increased by preventing the outflow of blood from them, the elastic vibrations are higher and nearer the apex of the curve. (6) They vary in number and length in the pulse curves obtained from different arteries of the body.

When the arm is held in an upright position, after five minutes the blood vessels empty themselves and collapse, while the elasticity of the arteries is diminished.

69. **DICROTIC PULSE.**—Sometimes during fever, especially when the temperature is high, a dicrotic pulse may be felt, each pulse beat, as it were, being composed of two beats (Fig. 83, X), one beat being large and the other small, and more like an after beat. Both beats correspond to *one* beat of the heart. The two beats are quite distinguishable by the touch. The phenomenon is only an exaggerated condition of what occurs in a normal pulse. *The sensible second beat is nothing*

FIG. 86.



Development of the Pulsus dicrotus—P. caprizans; P. monocrotus.

more than the greatly increased dicrotic elevation, which, under ordinary conditions, is not felt by the finger.

Conditions.—The occurrence of a dicrotic pulse is **favored** (1) by a short primary pulse wave, as in fevers, where the heart beats rapidly.

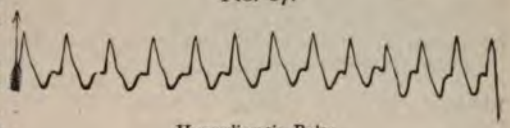
(2) By *diminished arterial tension*. A short systole and diminished arterial blood pressure are the most favorable conditions for causing a dicrotic pulse. [So that dicrotism is best marked in a soft pulse.] The double beat may be felt only at certain parts of the arterial system, while at other parts only a single beat is felt. A favorite site is the radial artery of one or other side, where conditions favorable to its occurrence appear to exist. This seems to be due to a local diminution of the blood pressure in this area, owing to the paralysis of its vasomotor nerves (*Landois*). If the tension be increased by compressing other large arterial trunks or the veins of the part, the double beat becomes a simple pulse beat. The dicrotic pulse in fever seems to be due to the increased temperature (39° to 40° C.), whereby the artery is more distended, and the heart beat is shorter and more prompt.

(3) It is absolutely necessary that the *elasticity of the arterial wall be normal.* The dicrotic pulse does not occur in old persons with atheromatous arteries.

Monocrotic Pulse.—In Fig. 86, A, B, C, we observe a gradual passage of the normal radial curve, A, into the dicrotic beat, B, and C, where the dicrotic wave, *r*, appears as an independent

elevation. If the frequency of the pulse increases more and more in fever, the next following pulse beat may occur in the ascending part of the dicrotic wave, D, E, F, and it may even occur close to the apex, G (**P. caprizans**). If the next following beat occurs in the depression, *i*, between the primary elevation, *p*, and the dicrotic elevation, *r*, the latter entirely disappears, and the curve, H, assumes what Landois calls the "monocrotic type."

FIG. 87.



Hyperdicrotic Pulse.

[**Degrees of Dicrotism.**—When the aortic notch reaches the respiratory or base line, the tidal wave having disappeared, the pulse is said to be **fully dicrotic.** When the aortic notch falls below the base line, *i. e.*, below where the up-stroke begins, the pulse is said to be **hyperdicrotic** (Fig. 87). This form occurs during high fever (104° F.), and is usually a grave sign, indicating exhaustion and the need for stimulants.]

70. CHARACTERS OF THE PULSE.—[The three factors concerned in the production of the pulse are, (1) the action of the heart, (2) the elasticity of the large vessels, (3) the resistance in the small arteries and capillaries. Any or all or several of these factors may be modified.] (1) **Frequency.**—According as a greater or less *number of beats* occurs in a given time, *e. g.*, per minute, the pulse is said to be frequent or infrequent. The **normal rate, in man** = 71 per minute, and somewhat more in the female; in fever it may exceed 120 (250 have been counted by Bowles), while in other diseases it may fall to 40, and even 10 to 15; but such cases are rare, and are probably due to an affection of the cardiac nerves (§ 41). The frequency of the pulse is usually increased when the respirations are *deeper*, but not more numerous, *i. e.*, rapid shallow respirations do not affect the frequency of the pulse, but deep respirations do. [The frequency may be regular or irregular with regard to time.]

(2) **Celerity or Rapidity.**—If the pulse wave is developed, so that the distention of the artery slowly reaches its height, and the relaxation also takes place gradually, we have the p. tardus or *slow* or *long* pulse; the opposite condition gives rise to the p. celer or *quick* or *short* pulse. The rapidity of the pulse is increased by quick action of the heart, power of expansion of the arterial walls, easy efflux of blood owing to the dilatation of the small arteries, and by nearness to the heart. [The *quickness* has reference to a *single* pulse beat, the *frequency* to a *number* of beats.] In a quick pulse, the curve is high and the angle at the apex is acute, while in a slow pulse the ascent is low and the angle at the apex is large.

(3) **Conditions Affecting the Pulse Rate.—Frequency in Health.**—In man the **normal pulse rate** = 71 to 72 beats per minute, in the female about 80. In some individuals the pulse rate may be higher (90 to 100), in others lower (50), and such a fact must be borne in mind.

(*a*) **Age**:—

	Beats per Minute.		Beats per Minute.		Beats per Minute
Newly born,	130 to 140	5 years,	94 to 90	25 to 50 years,	70
1 year,	120 to 130	10 "	about 90	60 years,	74
2 years,	105	10 to 15 years,	78	80 "	79
3 "	100	15 to 20 "	70	80 to 90 years,	over 80
4 "	97	20 to 25 "	70		

(*b*) The **length of the body** has a certain relation to the frequency of the pulse. The following results have been obtained by Czarnecki from the formulæ of Volkmann and Rameaux:—

Length of Body in 10 cm.	Pulse. Calculated.	Observed.	Length of Body in 10 cm.	Pulse. Calculated.	Observed.
80 to 90,	90	103	140 to 150,	69	74
90 to 100,	86	91	150 to 160,	67	68
100 to 110,	81	87	160 to 170,	65	65
110 to 120,	78	84	170 to 180,	63	64
120 to 130,	75	78	Above 180,	60	60
130 to 140,	72	86			

(*c*) The **pulse rate is increased** *by muscular activity, by every increase of the arterial blood pressure, by taking of food, increased temperature, painful sensations, by psychical disturbances, and* [*in extreme debility*]. *Increased heat,* **fever,** or pyrexia increases the frequency, and as a rule the increase varies with the height of the temperature. [Dr. Aitken states that an increase of the temperature of 1° F. above 98° F. corresponds with an increase of ten pulse beats per minute; thus—

Temp. F.	Pulse Rate.	Temp. F.	Pulse Rate.	Temp. F.	Pulse Rate.
98°	60	101°	90	104°	120
99°	70	102°	100	105°	130
100°	80	103°	110	106°	140

This is merely an approximate estimate.] It is more frequent when a person is *standing* than when he lies down. *Music* accelerates the pulse and increases the blood pressure in dogs and men. Increased barometric pressure diminishes the frequency.

The Variation of the Pulse Rate during the Day.—3 to 6 A.M. = 61 beats; 8 to 11½ A.M. = 74. It then falls toward 2 P.M.; toward 3 (at dinner time) another increase takes place and goes on until 6 to 8 P.M. = 70; and it falls until midnight = 54. It then rises again toward 2 A.M., when it soon falls again, and afterward rises as before toward 3 to 6 A.M.

[**Pulse Rate in Animals.**—(*Colin.*)]

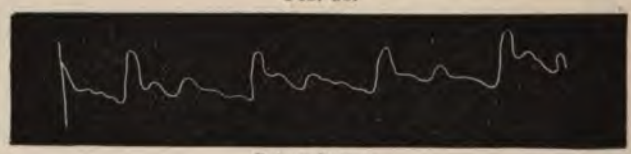
(4) **Variations in the Pulse Rhythm (Allorhythmia).**—On applying the fingers to the normal pulse, we feel beat after beat occurring at apparently equal intervals. Sometimes in a normal series a beat is omitted = pulsus intermittens, or **intermittent pulse.** [In feeling an intermittent pulse, we imagine or have the impression that a beat is omitted. This may be due to a reflex arrest of the ventricular contraction, caused by digestive derangement, in which case it has no great significance; but if it be due to failure of the ventricular action, intermittent pulse is a serious symptom, being frequently present when the muscular walls are degenerated.] At other times the beats become smaller and smaller, and after a certain time begin as large as before = **p. myurus.** When an extra beat is intercalated in a normal series = **p. intercurrens.** The regular alternation of a high and a low beat = **p. alternans** (Fig. 88). In the **p. bigeminus** of Traube the beats occur in

FIG. 88.



Pulsus alternans.

pairs, so that there is a longer pause after every two beats. Traube found that he could produce this form of pulse in curarized dogs by stopping the artificial respiration for a long time. The **p. trigeminus** and **quadrigeminus** occur in the same way, but the irregularities occur after every third and fourth beat. Knoll found that in animals such irregularities of the pulse were apt to occur, as well as great irregularity in the rhythm generally, when there is much resistance to the circulation, and consequently the heart has great demands upon its energy. The same occurs in man when an improper relation exists between the force of the cardiac muscle and the work it has to do (*Riegel*). Complete irregularity of the heart's action is called **arhythmia cordis.**

71. VARIATIONS IN THE CHARACTERS OF THE PULSE.—Compressibility.—The relative **strength** or **compressibility** of the pulse (p. fortis and debilis), *i. e.*, whether the pulse is *strong* or *weak*, is estimated by the weight which the pulse is able to raise. A sphygmograph, provided with an index indicating the amount of pressure exerted upon the spring pressing upon the artery, may be used (Fig. 73). In this case, as soon as the pressure exerted upon the artery overcomes the pulse beat, the lever ceases to move. *The weight employed indicates the strength of the pulse.* [The finger may be, and generally is used. The finger is pressed upon the artery until the pulse beat in the artery *beyond* the point of pressure is obliterated. In health it requires a pressure of several ounces to do this. Handfield Jones uses a **sphygmometer** for this purpose. It is constructed like a cylindrical letter weight, and the pressure is exerted by means of a spiral spring which has been carefully graduated.] The pulse is *hard* or *soft* when the artery, according to the mean blood pressure, gives a feeling of greater or less resistance to the finger, and this quite independent of the energy of the individual pulse beats (p. durus and mollis). In estimating the **tension** of the artery and the pulse, *i. e.*, whether it is *hard* or *soft*, it is important to observe whether the artery has this quality only during the pulse wave, *i. e.*, if it is hard during diastole, or whether it is hard or soft during the period of rest of the arterial wall. All arteries are harder and less compressible during the pulse beat than during the period of rest, but an artery which is very hard during the pulse beat may be hard also during the pause between the pulse beats, or it may be very soft, as in insufficiency of the aortic valves. In this case, after the systole of the left ventricle, owing to the

incompetency of the aortic semilunar valves, a large amount of blood flows back into the ventricle, so that the arteries are thereby suddenly rendered partially empty. [The sudden collapse of the artery gives rise to the characteristic "pulse of unfilled arteries" (Fig. 85).]

Under similar conditions, the **volume** of the pulse is obvious from the size of the sphygmogram, so that we speak of a *large* and a *small* pulse (p. magnus and parvus). Sometimes the pulse is so thready and of such diminished volume that it can scarcely be felt. A *large* pulse occurs in disease when, owing to hypertrophy of the left ventricle, a large amount of blood is forced into the aorta. A *small* pulse occurs under the opposite condition, when a small amount of blood is forced into the aorta, either from a diminution of the total amount of the blood, or from the aortic orifice being narrowed [aortic stenosis], or from disease of the mitral valve; again, where the ventricle contracts feebly, the pulse becomes small and thready.

Compare the **two radials.** Sometimes the pulse differs on the two sides, or it may be absent on one side. [The pulse wave in the two radials is often different when an aneurism is present on one side.]

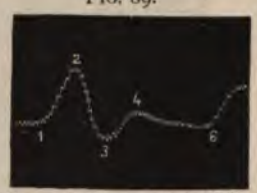
Angiometer.—Waldenburg constructed a "pulse clock," to register the tension, the diameter of the artery, and the volume of the pulse upon a dial. It does not give a graphic tracing, the results being marked by the position of an indicator.

72. THE PULSE CURVES OF VARIOUS ARTERIES.—1. Carotid (Fig 83, I, II, III; Fig. 93, C and C_1). The ascending part is very steep—the apex of the curve (Fig. 83, P) is sharp and high. Below the apex there is a small notch—the "**aortic notch**" (Fig. 83, K)—which depends on a positive wave formed in the root of the aorta, owing to the closure of the aortic valves, and propagated with almost wholly undiminished energy into the carotid artery. Quite close to this notch, if the curve be obtained with minimal friction, the first elastic vibration occurs (Fig. 83, II, *e*). Above the middle of the descending part of the curve is the dicrotic elevation, R, produced by the reflection of a positive wave from the already closed semilunar valves. The dicrotic wave is relatively small on account of the high tension in the carotid artery. After this the curve falls rapidly, but in its lowest third two small elevations may be seen. Of these the former is due to elastic vibration. The latter represents a *second* dicrotic wave (Fig. 83, III, R). Here there is a *true tricrotism*, which is more easily obtained from the carotid on account of the shortness of the arterial channel.

2. Axillary Artery (Fig. 83, IV). In this curve the ascent is very steep, while in the descent near the apex there is a small (aortic) elevation, K, caused by a positive wave, produced by the closure of the aortic valves. Below the middle there is a tolerably high dicrotic elevation, R, higher than in the carotid curve; because in the axillary artery the arterial tension is less, and permits a greater development of the dicrotic wave. Further on, two or three small elastic vibrations occur, *e*, *e*.

3. Radial Artery (Fig. 78; Fig. 83, V to X; Fig. 93, R and R_1). The line of ascent (Fig. 83) is tolerably high and sudden—somewhat in the form of a long *f*. The apex, P, is well marked. Below this, if the tension be high, two elastic vibrations may occur (V, *e*, *e*), but if it be low, only one (VI to IX, *e*). About the middle of the curve is the well-marked dicrotic elevation, R. This wave is least pronounced in a small hard pulse, and when the artery is much distended (Fig. 83, VII, R_1); it is larger when the tension is low (Fig. 83, IX, R), and is greatest of all when the pulse is dicrotic (X, R). Two or three small elastic elevations occur in the lowest part of the curve.

FIG. 89.



Curve of posterior tibial. Written by the angiograph upon a vibrating plate.

4. Femoral Artery (Fig. 83, XI, XII). The ascent is steep and high—the apex of the curve is not unfrequently broad, and in it the closure of the aortic valves (K) is indicated. The curve falls rapidly toward its lowest third. The dicrotic elevation, R, occurs late after the beginning of the curve, and there are also small elastic elevations (*e*, *e*).

5. Pedal Artery (Fig. 83, XIV, XV), and **Posterior Tibial** (Fig. 89 and Fig. 83, XIII). In pulse curves obtained from these arteries, there are well-marked indications that the apparatus (heart) producing the waves is placed at a considerable distance. The ascent is oblique and low—the dicrotic elevation occurs late. Two elastic vibrations (Fig. 83, XIV, *e*, *e*) occur in the descent, but they are very close to the apex, while the elastic vibrations at the lower part of the curve are feebly marked. Fig. 89 is from the posterior tibial. When measured it gives the following result:—

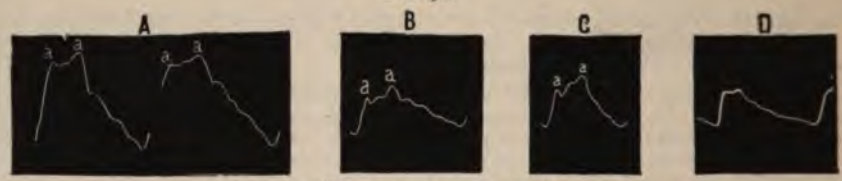
1 to 2 . . . . . 9.5	1 vibration is = 0.01613 sec.
1 to 3 20	
1 to 4 . . . . . 30.5	
1 to 6 61	

73. ANACROTISM.—As a general rule, the line of ascent of a pulse curve has the form of an *f*, and is nearly vertical. The arterial walls are thrown into elastic vibration by the pulse beat, and the number of vibrations depends greatly upon the tension of the arterial walls. The disten-

tion of the artery, or what is the same thing, the ascent of the sphygmogram usually occurs so rapidly that it is equal to *one* elastic vibration. The elongated *f*-shape of the ascent is fundamentally just a prolonged elastic vibration. When the number of vibrations causing the elastic variation is small, and when the line of ascent is prolonged, two elevations occasionally occur in the line of ascent. Such a condition may occur normally (Fig. 83, VIII, at 1 and 2; X, at 1 and 2). When a series of closely-placed elastic vibrations occur in the upper part of the line of ascent, so that the apex appears dentate and forms an angle with the line of ascent, then the condition becomes one of **anacrotism** (Fig. 90, *a*, *a*), which, when it is so marked, may be characterized as pathological. Anacrotism of the pulse occurs when the time of the influx of the blood is longer than the time occupied by an elastic vibration. Hence it takes place—

(1) In **dilatation** and **hypertrophy of the left ventricle**, *e*, *g*., Fig. 90, A, a tracing from the

FIG. 90.



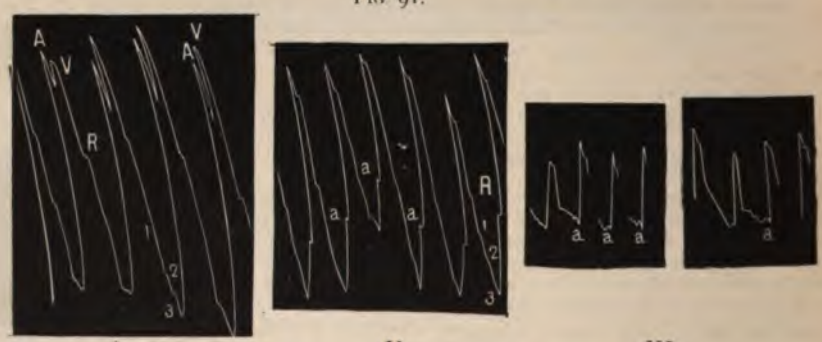
Anacrotic radial curves. *a*, *a*, the anacrotic parts.

radial artery of a man suffering from contracted kidney. The large volume of blood expelled with each systole requires a long time to dilate the tense arteries.

(2) When the **extensibility** of the arterial wall is **diminished**, even the normal amount of blood expelled from the heart at every systole requires a long time to dilate the artery. This occurs in old people where the arteries tend to become rigid, *e. g.*, in atheroma. Cold also stimulates the arteries, so that they become less extensile. Within one hour after a tepid bath, the pulse assumes the anacrotic form (Fig 90, D) *G. v. Liebig*).

(3) When the blood stagnates in consequence of great diminution in the velocity of the blood stream, as occurs in **paralyzed limbs**, the volume of blood propelled into the artery at every sys-

FIG. 91.



I. II. III.

I, II, III, curves with anacrotic elevations *a*, in insufficiency of the aortic valves.

tole no longer produces the normal distention of the arterial coats, and anacrotic notches occur (Fig. 90. B).

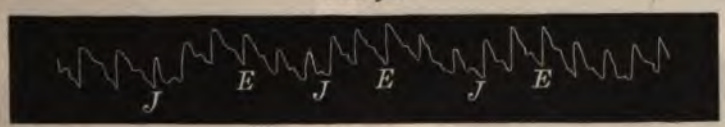
(4) After **ligature** of an artery, when blood slowly reaches the peripheral part of the vessel through a relatively small collateral circulation, it also occurs. If the brachial artery be compressed so that the blood slowly reaches the radial, the radial pulse may become anacrotic. It often occurs in stenosis of the aorta, as the blood has difficulty in getting into the aorta (Fig. 90, C).

Recurrent Pulse.—If the radial artery be compressed at the wrist, the pulse beat reappears on the distal side of the point of pressure through the arteries of the palm of the hand (*Janaud, Neidert*). The curve is **anacrotic**, and the dicrotic wave is diminished, while the elastic elevations are increased.

(5) A special form of anacrotism occurs in cases of well-marked **insufficiency of the aortic valves.** Practically, in these cases, the aorta remains permanently open. The contraction of the left auricle causes in the blood a wave motion, which is at once propagated through the open mouth of the aorta into the large blood vessels. This wave is followed by the wave caused by the contraction of the hypertrophied left ventricle, but of course the former wave is not so large as the latter. In insufficiency of the aortic valves, the auricular wave occurs before the ventricular wave in the ascending part of the curve. The auricular is well marked only in the large vessels, for it soon becomes lost in the peripheral vessels. Fig. 91, I, was obtained from the carotid of a man suffering from *well-marked* insufficiency of the aortic valves, with considerable hypertrophy of the left ventricle and left auricle. The ascent is steep, caused by the force of the contracting heart. In the apex of the curve are two projections; A is the anacrotic auricular wave, and V is the ventricular wave. Fig. 91, II, is a curve obtained from the *subclavian artery* of the same individual. In the femoral artery the auricular projection is only obtained when the friction of the writing style is reduced to the minimum, and when it occurs it immediately precedes the beginning of the ascent (Fig. 86, III, *a*). The pulse curve, in cases of aortic insufficiency, is also characterized by (1) its considerable height; (2) the rapid fall of the lever from the apex of the curve, because a large part of the blood which is forced into the aorta regurgitates into the left ventricle when the ventricle relaxes; (3) not unfrequently a projection occurs at the apex, due to the elastic vibration of the tense arterial wall; (4) the dicrotic wave (R) is small compared with the size of the curve itself, because the pulse wave, owing to the lesion of the aortic valves, has not a sufficiently large surface to be reflected from (Fig. 85). The great height of the curve is explained by the large amount of blood projected into the aortic system by the greatly hypertrophied and dilated ventricle.

74. INFLUENCE OF RESPIRATION ON THE PULSE CURVE.—The **respiratory movements** influence the pulse (1) in a purely **physical** way. Stated broadly, the blood pressure rises during inspiration and falls during expiration, but when we consider the effect on the pulse curve, it is found that it varies with the depth, rapidity, and ease of respiration; (2) the res-

FIG. 92.



Influence of the respiration upon the pulse. J, inspiration; E, expiration.

piratory movements are accompanied by stimulation of the **vasomotor centre,** which produces variations of the blood pressure.

1. **Normal Respiration.**—Fig. 92 shows what sometimes, but by no means always, happens. During **inspiration,** owing to the dilatation of the thorax, more arterial blood is retained within the chest, while at the same time venous blood is sucked into the right auricle by the aspiration of the thorax; as a consequence of this, the tension in the arteries during inspiration must be less. The diminution of the chest during **expiration** favors the flow in the arteries, while it retards the flow of the venous blood in the venæ cavæ, two factors which raise the tension in the arterial system. The difference of pressure explains the difference in the form of the pulse curve obtained during inspiration and expiration, as in Fig. 92 and Fig. 83, I, III, IV, in which J indicates the part of the curve which occurred during inspiration, and E the expiratory portion. The following are the points of difference: (1) The greater distention of the arteries during expiration causes all the parts of the curve occurring during this phase to be higher; (2) the line of the ascent is lengthened during expiration, because the expiratory thoracic movement helps to increase the force of the expiratory wave; (3) owing to the increase of the pressure, the dicrotic wave must be less during expiration; (4) for the same reason the elastic elevations are more distinct and occur higher in the curve near its apex. The **frequency of the pulse** is slightly greater during expiration than during inspiration.

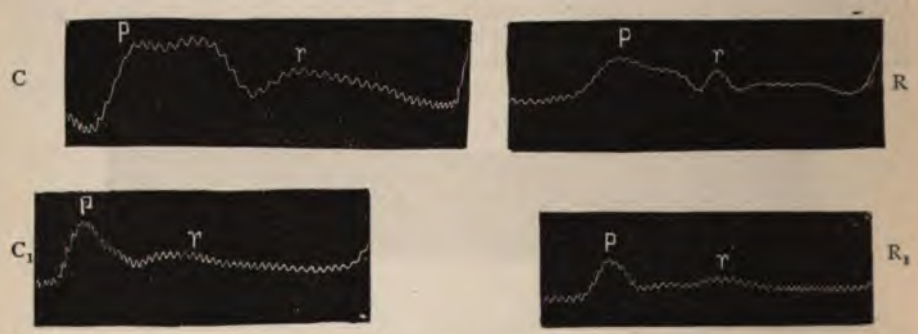
2. This purely mechanical effect of the respiratory movements is modified by the simultaneous stimulation of the **vasomotor centre** which accompanies these

movements. At the beginning of inspiration the blood pressure in the arteries is lowest, but it begins to rise during inspiration, and increases until the end of the inspiratory act, reaching its maximum at the beginning of expiration ; during the remainder of the expiration the blood pressure falls until it reaches its lowest level again at the beginning of inspiration (compare § 85, *f*); the pulse curves are similarly modified, and exhibit the signs of greater or less tension of the arteries corresponding to the phases of the respiratory movements. [There is, as it were, a displacement of the blood-pressure curve relative to the respiratory curve.]

Forced Respiration.—With regard to the effect produced on the pulse curve by a powerful expiration and a forced inspiration, observers are by no means agreed.

Valsalva's Experiment.—Strong expiratory pressure is best produced by closing the mouth and nose, and then making a great expiratory effort (§ 60); *at first* there is increase of blood pressure, while the form of the pulse waves resembles that which occurs in ordinary expiration, the dicrotic wave being less developed; but, when the forced pressure is long continued, the pulse curves have all the signs of diminished tension. This effect is due to the action of the vasomotor centre, which is affected reflexly from the pulmonary nerves. We must assume

FIG. 93.



C, curve from the carotid, and R, radial, during Müller's experiment; C_1 and R_1, during Valsalva's experiment. Curves written on a vibrating surface.

that forced expiration, such as occurs in Valsalva's experiment, acts by *depressing* the activity of the vasomotor centre (§ 371, II). Coughing, singing, and declaiming act like Valsalva's experiment, while the frequency of the pulse is increased at the same time. *After* the cessation of Valsalva's experiment, the blood pressure *rises* above the normal state (*Sommerbrodt*), almost as much as it fell below it; the normal condition being restored within a few minutes (*Lenzmann*).

Müller's Experiment.—When the thorax is in the expiratory phase, close the mouth and nose, and take a deep inspiration so as forcibly to expand the chest (§ 60). At first the pulse curves have the characteristic signs of diminished tension, viz., a higher and more distinct dicrotic wave; then the tension can, by nervous influences, be increased, just as in Fig. 93, where C and R are tracings taken from the carotid and radial arteries respectively, during Müller's experiment, in which the dicrotic waves, *r*, *r*, indicate the diminished tension in the vessels. In C_1 and R_1, taken from the same person during Valsalva's experiment, the opposite condition occurs.

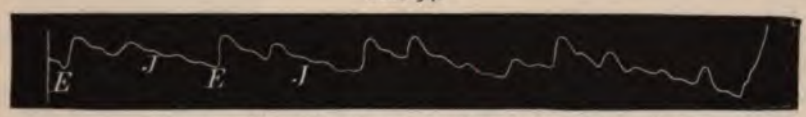
Compressed Air.—On *expiring* into a vessel resembling a spirometer (see Respiration), (Waldenburg's respiration apparatus), and filled with compressed air, the same result is obtained as in

Valsalva's experiment—the blood pressure falls and the pulse beats increase; conversely, the *inspiration* from this apparatus of air under less pressure acts like Müller's experiment, *i. e.*, it increases the effect of the inspiration, and afterward increases the blood pressure, which may either remain increased on continuing the experiment, or may fall (*Lenzmann*).

The *inspiration* of compressed air diminishes the mean blood pressure (*Zuntz*), and the after-effect continues for some time. The pulse is more frequent both during and after the experiment. *Expiration* in rarefied air increases the blood pressure. The effects which depend upon the action of the nervous system do not occur to the same extent in all cases. Exposure to compressed air in a **pneumatic cabinet** lowers the pulse curve, the elastic vibrations become indistinct, and the dicrotic wave diminishes and may disappear (*v. Vivenot*). The heart's beat is slowed and the blood pressure raised (*Bert*). Exposure to rarefied air causes the opposite result, which is a sign of diminished arterial tension.

Pulsus Paradoxus.—Under pathological conditions, especially when there is union of the heart or its large vessels with the surrounding parts, the pulse during inspiration may be extremely

FIG. 94.

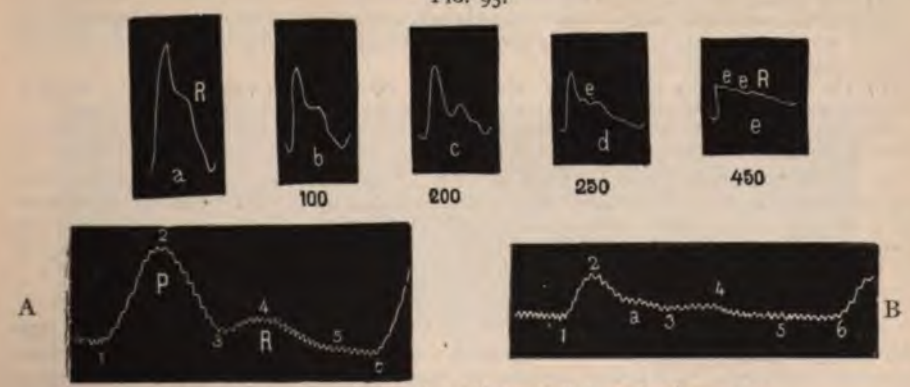


Pulsus paradoxus (after *Kussmaul*). E, expiration; J, inspiration.

small and changed, or may even be absent (Fig. 94). This condition has been called **pulsus paradoxus** (*Griesinger, Kussmaul*). It depends upon a diminution of the arterial lumen during the inspiratory movement. Even in health, it is possible by a change of the inspiratory movement to produce the p. paradoxus (*Riegel, Sommerbrodt*).

75. **INFLUENCE OF PRESSURE ON THE PULSE CURVE.**—It is most important to know the **actual pressure** which is applied to an artery while a sphygmogram is being taken. The changes affect the *form* of the curve as well as the relation of individual parts thereof. In Fig. 95, *a*, *b*, *c*, *d*, *e* are radial curves; *a* was taken with a minimal pressure, *b* with 100, *c* 200, *d* 250, and *e* 450 grams pressure, while A, B, C, D show the relations as to the time of occurrence of the individual phenomena where the weight was successively increased. The study of these curves yields the following results: (1) When the weight is small, the dicrotic wave is relatively less; the whole curve is high; (2) with a moderate weight (100 to 200 grams) the

FIG. 95.



Various forms of curves (radial) obtained by gradually increasing the pressure.

dicrotic wave is best marked, the whole curve is somewhat lower; (3) on increasing the weight the size of the dicrotic wave again diminishes; (4) the fine elastic vibrations preceding the dicrotic wave appear first when a weight of 220 to 300 grams is used; (5) the rapidity of the pulse changes with increasing weight, the time occupied by the ascent becoming shorter, the descent becoming longer; (6) the height of the entire curve decreases as the weight increases. In every sphygmogram the pressure under which it was obtained ought always to be stated. In Fig. 95, A, B are curves obtained from the radial artery of a healthy student. The pressure exerted upon the artery for A was 100; B, 220 grms. (1 vibration = 0.01613 sec.).

If pressure be exerted upon an artery for a long time, the strength of the pulse is gradually increased. If, after subjecting an artery to considerable pressure, a lighter weight be used, not unfrequently the pulse curve assumes the form of a dicrotic pulse, owing to the greater development of the dicrotic elevation. When strong pressure is applied, the blood is forced to find its way through collateral channels. When the chief artery ceases to be compressed, the total area is, of course, considerably and suddenly enlarged, which results in the production of a dicrotic elevation. Fig. 83, X, is such a dicrotic curve obtained after considerable pressure had been applied to the artery.

76. TRANSMISSION OF PULSE WAVES.—The pulse wave proceeds throughout the arterial system from the root of the aorta, so that the pulse is felt sooner in parts lying near the heart than in the peripheral arteries. E. H. Weber calculated the **velocity of the pulse wave** as 9.240 metres [28½ feet] per second, from the difference in time between the pulse in the external maxillary artery and the dorsal artery of the foot. Czermak showed that the elasticity was not equal in all the arteries, so that the velocity of the pulse wave cannot be the same in all. The pulse wave is propagated more slowly in the arteries with soft extensile walls than in arteries with resistant and thick walls, so that it is transmitted more rapidly in the arteries of the lower extremities than in those of the upper. It is still slower in children.

77. PULSE WAVE IN ELASTIC TUBES.—Waves similar to the pulse may be produced in elastic tubes. (1) According to E. H. Weber the velocity of propagation of the waves is 11.205 metres per sec.; according to Donders, 11–13 metres (34–42 feet). (2) According to E. H. Weber increased internal tension causes only an inconsiderable decrease; Rive found a great decrease; Donders found no obvious difference; while Marey found an increased velocity. (3) Donders found the velocity to be the same in tubes 2 mm. in diameter as in wider tubes, but Marey believes that the velocity varies when the diameter of the tube changes. (4) The velocity is less, the smaller the elastic coefficient. (5) The velocity increases with increased thickness of the wall, while it diminishes when the specific gravity of the fluid increases.

Moens has recently formulated the following **laws** as to the velocity of propagation of waves in elastic tubes: (1) It is inversely proportional to the square root of the specific gravity of the fluid; (2) it is as the square root of the thickness of the wall, the lateral pressure being the same; (3) it is inversely as the square root of the diameter of the tube, the lateral pressure being the same; (4) it is as the square root of the elastic coefficient of the wall of the tube, the lateral pressure being the same (*Valentin*).

(A) The velocity of the wave is 11.809 metres per second.

(B) The *intra-vascular pressure* has a decided influence on the velocity: thus, in the tube, A, with 18 cm. (Hg.) pressure, the velocity per metre = 0.093 second, while with 21 cm. pressure (Hg.) = 0.095 second per metre.

(C) The *specific gravity of the liquid* influences the velocity of the pulse wave. In *mercury* the wave is propagated four times more slowly than in water.

(D) The velocity in a tube which is more rigid and not so extensile is greater than in a tube which is easily distended.

78. VELOCITY OF THE PULSE WAVE IN MAN.—Landois obtained the following results in a student: Difference between carotid and radial = 0.074 second (the distance being taken as 62 centimetres); carotid and femoral = 0.068 second; femoral (inguinal region) and posterior tibial = 0.097 second (distance estimated at 91 centimetres). [Waller obtained between the heart and carotid 0.10 second; heart and femoral, 0.18 sec.; heart and dorsalis pedis, 0.22.]

The **velocity of the pulse wave** in the arteries of the upper extremities = 8.43 metres per second, and in those of the lower extremity 9.40 metres per second, [*i.e.*, about 30 feet per second]. The velocity is greater in the less extensile arteries of the lower extremities than in those of the upper limb. For the same reason it is less in the peripheral arteries and in the yielding arteries of children (*Czermak*).

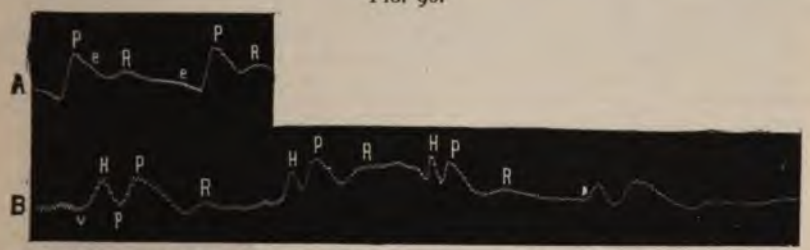
E. H. Weber estimated the velocity at 9.24 metres per second; Garrod, 9–10.8 metres; Grashey, 8.5 metres; Moens, 8.3 metres, and with diminished pressure during Valsalva's experiment 7.3 metres (§ 60, § 74).

Influencing Conditions.—In animals, hemorrhage, slowing of the heart produced by stimulation of the vagus (*Moens*), section of the spinal cord, deep morphia narcosis, and dilatation of the blood vessels by heat, produce *slowing* of the velocity, while stimulation of the spinal cord *accelerates* it (*Grunmach*).

The **wave length of the pulse wave** is obtained by multiplying the duration of the inflow of blood into the aorta = 0.08 to 0.09 second (§ 51), by the velocity of the pulse wave.

Method.—Place the knobs of two tambours (Fig. 76) upon the two arteries to be investigated, or place one over the apex beat and the other upon an artery. These receiving tambours are connected with two registering tambours, as in Brondgeest's pansphygmograph (§ 67, Fig. 76), so that their writing levers are directly over each other, and so arranged as to write simultaneously on *one* vibrating plate attached to a tuning-fork. [Or they may be made to write upon a revolving cylinder, whose rate of movement is ascertained by causing a tuning-fork of a known rate of vibration to write under them.] The apparatus is improved by using rigid tubes and filling them with water, in which all impulses are rapidly communicated. In arteries which are distant from each

FIG. 96.



A, curve of radial artery on a vibrating surface (1 vib. = 0.01613 sec.); P, apex of curve; *e*, *e*, elastic vibrations; R, dicrotic wave. B, curve of same radial taken along with the heart beat; *v*, H, P, contraction of the ventricle.

other, or in the case of the heart and an artery, the two knobs of the receiving tambours may be connected by means of a **Y**-tube with *one* writing lever. In Fig 96, B is a curve from the radial artery taken in this way. In it *v* H P indicates contraction of the ventricle; H, the apex of the ventricular contraction; P, the primary apex of the radial curve; *v*, the beginning of the ventricular contraction; *p*, of the radial pulse. A is the curve of the radial artery alone. From these curves it is evident that in this instance nine vibrations occur between the beginning of the ventricular contraction and the beginning of the pulse in the radial artery = 0.15 sec.

In Fig. 97 the difference between the carotid and the posterior tibial pulse = 0.137 sec.

Pathological.—In cases of *diminished extensibility* of the arteries, *e. g.*, in atheroma (§ 77, D), the pulse wave is propagated more rapidly. Local dilatations of the arteries, as in **aneurisms**, cause a retardation of the wave, and a similar result arises from local constrictions. Relaxation of the walls of the vessels in high fever retards the movement (*Hamernik*).

FIG. 97.

Curves of the carotid and posterior tibial taken simultaneously with Brondgeest's pansphygmograph writing upon a vibrating plate attached to a tuning-fork. The arrows indicate the identical moment of time in each curve.

79. **OTHER PULSATILE PHENOMENA.**—1. In the **mouth and nose**, when they are filled with air, and the glottis closed, pulsatile phenomena (due to the arteries in their soft parts) may be found communicating a movement to the contained air. The curves obtained are relatively small, and closely resemble the curve of the carotid. A similar pulse is obtained in the tympanum with intact membrana tympani, and when the soft parts of the tympanum are congested (*Schwartze*, *Tröltsch*).

2. **Entoptical Pulse.**—After violent exercise, an illumination, corresponding to each pulse beat, occurs on a dark optical field. When the optical field is bright, an analogous darkening occurs. The ophthalmoscope occasionally reveals pulsation of the retinal arteries (*Jäger*), which becomes marked in insufficiency of the aortic valves.

3. **Pulsatile Muscular Contraction.**—The *orbicularis palpebrarum muscle* contracts under similar conditions synchronously with the pulse; and it is perhaps due to the pulse beat exciting the sensory nerves reflexly. The Brothers Weber found that not unfrequently, while walking, the step and pulse gradually and involuntarily coincide.

4. When the legs are crossed as one sits in a chair, the leg which is supported is raised with each pulse beat, and it gives also a second or dicrotic elevation.

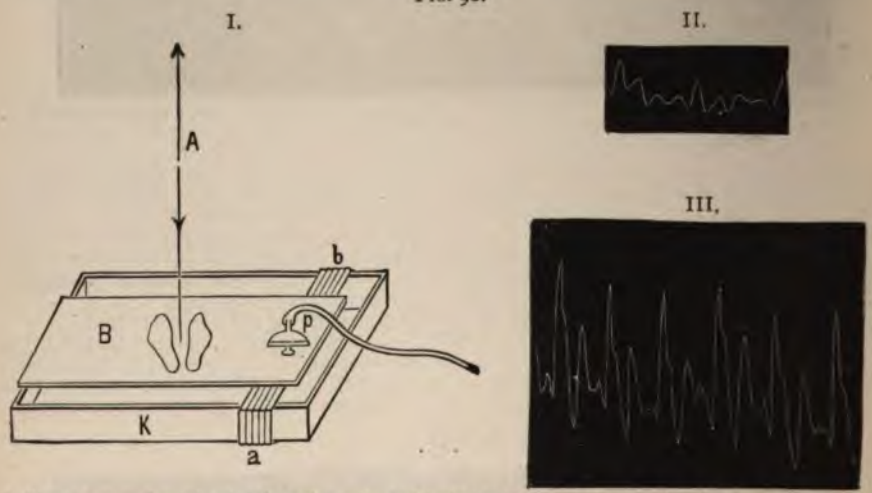
5. If, while a person is quite quiet, the incisor teeth of the lower jaw be made just to touch the upper incisors very lightly, we detect a double beat of the lower against the upper teeth, owing to the pulse beat in the external maxillary artery raising the lower jaw. The second elevation is due to the closure of the semilunar valves, and not to a dicrotic wave.

6. **Brain and Fontanelles.**—The large arteries at the base of the *brain* communicate a movement to it, while similar movements occur with respiration—rising during expiration and falling during inspiration. These movements are visible in the *fontanelles of infants*. The respiratory movements depend upon variations in the amount of blood in the veins of the cranial cavity, and also upon the respiratory variations of the blood pressure.

7. Among **pathological** phenomena are (*a*) the beating in the epigastrium, *e. g.*, in the hypertrophy of the right or left ventricle, caused, it may be, by deep insertion of the diaphragm, and it may be, partly, by the beating of a dilated abdominal aorta or cœliac axis.

(*b*) **Aneurisms** or *abnormal dilatations* of the arteries cause an abnormal pulsation, while they

FIG. 98.



I. Elastic support for registering the molar motions of the body—K, wooden box; B, feet of patient; *p*, cardiograph; *a b*, elastic tubing. II. Vibration curves of a healthy person. III. Curve obtained from a patient with insufficiency of the aortic valves and great hypertrophy of the heart.

produce a *slowing in the velocity of the pulse wave* in the corresponding artery. Hence the pulse appears later in such an artery than in the artery on the healthy side. *Hypertrophy and dilatation of the left ventricle* cause the arteries near the heart to pulsate strongly. In the analogous condition of the right ventricle, the beat of the pulmonary artery may be seen and felt in the second left intercostal space.

80. **VIBRATIONS OF THE BODY DUE TO THE HEART.**—The beating of the heart and large arteries communicates vibrations to the body as a whole; the vibration being not simple but compound. Gordon was the first to represent this pulsatory vibration graphically. If a person be placed in an erect attitude in the scale-pan of a large balance, the index oscillates, and its movements coincide with the heart's movements.

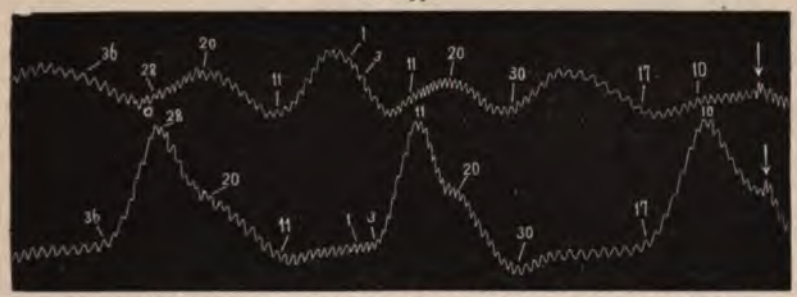
Method.—Take a long four-sided box, K, open at the top, and arrange several coils, *a*, *b*, of stout caoutchouc tubing round one end (Fig. 98). A wooden board, B, is so placed that it rests with one end on the caoutchouc tubing, and with the other on the narrow end of the box. The person to be experimented upon, A, stands vertically and firmly on this board. A receiving tambour, *p*, is placed against the surface of the board next the elastic tube, which registers the vibrations of the foot support. Fig. III is a curve showing such vibrations, each heart beat being followed in this case by four oscillations. To ascertain the relations and causes of these vibrations, it is necessary to obtain, simultaneously, a tracing of the heart and the vibratory curve. For this purpose use the

two tambours of Brondgeest's pansphygmograph (§ 67, 76), placing one knob or pad over the heart and the other on the foot support, and allow the writing tambours to inscribe their vibrations on a glass plate attached to a tuning-fork.

In the *lower* or *cardiac impulse curve* (Fig. 99), the rapidly rising part is due to the ventricular systole. It contains eight vibrations (1 vib. = 0.01613 sec.). The beginning of the ventricular systole is indicated in the figure by -36, -3, -17.

If the corresponding numbers in the upper or *vibratory curve* are studied, it is obvious that *at the moment of ventricular systole the body makes a downward vibration, i. e.*, it exercises greater pressure upon the foot support. Gordon interprets his curve as giving exactly the opposite result. This downward motion, however, lasted only during five vibrations of the tuning-fork; during the last

FIG. 99.



The upper curve is the vibration curve of a healthy person, and the lower one a tracing of the apex beat.

three vibrations, corresponding to the systole, there is an ascent of the body corresponding to a less pressure upon the foot plate. When the ventricle empties itself, it undergoes a movement in a downward and outward direction—Gutbrodt's "reaction impulse."

In the *upper curve* analogous numbers are employed to indicate the vibrations occurring simultaneously, viz., -28, -11, -10. The closure of the semilunar valves is well marked in the three heart beats at 20, -20. This closure is indicated in analogous points in both curves, after which there is a descent of the foot support, and this corresponds to the downward propagation of the pulse wave through the aorta to the vessels of the feet.

Pathological.—In insufficiency of the aortic valves, as shown in Fig. 98, III, the vibration communicated to the body is very considerable.

81. THE BLOOD CURRENT.—Cause.—The closed and much-branched vascular system, whose walls are endowed with elasticity and contractility, is not only completely filled with blood, but it is **over-filled**. The total volume of the blood is somewhat greater than the capacity of the entire vascular system. Hence it follows that the mass of blood must exert **pressure** on the walls of the entire system, thus causing a corresponding dilatation of the elastic vascular walls (*Brunner*). This occurs during life; after death the muscles of the vessels relax, and fluid passes into the tissues, so that the blood vessels come to contain less fluid, and some of them may be empty.

If the blood were uniformly distributed throughout the vascular system and under the same pressure, it would remain in a position of equilibrium (as after death). If, however, the pressure be raised in one section of the tube, the blood will move from the part where the pressure is higher to where it is lower; so that the **blood current is a result of the difference of pressure** within the vascular system. If either the aorta or the venæ cavæ be suddenly ligatured in a living animal, the blood continues to flow, but gradually more slowly, until the difference of pressure is equalized throughout the entire vascular system.

The **velocity** of the current will be greater the greater the difference of pressure, and the less the resistance opposed to the blood stream.

The **difference of pressure which causes the current is produced by the heart.** Both in the systemic and pulmonary circulation the point of greatest pressure is in the root or beginning of the arterial system, while the point of

lowest pressure is in the terminal portion of the venous orifices at the heart. Hence the blood flows continually from the arteries through the capillaries into the venous trunks. The heart keeps up the difference of pressure required to produce this result; with each systole of the ventricles a certain quantity of blood is forced into the beginning of the arteries, while at the same time an equal amount flows from the venous orifices into the auricles during their diastole (*E. H. Weber*).

Donders showed that the action of the heart not only causes the difference of pressure necessary to establish a blood current, but also **raises the mean pressure** within the vascular system. The terminations of the veins at the heart are wider and more extensible than the arteries where they arise from the heart (Fig. 133). As the heart propels a volume of blood into the arteries equal to that which it receives from the veins, it follows that the arterial pressure must rise more rapidly than the venous pressure diminishes, since the arteries are not so wide nor so extensible as the veins. Thus the total pressure must also increase.

Cause of Continuous Flow.—The volume of blood expelled from the ventricles at every systole would give rise to a *jerky* or intermittent movement of the blood stream (1) if the tubes had rigid walls, as in such tubes any pressure exerted upon their contents is propagated momentarily throughout the length of the tube, and the motion of the fluid ceases when the propelling force ceases; (2) the flow would also be intermittent in character in elastic tubes if the time between two successive systoles were longer than the duration of the current necessary for the compensation of the difference of pressure caused by the systole. If the time between two successive systoles be shorter than the time necessary to equilibrate the pressure, the current will become **continuous**, provided the resistance at the periphery of the tube be sufficiently great to bring the elasticity of the tube into action. The more rapidly systole follows systole, the greater the difference of pressure becomes, and the more distended the elastic walls. Although the current thus produced is continuous, a sudden rise of pressure is caused by the forcing in of a mass of blood at every systole, so that with every systole there is a sudden jerk and *acceleration of the blood stream* corresponding to the pulse (compare § 64).

The sudden jerk-like acceleration of the blood current is propagated throughout the arterial system with the velocity of the pulse wave; both phenomena are due to the same fundamental cause. Every pulse beat causes a temporary rapid progressive acceleration of the particles of the fluid. But just as the form movement of the pulse is not a simple movement, neither is the pulsatile acceleration a simple acceleration. It follows the course of the development of the pulse wave. The pulse curve is the graphic representation of the pulsatory acceleration of the blood stream. Every rise in the curve corresponds to an acceleration, every depression to a retardation of the current.

[**Method: Rigid and Elastic Tubes.**—These facts are easily demonstrated. Tie a Higginson's syringe to a piece of an ordinary gas pipe. On forcing water through the tube, by compressing the elastic pump, the water will flow out at the other end of the tube in jets, while during the intervals of pulsation no water will flow out. As the walls of the tube are rigid, just as much fluid flows out as is forced into the tube. If a similar arrangement be made, and a long elastic tube be used, a **continuous** outflow is obtained, provided the pulsations occur with sufficient rapidity and the length of the tube, or the resistance at its periphery, be sufficient to bring the elasticity of the tube into action. This can be done by putting a narrow cannula in the outflow end of the tube, or by placing a clamp on it so as to diminish the exit aperture. This apparatus converts the intermittent flow into a continuous current.] The fire-engine is a good example of the conversion of an intermittent inflow into a uniform outflow. The air in the reservoir is in a state of elastic tension, and it represents the elasticity of the vascular walls. When the pump is worked slowly, the outflow of the water occurs in jets, and is interrupted. If the pumping movement be sufficiently rapid, the compressed air in the reservoir causes a continuous outflow, which is distinctly accelerated at every movement of the pump. [The ordinary spray-producer is another good example.]

[Thus, there are two factors—a **central** one, the **heart**,—and a **peripheral**

one, the amount of **resistance** in the arterioles. Either or both may be varied, and as this is done, so will the pressure and velocity vary.]

Current in the Capillaries.—In the *capillaries* the pulsatile acceleration of the current ceases with the extinction of the pulse wave. The great resistance which is offered to the current toward the capillary area causes both to disappear. It is only when the capillaries are greatly dilated, and when the arterial blood pressure is high, that the pulse is propagated through the capillaries into the beginning of the veins. A **venous pulse** is observed in the veins of the sub-maxillary gland after stimulation of the chorda tympani nerve, which contains the vaso-dilator nerves for the blood vessels of this gland. If the finger be constricted with an elastic band, so as to hinder the return of the venous blood, and to increase the arterial blood pressure, while at the same time dilating the capillaries, an intermittent increased redness occurs, which corresponds with the well-known throbbing sensation in the swollen finger. This is due to the **capillary pulse.** [Roy and Graham Brown found that pulsatile phenomena were produced in the capillaries by increasing the extra-vascular pressure (§ 86). Quincke called attention to the capillary pulse, which can often be seen under the finger nails. Extend the fingers completely, when a whitish area appears under the nails. A red area near the free margin of the nail advances and retires with each pulse beat. It is well marked in some diseased conditions of the heart, especially in incompetence of the aortic valves, and is probably produced by increased extra-vascular pressure.]

82. **SCHEMATA OF THE CIRCULATION.**—E. H. Weber constructed a scheme of the circulation. It consisted of a force pump with properly arranged valves to represent the heart, portions of gut for the arteries and veins, and a piece of glass tubing containing a piece of sponge to represent the capillaries. Various schemes have been invented, including the very complicated one of Marey [the extremely ingenious one of v. Thanhoffer, and the thoroughly practical one of Rutherford].

83. CAPACITY OF THE VENTRICLES.—Since the right and left ventricles contract simultaneously, and just the same volume of blood passes through the pulmonary as through the systemic circulation, it follows that the right ventricle must be just as capacious as the left. The capacity of the ventricles has been estimated in the following ways:—

Methods.—(1) **Directly,** by filling the *dead* relaxed ventricle with blood or an injection mass. This method is unsatisfactory and inaccurate.

(2) **Indirectly.** Volkmann (1850) estimated it thus: Estimate the sectional area of the aorta, and the velocity of the blood stream in it (§ 1). From this calculate the amount of blood passing through the aorta in the unit of time. As the total quantity of blood in the body is known ($= \frac{1}{13}$ of the body weight), we can easily calculate how long this takes to flow through the aorta. We must also know the number of beats during the time of the circulation. From these data, and from experiments on animals, Volkmann estimated the volume of blood discharged at each systole by the ventricle to be $\frac{1}{400}$ of the body weight. For a man weighing 75 kilos. this is 187.5 grams. This estimate still leaves much to be desired.

Place calculates it in the following manner: A man uses about 500 litres of O in 24 hours. To absorb this into the venous blood (which contains about 7 vols. per cent. less O than arterial), about 7000 litres of blood must pass through the lungs in 24 hours. If one calculates 100,000 heart beats in 24 hours, then at each systole only 70 cubic centimetres are discharged.

84. ESTIMATION OF THE BLOOD PRESSURE.—(A) In Animals: (1) Methods of Hales.—The Rev. Stephen Hales (1727) was the first to introduce a long glass tube into a blood vessel in order to estimate the blood pressure by measuring the height of the column of blood.

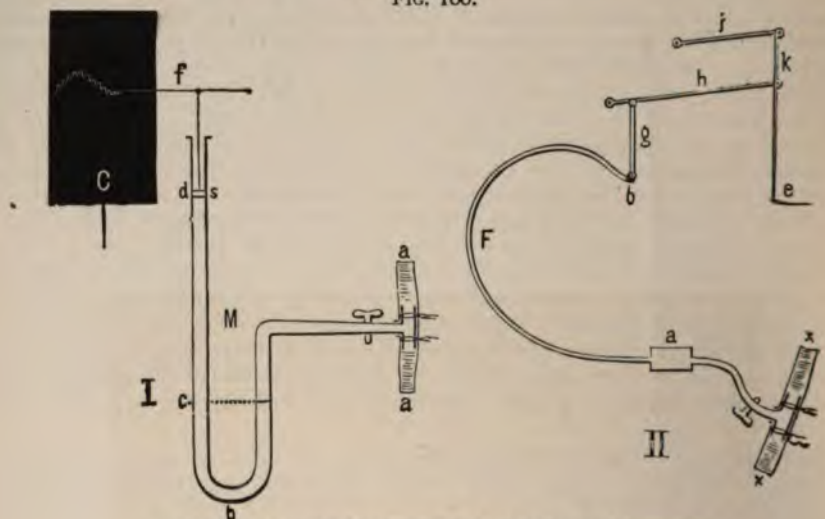
The tube was provided at its lower end with a copper tube bent at a right angle (Pitot's tube). [The tube he used was one-sixth of an inch bore and about 9 feet long, and was inserted into the femoral artery of a horse. The height to which the blood rose in the tube was noted, as well as the oscillations that occurred with every pulsation. From the height of the column of fluid he calculated the force of the heart.]

(2) **The Hæmadynamometer of Poiseuille** (1828).—This observer used a **U**-shaped tube partially filled with mercury—a **manometer**—which was brought into connection with a blood vessel by means of a *rigid* tube. [The mercury oscillated with every pulsation, and the extent of

the oscillations was read off by means of a scale attached to the bent tube. He called the instrument a *hæmädynamometer*.]

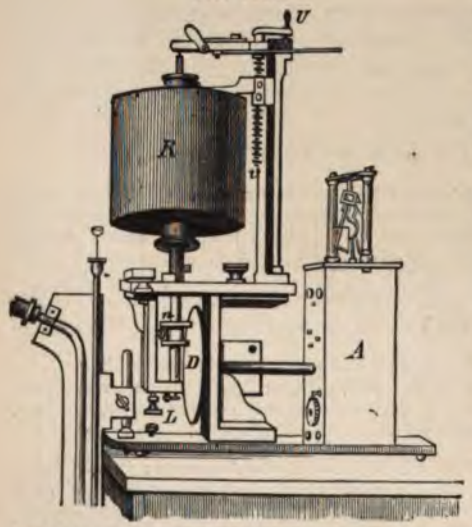
[(3) **Vierordt** used a tube 5 or 6 feet long, and filled it with a solution of sodium carbonate, thus preventing much blood from entering the tube, while at the same time the soda solution prevented the coagulation of the blood.]

FIG. 100.



I. Scheme of C. Ludwig's kymograph. II. Fick's spring kymograph.

FIG. 101.



Ludwig's improved revolving cylinder, *R*, moved by the clockwork in the box *A*, and regulated by a Foucault's regulator placed on the top of the box. The disk, D, moved by the clockwork, presses upon the wheel, *n*, which can be raised or lowered by the screw, *L*, thus altering the position of *n* on *D*, so as to cause the cylinder to rotate at different rates. The cylinder itself can be raised by the handle, *U*. On the left side of the figure is a mercurial manometer. When the cylinder is used, it is covered with smoked smooth paper.

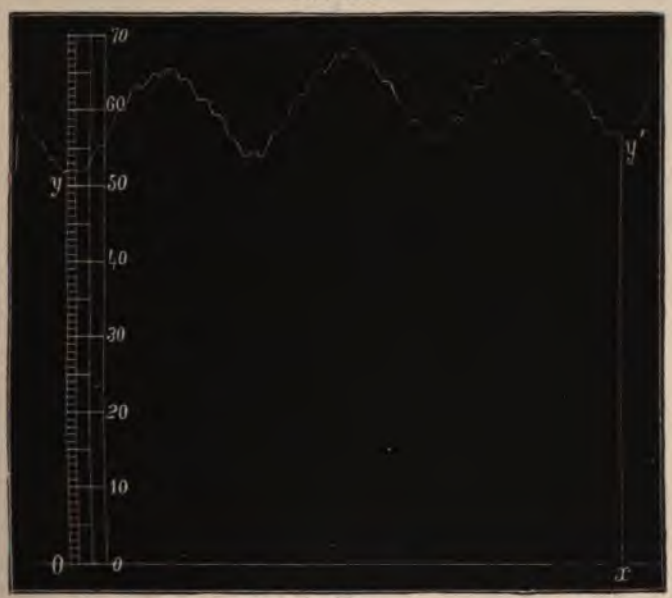
(4) **C. Ludwig's Kymograph.**—C. Ludwig employed a **U**-shaped manometer, but he placed a light float (Fig. 100, *d*, *s*) upon the surface of the mercury in the open limb of the tube. A writing style, *f*, placed transversely on the free end of the float, inscribed the movements of the float—and, therefore, of the mercury—upon a cylinder, *c*, caused to revolve at a uniform rate. This apparatus *registered* the height of the blood pressure, as well as the pulsatile and other oscillations occurring in the mercury. Volkmann called this instrument a **kymograph** or "wave writer." The difference of the height of the column of mercury, *c*, *d*, in both limbs of the tube indicates the pressure within the vessel. If the height of the column of mercury be multiplied by 13.5, this gives the height of the corresponding column of blood. Setschenow placed a stop-cock in the lower bend, *h*, of the tube. If this be closed so as just to permit a small aperture of communication to remain, the pulsatile vibrations no longer appear, and the apparatus indicates the *mean pressure*.

By the term *mean pressure* is meant the limit of pressure, above and below which the oscillations occurring in an ordinary blood-pressure tracing range. [Briefly, it is the *average* elevation of the mercurial column.]

In a **blood-pressure tracing**, such as Fig. 102, each of the **smaller waves** corresponds to a **heart beat**, the ascent corresponds to the systole and the descent to the diastole. The **large undulations** are due to the **respiratory movements**. It is clear that the heart beat is expressed as a simple rise and fall (Fig. 102), so that the curve of the heart beat obtained with a mercurial kymograph differs from a sphygmographic curve.

Faults of a Mercurial Manometer.—A perfect recording instrument ought to indicate the height of the blood pressure, and also the size, form, and duration of any wave motion communicated to it. The mercurial manometer does not give the true form of the pulse wave, as the mercury, when once set in motion, executes vibrations of its own, owing to its great inertia, and thus the finer movements of the pulse wave are lost. Hence a mercurial kymograph is used for registering the blood pressure, and not for obtaining the *exact* form of the pulse wave. Instruments with less inertia, and with no vibrations peculiar to themselves, are required for this purpose.

FIG. 102.



Blood-pressure curve of the carotid of a dog obtained with a mercurial manometer. $O-x$ = line of no pressure, zero line, or abscissa; $y-y'$ is the blood-pressure tracing with small waves, each one caused by a heart beat, and the large waves due to the respiration. A millimetre scale shows the height of the pressure in millimetres of mercury.

[**Method.**—Expose the carotid of a chloralized rabbit, and isolate a portion of the vessel between two ligatures, or two spring clamps. With a pair of scissors make an oblique slit in the artery, and into it tie a straight glass **cannula**, directing the pointed end of the cannula toward the heart. Fill the cannula with a saturated solution of sodium carbonate, taking care that no air bubbles enter, and connect it with the **lead tube** which goes to the ascending limb of the manometer. The tube which connects the artery with the manometer must be flexible and yet inelastic, and a lead tube is best. It is usual to connect a **pressure bottle**, containing a saturated solution of sodium carbonate, by means of an elastic tube, with the tube attached to the manometer. This bottle can be raised or lowered. Before beginning the experiment, raise the pressure bottle until there is a *positive* pressure of mercury in the manometer about equal to the estimated blood pressure, and then clamp the tube of the pressure bottle where it joins the lead tube. This positive pressure prevents the escape of blood from the artery into the solution of sodium carbonate. When all is ready, the ligature on the *cardiac* side of the cannula is removed, and immediately the float begins to oscillate and inscribe its movements upon the recording surface. The fluid within the artery exerts pressure latterly upon the sodium carbonate solution, and this in turn transmits it to the mercury. Peptones,

or rather the albumoses, when injected into the blood keep it from coagulating (p. 73). Roy finds that oil may take the place of sodic carbonate.]

[**Precautions.**—In taking a blood-pressure tracing, after seeing that the apparatus is perfect, care must be taken that the animal is perfectly quiescent, as every movement causes a rise of blood pressure. This may be secured by giving curara and keeping up artificial respiration, or by the carefully regulated inhalation of ether. When a drug is to be injected to test its action, if it be introduced into the jugular vein it is apt to affect the heart directly. This may be avoided by injecting it into a vein of the leg, or under the skin. The solution of the drug must not contain particles which will block up the capillaries. Care should also be taken that the carbonate of soda does not flow back into the artery.]

[**Continuous Tracing.**—When we have occasion to take a tracing for any length of time, it must be written upon a strip of paper which is moved at a uniform rate in front of the writing style on the float (Fig. 100). Various arrangements are employed for this purpose, but it is usual to cause a cylinder to revolve, so as to unfold a roll or riband of paper placed on a movable bobbin. As the cylinder revolves, it gradually winds off the strip of paper, which is kept applied to the revolving surface by ivory friction wheels. In Hering's complicated kymograph a long strip of smoked paper is used. The writing style may consist of a sable brush, or a fine glass pen filled with aniline blue dissolved in water, to which a little alcohol and glycerine are added.]

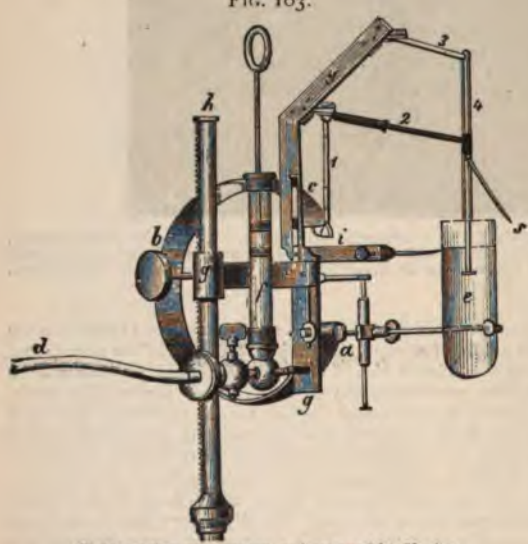
[In order to measure the height of the pressure, we must know the position of the **abscissa** or line of no pressure, and it may be recorded at the same time as the blood pressure, or afterward. In Fig. 102 $O-x$ is the zero line or the abscissa, and the height of the vertical lines or **ordinates** may be measured by the millimetre scale on the left of the figure. The height of the blood pressure is obtained by drawing ordinates from the curve to the abscissa, measuring their length, and **multiplying by two.**]

(5) **Spring Kymograph.—A. Fick** (1864) uses a "hollow spring kymograph" on the principle of Bourdon's manometer (Fig. 100, II).

A hollow **C**-shaped metallic spring, F, is filled with alcohol. One end of the hollow spring is closed, and the other end, covered by a membrane, is brought into connection with a blood vessel by a junction piece filled with a solution of sodium carbonate. As soon as the communication with the artery is opened, the pressure rises, and the spring, of course, tends to straighten itself. To the closed end, *b*, there is fixed a vertical rod attached to a series of levers, *h*, *i*, *k*, *e*, one of which writes its movements upon a surface moving at a uniform rate. The blood pressure and the periodic variations of the pulse are both recorded, although the latter is not done with absolute accuracy.

[**Hering** improved Fick's instrument (Fig. 103). *a*, *b*, *c*, is the hollow spring filled with alcohol, and communicating at *a* with the lead tube, *d*, passing to the cannula in the artery. To *c* is attached a series of light wooden levers with a writing style, *s*. The lower part of 4 dips into a vessel, *e*, filled with oil or glycerine, which serves to damp the vibrations of the levers. At *f* is a syringe communicating with the tube, *d*, filled with solution of sodic carbonate, and used for regulating the amount of fluid in the tube connecting the manometer with the blood vessel. The whole apparatus can be raised or lowered on the toothed rod, *h*, by means of the mill-head opposite, *g*, to which all the parts of the apparatus are attached.]

FIG. 103.



Fick's spring manometer, as improved by Hering.

(6) **Fick's Flat Spring Kymograph.**—The narrow tube *a*, *a* (1 mm. diam.) is placed in connection with a blood vessel by means of the cannula, *c*, and over its vertical expanded end, A, is fixed a caoutchouc membrane, with a projecting point, *s*, which presses against a horizontal spring, F, joined to a writing lever, H, by an intermediate piece, *b*. The whole is held in the metallic frame, R R (Fig. 104). In order to estimate the absolute pressure, the instrument must be compared previously with a mercurial manometer.

(B) **In man** the blood pressure may be estimated by means of (1) a properly

graduated sphygmograph (§ 67). The pressure required to abolish the movement of the lever indicates approximately the vascular tension. The mean blood pressure in the radial artery is equal to 550 grams.

(2) **Sphygmomanometer of v. Basch.**—A capsule containing fluid was placed upon a pulsating artery, while the capsule itself communicated with a mercurial manometer. As soon as the pressure within the manometer *slightly exceeded* that within the artery, the artery was compressed so that a sphygmograph placed on a peripheral portion of the vessel ceased to beat. Both arrangements do not give the exact pressure within the artery; they only indicate the pressure which is required to compress the artery and the overlying soft parts. The pressure required to compress the arterial walls, however, is very small compared with the blood pressure. It is only 4 mm. Hg. V. Basch estimated the pressure in the radial artery of a healthy man to be 135 to 165 millimetres of mercury.

Variations.—**In children** the blood pressure increases with age, height and weight. In the superficial temporal artery, at 2 to 3 years, it is = 97 mm.; 12 to 13 years, 113 mm. Hg. (*A. Eckert*, c. § 100). The blood pressure is raised immediately after **bodily movements**; it is higher when a person is in the horizontal position than when sitting, and in sitting than in standing. After a cold as well as after a warm bath, the first effect is an increase of blood pressure and of the quantity of urine.

FIG. 104.

Fick's flat spring kymograph.

85. BLOOD PRESSURE IN THE ARTERIES.—The following results have been obtained by experiment on **systemic arteries**:—

(*a*) **Mean Blood Pressure.**—The blood pressure is very considerable, varying within pretty wide limits; in the large arteries of large mammals, and perhaps in man, it = 140 to 160 millimetres [5.4 to 6.4 inches] of a mercurial column.

The following results have been obtained, those marked thus * by Poiseuille, and those + by Volkmann:—

* Carotid, Horse, 161 mm.
\+ " " 122 to 214 mm.
* " Dog, 151 mm.
" " 130 to 190 mm. (*Ludwig*).
\+ " Goat, 118 to 135 mm.
\+ " Rabbit, 90 mm.
\+ Carotid, Fowl, 88 to 171 mm.
\+ Aorta of Frog, 22 to 29 mm.
\+ Gill artery of Pike, 35 to 84 mm.
Brachial artery of Man during an operation, 110 to 120 mm. (*Faivre*). Perhaps too low, owing to the injury.

E. Albert estimated the blood pressure by means of a manometer, placed in connection with the anterior tibial artery of a boy whose leg was to be amputated, to be 100 to 160 mm. Hg. The elevation with each pulse beat was 17 to 20 mm.; coughing raised it to 20 or 30 mm.; tight bandaging of the healthy leg, 15 mm.; while passive elevation of the body, whereby the hydrostastic action of the column of blood was brought into play, raised it 40 mm.

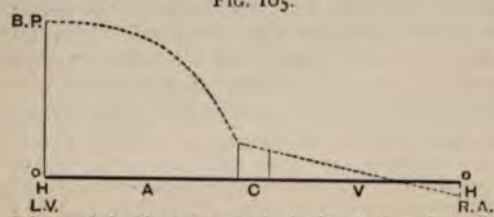
The pressure in the aorta of mammals varies from 200 to 250 mm. Hg. As a general rule, the blood pressure in large animals is higher than in small animals, because in the former the blood channel is considerably longer, and there is greater resistance to be overcome. In very young and in very old animals the pressure is lower than in individuals in the prime of life.

The arterial pressure in the **fœtus** is scarcely half that of the newly-born, while the venous pressure is higher, the difference of pressure between arterial and venous blood being scarcely half so great as in adult animals (*Cohnstein and Zuntz*).

The **arterial blood pressure is highest** in the aorta, and falls toward the smaller vessels, but the fall is very gradual, as shown in Fig. 105. A great fall takes place on passing from the area of the arterioles into the capillary area (C), while it is less in the venous area, and negative near the heart, as indicated in the dotted line passing below the abscissa, so that the pressure is **lowest** in the cardiac ends of the venæ cavæ (compare Fig. 111).

(*b*) **Branching of the Blood Vessels.**—Within the large arteries the blood pressure diminishes relatively little as we pass toward the periphery, because the difference of the resistance in the different sections of large tubes is very small. As soon, however, as the arteries begin to divide frequently, and undergo a considerable diminution in their lumen, the blood pressure in them rapidly diminishes, because the propelling energy of the blood is much weakened, owing to the resistance which it has to overcome (§ 99).

FIG. 105.



Scheme of the blood pressure, in A, the arteries; C, capillaries, and V, veins; O–O, is the abscissa or line of no pressure; L. V., left ventricle, and R. A. right auricle; B. P., the height of the blood pressure.

(*c*) **Amount of Blood.**—The blood pressure is increased with *greater filling of the arteries*, and *vice versâ*; hence it—

Increases.	*Decreases.*
1. With increased and accelerated action of the heart;	1. During diminished and enfeebled action of the heart;
2. In plethoric persons;	2. In anæmic persons;
3. After considerable increase of the quantity of blood by direct transfusion, or after a copious meal.	3. After hemorrhage or considerable excretions from the blood by sweating, the urine, severe diarrhœa.

The blood pressure does not vary in the same proportion as the variations in the amount of blood. The vascular system, in virtue of its muscular tissue, has the property, within liberally wide limits, of accommodating itself to larger or smaller quantities of blood (*C. Ludwig and Worm Müller*, § 102, *d*). [In fact, a large amount of blood may be transfused without materially raising the blood pressure.] Small and moderate hemorrhages (in the dog to 2.8 per cent. of the body weight) have no obvious effect on the blood pressure. After a slight loss of blood the pressure may even rise (*Worm Müller*). If a large amount of blood be withdrawn, it causes a great fall of the blood pressure, and when hemorrhage occurs to 4–6 per cent. of the body weight, the blood pressure = 0. The transfusion of a *moderate* amount of blood does not raise the mean arterial blood pressure. There are important practical deductions from these experiments, viz., that the arterial blood pressure cannot be diminished directly by moderate bloodletting, and that the blood pressure is not necessarily high in plethoric persons.]

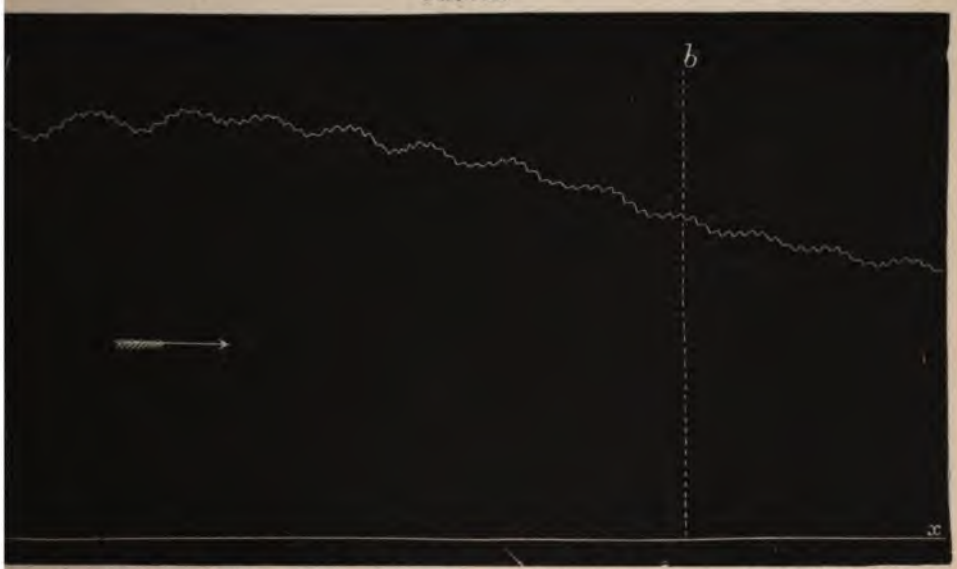
(*d*) **Capacity of the Vessels.**—The arterial pressure rises when the capacity of the arterial system is diminished, and conversely. The circularly-disposed smooth muscular fibres of the arteries are the chief agents concerned in this process. When they relax, the arterial blood pressure falls, and when they contract, it rises. These actions of muscular fibres are controlled and regulated by the action of the vasomotor nerves (§ 371).

(*e*) **Collateral Vessels.**—The arterial pressure within a *given area* of the vascular system must rise or fall according as the neighboring areas are diminished, whether by the application of pressure, or a ligature, or are rendered impervious, or as these areas dilate. The application of cold or warmth to limited areas of the body—increasing or diminishing the atmospheric pressure on a part—the paralysis or stimulation of certain vasomotor areas (§ 371), all produce remarkable variations in the blood pressure. [The effect of dilatation of a large vascular area on the arterial pressure is well shown by what happens when the blood vessels of the abdomen are dilated. Divide both vagi in the neck of a

rabbit and stimulate the **central end** of the **superior cardiac** or **depressor nerve**; after a few seconds, the blood vessels of the abdomen dilate, and gradually there is a steady fall of the blood pressure in the systemic arteries. Fig. 106 is a blood-pressure tracing showing the height of the blood pressure before stimulation, *a*. The stimulation was continued from *a* to *b*, and after a certain *latent* period there is a steady fall of the blood pressure.]

(*f*) **Respiratory Undulations.**—The arterial pressure also undergoes regular variations or undulations owing to the respiratory movements. These undulations are called *respiratory undulations* (Figs. 102 and 107). Stated broadly, during every strong inspiration the blood pressure rises, and during expiration it falls (§ 74). This is not quite correct. These undulations may be explained by the fact that, with every expiration, the blood in the aorta is subjected to an increase of pressure through the compressed air in the chest; with every inspiration, on the other hand, it is diminished, owing to the rarefaction of the air in the lungs acting

FIG. 106.



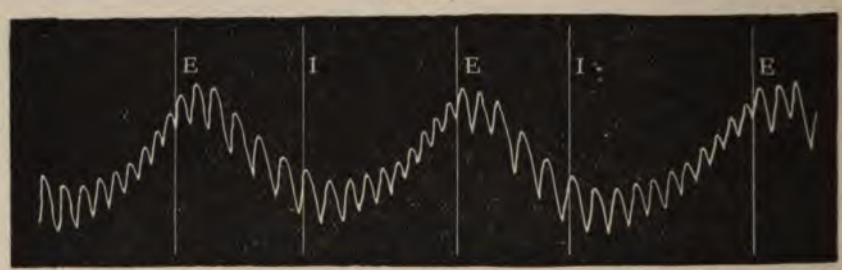
Kymographic tracing showing the effect on the blood pressure of stimulation of the central end of the depressor nerve in the rabbit after section of both vagi in the neck. Stimulation began at *a* and ended at *b*; *o* – *x*, the abscissa.

upon the aorta. Besides, the inspiratory movements of the chest aspirate blood from the venæ cavæ toward the heart, while expiration retards it, and thus influences the blood pressure. The undulations are most marked in the arteries lying nearest to the heart. The respiratory undulations are due in part to a stimulation or condition of excitement of the vasomotor centre, which runs parallel with the respiratory movements. This stimulation of the vasomotor centre causes the arteries to contract, and thus the blood pressure is raised. The variations in the pressure which depend upon a varying activity of the vasomotor centre are known as the "curves of Traube and Hering." Fig. 107 shows the carotid blood-pressure tracing of a dog. In this curve, when inspiration begins (I) the blood pressure is still falling slightly, but gradually rises until it reaches its maximum shortly after the beginning of expiration (E). [The maxima and minima of the respiratory and blood-pressure curves do not coincide exactly, but in addition the *number* of pulse beats is greater in the ascent than in the descent.

This is well marked in a blood-pressure tracing from a dog's carotid (Fig. 107), while in a rabbit this difference of the pulse rate is but slightly marked (Fig. 106). The smaller number of pulse beats during the descent, *i.e.*, during the greater part of expiration—is due to the activity of the cardio-inhibitory centre in the medulla oblongata. This is proved by the fact that section of both vagi in the dog causes the difference of pulse rate to disappear, while other conditions remain the same as before, except that the heart beats more rapidly. It would seem that, during the ascent, the cardio-inhibitory centre is comparatively inactive. It is clear, therefore, that the **respiratory** and **cardio-inhibitory centres** in the medulla oblongata act to a certain extent in unison, so that it is reasonable to suppose that other centres situated in close proximity to these may also act in unison with them, or, as it were, "in sympathy." As already stated, the **vaso-motor centre** is also in action during a particular part of the time.]

[If a dog be curarized and **artificial respiration** established, the respiratory undulations still occur, although in a modified form. In artificial respiration, the mechanical conditions, as regards the intra-thoracic pressure, are exactly the reverse of those which obtain during ordinary respiration. Air is forced into the chest during artificial respiration, so that the pressure within the chest is increased during inspiration, while in ordinary inspiration the pressure is diminished. Thus, the same mechanical explanation will not suffice for both cases.]

FIG. 107.



Carotid blood-pressure tracing of dog; vagi not divided; I = inspiration, E = expiration (*Stirling*).

If the artificial respiration be suddenly interrupted in a curarized animal, the blood pressure rises steadily and rapidly. This rise is due to the stimulation of the vasomotor centre in the medulla oblongata by the impure blood. This causes contraction of the small arteries throughout the body, which retards the outflow from the large arteries, and thus the pressure within them is raised. [Stated broadly, the arterial pressure depends on the **central** organ—the heart, and on the condition of the **peripheral** organs—the small arteries. Both are influenced by the nervous system. If the action of the vasomotor centre be eliminated by dividing the spinal cord in the cervical region, arrest of the respiration causes a very slight rise of the blood pressure; hence, it is evident that venous blood acts but slightly on the heart, or on any local peripheral nervous mechanism, or on the muscular fibres of the arteries. This experiment shows that it is the vasomotor centre which is specially acted upon by the venous blood.]

[**Traube-Hering Curves.**—The following experiment proves that the varying activity of the vasomotor centre suffices to produce undulations in the blood-pressure tracing. Take a dog, curarize it, expose both vagi and establish artificial respiration; then estimate the blood pressure in the carotid. After section of the vagi, the heart will continue to beat more rapidly, but it will be undisturbed by the cardio-inhibitory centre. Thus the central factor in the causation of the blood pressure remains constant. Suddenly interrupt the respiration, and, as already stated, the blood pressure will rise steadily and uniformly, owing to the stimu-

lation of the vasomotor centre by the venous blood. In this case the *peripheral* factor, or state of tension of the small arteries throughout the body, is influenced by the condition of the nerve centre, which controls their action. After a time, the blood-pressure tracing shows a series of bold curves higher than the original tracing. These can only be due to an alteration in the state of the small arteries, brought about by a condition of rythmical activity of the vasomotor centre. These curves were described and figured by Traube, and are called the Traube or Traube-Hering curves. As in other conditions, stimulation causes exhaustion, and soon the venous blood paralyzes the vasomotor centre and the small arteries relax, blood flows freely out of the larger arteries, and the blood pressure rapidly sinks. Variations in the blood pressure have been observed after a mechanical pump has been substituted for the heart, *i.e.*, after all respiratory movements have been set aside, so that the only factor which would account for the phenomena of the Traube-Hering curves is the variation in the peripheral resistance in the small arteries, determined by the condition of the vasomotor centre.]

Variations.—The respiratory undulations of the blood pressure become more pronounced the greater the force of the respirations, which produce greater variations of the intra-thoracic pressure. In man, the diminution of the pressure within the trachea is 1 mm. Hg. during tranquil inspiration]; while during forced respiration, when the respiratory passage is closed, it may be 57 mm. Conversely, during ordinary expiration, the pressure is increased within the trachea 2–3 mm. Hg., while during forced expiration, owing to the compression of the abdominal muscles, it may reach 87 mm. Hg.

Other Factors.—The increase of the blood pressure during inspiration, as well as the fall during expiration, must in part depend upon the pressure within the abdomen. As the diaphragm descends during inspiration, it presses upon the abdominal contents, including the abdominal vessels, whereby the blood pressure must be increased. The reverse effect occurs during expiration (*Schweinburg*). [Section of both phrenic nerves and opening of the abdominal cavity cause the respiratory undulations almost entirely to disappear. The respiratory undulations, therefore, depend in great part upon the changes of the abdominal pressure and the effect of these changes on the amount of blood in the abdominal vessels. When making a blood-pressure experiment, pressure upon the abdomen of the animal with the hand causes the blood pressure to rise rapidly.]

(*g*) **Variations with each Pulse Beat.**—The mean arterial pressure undergoes a variation with each heart beat or *pulse beat*, causing the so-called **pulsatory undulations** (Fig. 107). The mass of blood forced into the arteries with each ventricular systole causes a positive wave and an increase of the pressure corresponding with it, which, of course, corresponds in its development and in its form with the pulse curve.

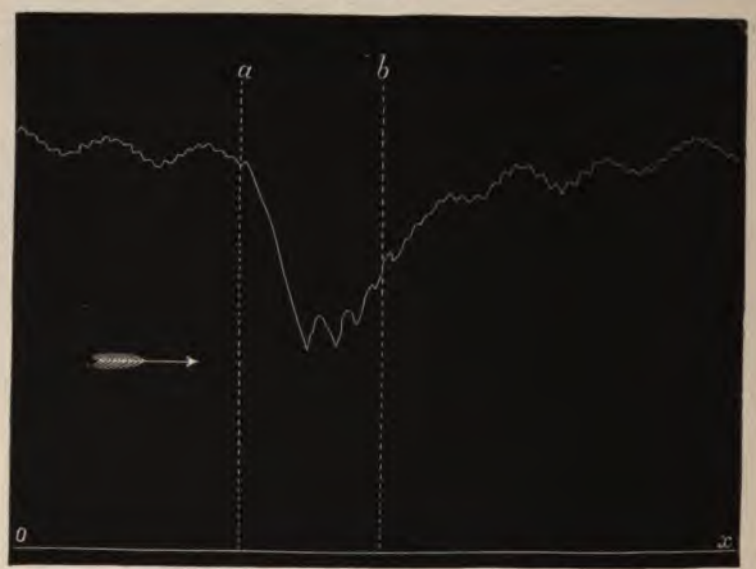
In the large arteries, Volkmann found the increase during the heart beat to be $= \frac{1}{16}$ (horse) and $\frac{1}{17}$ (dog) of the total pressure.

None of the apparatus described in § 84 gives an exact representation of the pulse curve. They all show simply a rise and fall, a simple curve. The sphygmograph alone gives a true expression of the undulations in the blood pressure which are due to the heart beat.

(*h*) **Arrest of the Heart's Action.**— If the heart's action be arrested or interrupted by continued **stimulation of the vagus**, or by high positive respiratory pressure, the arterial blood pressure falls enormously, while it rises in the veins as the blood flows into them from the arteries to equilibrate the difference of pressure in the two sets of vessels. This experiment shows that, even when the difference of pressure is almost entirely set aside, the passive blood presses upon the arterial walls, *i.e.*, on account of the overfilling of the blood vessels a slight pressure is exerted upon the walls, even when there is no circulation. [As already stated, the arterial pressure depends on the condition of the central organ—the heart—and on the peripheral organs—the small arteries. If the action of the heart be arrested, then the blood pressure rapidly falls. Fig. 108 shows the effect on the blood pressure of arresting the action of the heart by stimulation of the **peripheral end of the vagus.** There is a sudden fall of the arterial pressure, as shown by the rapid fall of the curve from *a*.]

[**Variations in Animals.**—The pressure in the arterial system depends upon the balance between the inflow and outflow, *i. e.*, upon the heart and the state of the arterioles. But it is to be noted that the central factor, the heart, varies in different animals. In the rabbit, the heart normally beats rapidly, so that section of the vagi does not cause any great increase in the number of beats, nor is the blood pressure much raised thereby. In the dog, on the other hand, the beats are considerably increased by section of the vagi, while the blood pressure rises considerably. Atropin paralyzes the cardiac terminations of the vagus, and thereby trebles the number of heart beats in the dog, while it only raises it 25 per cent. in the rabbit; in man, again, the number may be doubled. As Brunton has shown, this difference of the initial number of heart beats and the action of the vagus have important relations to the action of drugs on the blood pressure. For example, if an intact rabbit be caused to inhale **amyl nitrite**, the blood pressure falls at once and rapidly, while in the dog the fall may be slight. The pulse of the dog, however, is greatly accelerated, so much so as to be nearly as rapid as that of the rabbit. In both, the vessels are dilated, but in the dog, notwithstanding this dilatation, which *per se* would cause the pressure to fall, the heart of the dog beats now so rapidly as to compensate for this, and thus keeps the blood pressure nearly normal; while the increased rate of beating in the rabbit is not sufficient for this purpose. If the vagi in the dog be divided, the subsequent inhalation of amyl nitrite causes a fall of blood pressure like that in the rabbit (*Brunton*).]

FIG. 108.



Blood-pressure tracing taken with a mercurial kymograph from the carotid of a rabbit. $o-x$, abscissa; stimulation of vagus begun at a and stopped at b.

[**Relation of Blood Pressure to Pulse Rate.**—When the blood pressure rises in an intact animal, as a rule the pulse rate falls, owing to stimulation of the vagus centre increasing the cardio-inhibitory action, while a fall of blood pressure is accompanied by an increase of the number of pulse beats for the opposite reason, the action of the medullary cardio-inhibitory centre being increased. But the blood pressure may be increased either by the action of the heart or the arterioles. If we divide the vagi the pulse beats more quickly, and in some animals the blood pressure rises; in this case, the rise in the two curves occurs together, and if the vagi be stimulated there is a sudden fall of the blood pressure, due to arrest of the heart's action, so that again the two curves are parallel. If the arterioles contract the blood pressure rises, but by and by the pulse rate falls, owing to the cardio-inhibitory action of the vagus; while, on the other hand, if the arterioles are dilated, the blood pressure falls, and the heart beats faster.

Thus, in both of these cases the pulse curve and blood-pressure curve run in opposite directions. These results only obtain when the vagi are intact (*Brunton*).]

[The increase in the pulse rate and blood pressure following section of the vagi do not run parallel. Both sooner or later reach a maximum, but the blood pressure gradually falls to or below the normal, while the pulse rate remains above the normal (*Münzel*).]

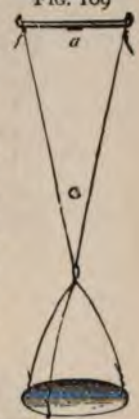
For the **effects of the nervous system** upon the blood pressure see § 371.

Pathological.—In persons suffering from granular or contracted kidney and sclerosis of the arteries, in lead poisoning, and after the injection of ergotin, which causes contraction of the small arteries, it is found, on employing the method of v. Basch, that the blood pressure is raised. It is also increased in cases of cardiac hypertrophy with dilatation, and by digitalis in cardiac affections, while it falls after the injection of morphia. The blood pressure falls in fever, a fact also indicated in the sphygmogram (§ 69), and it is low in chlorosis and phthisis.

86. BLOOD PRESSURE IN THE CAPILLARIES.—Methods.—Direct estimation of the capillary pressure is not possible, on account of the smallness of the capillary tubes. If a glass plate of known dimensions be placed on a portion of the skin rich in blood vessels, and if it be weighted until the capillaries become pale, we obtain approximately the pressure necessary to overcome the capillary pressure. N. v. Kries placed a small glass plate (Fig. 109) 2.5–5 sq. mm., on a suitable part of the skin, *e. g.*, the skin at the root of the nail on the terminal phalanx, or on the ear in man, and on the gum in rabbits. Into a scale pan attached to this, weights were placed until the skin became pale. The pressure in the capillaries of the hand, when the hand is raised, Kries found to be 24 mm. Hg.; when the hand hangs down, 54 mm. Hg.: in the ear, 20 mm., and in the gum of a rabbit, 32 mm.

Roy and Graham Brown compressed from below transparent vascular membranes against a glass plate by means of an elastic bag connected with a manometer, while the variations in the capillaries were observed from above by a microscope.

FIG. 109



V. Kries's apparatus for capillary pressure. *a*, square of glass.

Conditions influencing Capillary Pressure.—The capillary blood pressure in a given area **increases** (1) When the afferent small arteries dilate, so that the blood-pressure within the large arteries is propagated more easily into them. (2) By increasing the pressure in the small afferent arteries. (3) By narrowing the diameter of the veins leading from the capillary area. Closure of the veins may quadruple the pressure. (4) By increasing the pressure in the veins (*e. g.*, by altering the position of a limb). A **diminution** of the capillary pressure is caused by the opposite conditions.

Changes in the **diameter of the capillaries** influence the internal pressure. We have to consider the movements of the capillary wall itself as well as the pressure, swelling, and consistence of the surrounding tissues. The resistance to the blood stream is greatest in the capillary area, and it is evident that the blood in a long capillary must exert more pressure at the commencement than at the end of the capillary; in the middle of the capillary area the blood pressure is just about one-half of the pressure within the large arteries (*Donders*). The capillary pressure must also vary in different regions of the body. Thus, the pressure within the intestinal capillaries, in those constituting the glomeruli of the kidney, and in those of lower limbs when the person is in the erect posture, must be greater than in other regions, depending in the former cases partly upon the double resistance caused by two sets of capillaries, and in the latter case partly on purely hydrostatic causes.

87. BLOOD PRESSURE IN THE VEINS.—In the **large venous trunks** near the heart (innominate, subclavian, jugular) a mean **negative pressure** of about —0.1 mm. Hg. prevails (*H. Jacobson*). Hence, the lymph stream can flow unhindered. As the distance of the veins from the heart increases, there is a *gradual* increase of the lateral pressure; in the external facial vein (sheep) = + 3 mm.; brachial, 4.1 mm., and in its branches 9 mm.; crural, 11.4 mm. [The pressure is said to be *negative* when it is less than that of the atmosphere. The gradual fall of the blood pressure from the capillary area (C) to the venous area (V) is shown in Fig. 108, while within the thorax, where the veins terminate in the right auricle, the pressure is negative.]

Modifying Conditions.—(1) All conditions which *diminish the difference of pressure* between the arterial and venous systems *increase the venous pressure*, and *vice versâ*.

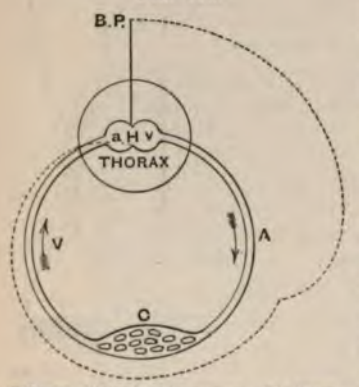
(2) General plethora of blood increases it; anæmia diminishes it.

(3) Respiration, or the **aspiration of the thorax**, affects specially the pressure in the veins near the heart; during inspiration, owing to the diminished tension, blood flows toward the chest, while during expiration it is retarded. The effects are greater, the deeper the respiratory movement, and these may be very great when the respiratory passages are closed (§ 60).

[When a vein is exposed at the root of the neck, it collapses during inspiration, and fills during expiration. The respiratory movements do not affect the venous stream in peripheral veins. The veins of the neck and face become distended with blood during crying, and on making violent expiratory efforts, as in blowing upon a wind instrument. Every surgeon is acquainted with the fact that air is particularly liable to be sucked into the veins, especially in operations near the root of the neck. This is due to the negative intra-thoracic pressure occurring during inspiration.]

(4) **Aspiration of the Heart.**—Blood is sucked or aspirated into the auricles when they dilate (p. 100), so that there is a double aspiration—one synchronous with inspiration, and the other, which is but slight, synchronous with the heart beat. There is a corresponding retardation of the blood stream in the venæ cavæ, caused by the contraction of the auricle (p. 99, *a*). The respiratory and cardiac undulations are occasionally observable in the jugular vein of a healthy person (§ 99).

FIG. 110.



Scheme of the blood pressure. H, heart; *a*, auricle; *v*, ventricle; A, arterial; C, capillary; and V, venous areas. The circle indicates the parts within the thorax; B. P., pressure in the aorta.

(5) Change in the *position* of the limbs or of the body, for hydrostatic reasons, greatly alters the venous pressure. The veins of the lower extremity bear the greatest pressure, while at the same time they contain most muscle (*K. Bardeleben*, § 65). Hence, when these muscles from any cause become insufficient, dilatations occur in the veins, giving rise to the production of **varicose veins.**

[Braune showed that the femoral vein under Poupart's ligament collapsed when the lower limb was rotated outward and backward, but filled again when the limb was restored to its former position. All the veins which open into the femoral vein have valves, which permit blood to pass into the femoral vein, but prevent its reflux. This mechanism acts to a slight degree as a kind of suction and pressure apparatus when a person walks, and thus favors the onward movement of the blood.]

[(6) **Muscular Movements.**—Veins which lie between muscles are compressed when these muscles contract, and as valves exist in the veins, the flow of blood is accelerated toward the heart; if the outflow of the blood be obstructed in any way, then the venous pressure on the distal side of the obstruction may be greatly increased. When a fillet is tied on the upper arm, and the person moves the muscles of the forearm, the superficial veins become turgid, and can be distinctly traced on the surface of the limb.]

(7) **Gravity** exercises a greater effect upon the blood stream in the extensile veins than upon the stream in the arteries. It acts on the distribution of the blood, and thus indirectly on the motion of the blood stream. It favors the emptying of descending veins, and retards the emptying of ascending veins, so that the pressure becomes less in the former and greater in the latter. If the position of the limb be changed, the conditions of pressure are also altered. If a person be suspended with the head hanging downward, the face soon becomes turgid, the position of the body favoring the inflow of blood through the arteries, and retarding the outflow through the veins. If the hand hangs down it contains more blood in the veins than if it is held for a short time over the head, when it becomes pale and bloodless. [As Lister has shown, the condition of the vessels

in the limb is influenced not only by the position of the limb, but also by the fact that a nervous mechanism is called into play.]

[**Ligature of the portal vein** causes congestion of the rootlets and dilatation of all the blood vessels in the abdomen; gradually nearly all the blood of the animal accumulates within its belly, so that, paradoxical as it may seem, an animal may be bled into its own belly. As a consequence of *sudden* and *complete* ligature of this vein, the arterial blood pressure gradually and rapidly falls, and the animal dies very quickly. If the ligature be removed before the blood pressure falls too much, the animal may recover. Schiff and Lautenbach regard the symptoms as due chiefly to the action of a poison, for when the blood of the portal vein in an animal treated in this way is injected into a frog, it causes death within a few hours, while the ordinary blood of the portal vein has no effect.]

[**Ligature of the Veins of a Limb.**—The effect of ligaturing or compressing *all* the veins of a limb is well seen in cases where a bandage has been applied too tightly. It leads to congestion and increase of pressure within the veins and capillaries, increased transudation of fluid through the capillaries, and consequent *œdema* of the parts beyond the obstruction. Ligature of *one* vein does not always produce œdema, but if several veins of a limb be ligatured, and the vasomotor nerves be divided at the same time, the rapid production of œdema is ensured. In pathological cases the pressure of a tumor upon a large vein may produce similar results (§ 203).]

88. BLOOD PRESSURE IN THE PULMONARY ARTERY.—Methods.—(1) **Direct estimation** of the blood pressure in the pulmonary artery by opening the chest was made by C. Ludwig and Beutner (1850). Artificial respiration was kept up, and the manometer was placed in connection with the left branch of the pulmonary artery. The circulation through the left lung of cats and rabbits was thereby completely cut off, and in dogs to a great extent interrupted. There was an additional disturbing element, viz., the removal of the elastic force of the lungs, owing to the opening of the chest, whereby the venous blood no longer flowed normally into the right heart, while the heart itself was under the full pressure of the atmosphere. The estimated pressure in the dog = 29.6; in the cat = 17.7; in the rabbit, 12 mm. Hg., *i. e.*, in the dog 3 times, the rabbit 4 times, and the cat 5 times less than the carotid pressure.

(2) Hering (1850) experimented upon a calf with ectopia cordis. He introduced glass tubes directly into the heart, by pushing them through the muscular walls of the ventricles. The blood rose to the height of 21 inches in the right tube, and 33.4 inches in the left.

(3) Faivre (1856) introduced a catheter through the jugular vein into the right ventricle, and placed it in connection with a recording tambour.

Indirect measurements have been made by comparing the relative thickness of the walls of the right and left ventricles, or the walls of the pulmonary artery and aorta.

Beutner and Marey estimated the relation of the pulmonary artery to the aortic pressure as 1 to 3; Goltz and Gaule as 2 to 5; Fick and Badoud found a pressure of 60 mm. in the pulmonary artery of the dog, and in the carotid 111 mm. Hg. The blood pressure within the pulmonary artery of a child is relatively higher than in the adult.

Elastic Tension of Lungs.—The lungs within the chest are kept in a state of distention, owing to the fact that a negative pressure exists on their outer pleural surface. When the glottis is open, the inner surface of the lung and the walls of the capillaries in the pulmonary air vesicles are exposed to the full pressure of the air. The heart and large blood vessels within the chest are not exposed to the full pressure of the atmosphere, but only to the pressure which corresponds to the atmospheric pressure *minus* the pressure exerted by the elastic traction of the lungs (§ 60). The trunks of the pulmonary artery and veins are subjected to the same conditions of pressure. The elastic traction of the lungs is greater the more they are distended. The blood of the pulmonary capillaries will, therefore, tend to flow toward the large blood vessels. As the elastic traction of the lungs acts chiefly on the thin-walled pulmonary veins, while the semilunar valves of the pulmonary artery, as well as the systole of the right ventricle, prevent the blood from flowing backward, it follows that *the blood in the capillaries of the lesser circulation must flow toward the pulmonary veins.*

If tubes with thin walls be placed in the walls of an elastic distensible bag, the lumen of these tubes changes according to the manner in which the bag enclosing them is distended. If the bag be directly inflated so as to increase the pressure within it, the lumen of the tubes is diminished (*Funke and Latschenberger*). If

the bag be placed within a closed space, and the tension within this space be diminished so that the bag thereby becomes distended, the tubes in its wall dilate. In the latter case—viz., by negative aspiration—the lungs are kept distended within the thorax, hence the blood vessels of the lungs containing air are wider than those of collapsed lungs (*Quincke and Pfeiffer, Bowditch and Garland, De Jäger*). Hence also, more blood flows through the lungs distended within the thorax than through collapsed lungs. The *dilatation* which takes place during *inspiration* acts in a similar manner. The negative pressure that obtains within the lungs during inspiration causes a considerable dilatation of the pulmonary veins, into which the blood of the lungs flows readily, while the blood under high pressure in the thick-walled pulmonary artery scarcely undergoes any alteration. The velocity of the blood stream in the pulmonary vessels is accelerated during inspiration (*De Jäger, Lalesque*). The blood pressure in the pulmonary circuit is raised when the lungs are inflated. Contraction of small arteries, which causes an increase of the blood pressure in the systemic circulation, also raises the pressure in the pulmonary circuit, because more blood flows to the right side of the heart.

The vessels of the pulmonary circulation are very distensible and their **tonus** is slight. [Occlusion of one branch of the pulmonary artery does not raise the pressure within the aorta. Even when one pulmonary artery is plugged with an embolon of paraffin, the pressure within the aortic system is not raised (*Lichtheim*). When a large branch of the pulmonary artery becomes impervious, the obstruction is rapidly compensated for, and this is not due to the action of the nervous system. The vasomotor system has much less effect upon the pulmonary blood vessels than upon those of the systemic circulation. The compensation seems to be due chiefly to the great distensibility and dilatation of the pulmonary vessels (*Lichtheim*).] We know little of the effect of physiological conditions upon the pulmonary artery. According to Lichtheim *suspension of the respiration* causes an increase of the pressure. [In one experiment he found that the pressure within the pulmonary artery was increased, while it was not increased in the carotid, and he regards this experiment as proving the existence of vasomotor nerves in the lung.]

During the act of great **straining**, the blood at first flows rapidly out of the pulmonary veins, and afterward ceases to flow, because the inflow of blood into the pulmonary vessels is interfered with. As soon as the straining ceases, blood flows rapidly into the pulmonary vessels (*Lalesque*).

Severini found that the blood stream through the lungs is greater and more rapid when the lungs are filled with air rich in CO_2 than when the air within them is rich in O. He supposes that these gases act upon the vascular ganglia within the lung, and thus affect the diameter of the vessels.

Pathological.—Increase of the pressure within the area of the pulmonary artery occurs frequently in man, in certain cases of heart disease. In these cases the second pulmonary sound is always accentuated, while the elevation caused thereby in the cardiogram is always more marked and occurs earlier (§ 52). Electrical and mechanical stimulation of abdominal organs raises the blood pressure in the pulmonary artery (*Morel*).

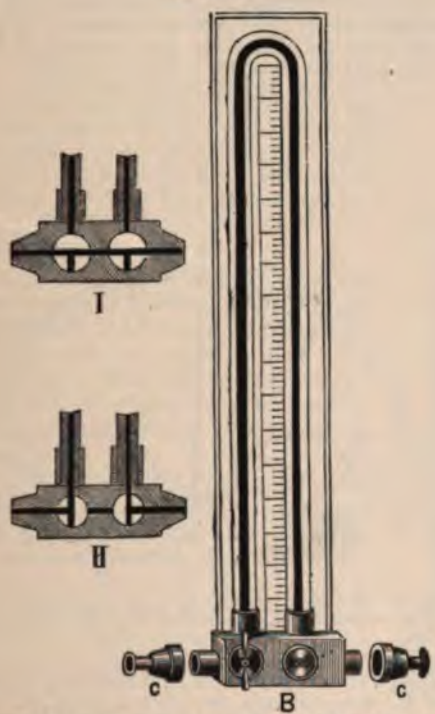
[**The action of drugs** on the pulmonary circulation may be tested by Holmgren's apparatus (§ 94), which permits of distention of the lung and retention of the normal circulation in the frog. Cold contracts the pulmonary capillaries to one-third of their diameter, and anæsthetics arrest the pulmonary circulation, chloroform being most and ether least active, while ethidene is intermediate in its effect.]

[**Influence of the Nervous System.**—The pulmonary circulation is much less dependent on the nervous system than the systemic circulation. Very considerable variations of the blood pressure within the other parts of the body may occur, while the pressure within the right heart and pulmonary artery is but slightly affected thereby. The pressure is increased by electrical stimulation of the medulla oblongata, and it falls when the medulla is destroyed. Section and stimulation of the central or peripheral ends of the vagi, stimulation of the

splanchnics, and of the central end of the sciatic, have but a minimal influence on the pressure of the pulmonary artery (*Aubert*).]

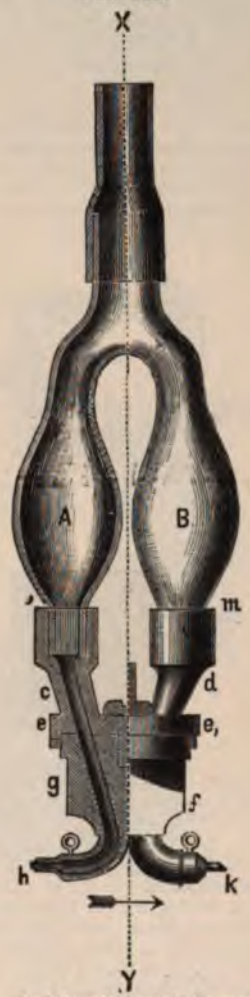
89. VELOCITY OF THE BLOOD STREAM.—Methods: (1) A. W. Volkmann's Hæmadromometer (1850).—A glass tube of the shape of a hair-pin, 60–130 cm. long and 2 or 3 mm. broad, with a scale etched on it, or attached to it, is fixed to a metallic basal plate, B, so

FIG. 111.



Volkmann's hæmadromometer (B). I, blood flows from artery to artery; II, blood must pass through the glass tube of B; *c*, *c*, cannulæ for the divided artery.

FIG. 112.



Ludwig and Dogiel's rheometer. X, Y, axis of rotation; A, B, glass bulbs; *h*, *k*, cannulæ inserted in the divided artery; *e*, e_1, rotates on *g*, *f*; *c*, *d*, tubes.

that each limb passes to a stop-cock with three channels. The basal plate is perforated along its length, and carries at each end short cannulæ, *c*, *c*, which are tied into the ends of a divided artery. The whole apparatus is first filled with water [or, better, with salt solution]. The stop-cocks are moved simultaneously, as they are attached to a toothed wheel, and have at first the position given in Fig. 111, I, so that the blood simply flows through the hole in the basal piece, *i. e.*, directly from one end of the artery to the other. If at a given moment the stop-cock is turned in the direc-

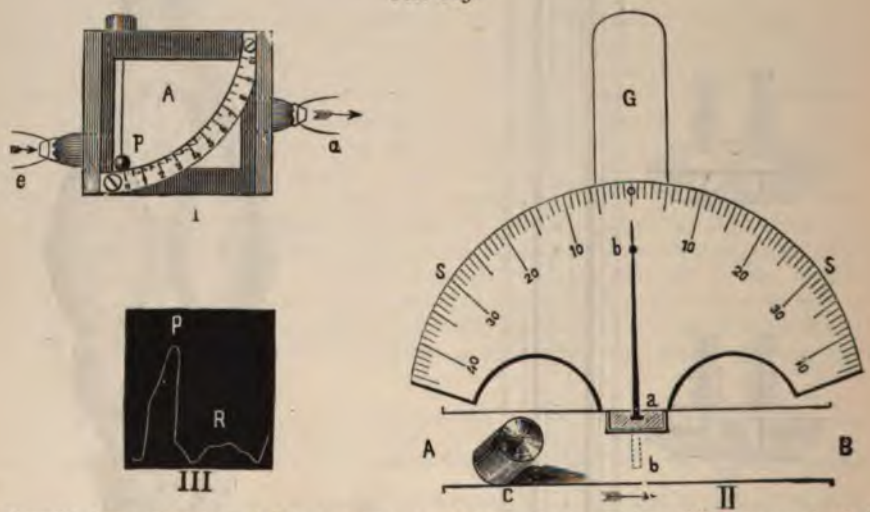
tion indicated in Fig. 111, II, the blood has to pass through the glass tube, and the time it takes to make the circuit is noted; and as the length of the tube is known, we can easily calculate the velocity of the blood. The method has very obvious defects arising from the narrowness of the tube; the introduction of such a tube offers new resistance, while there are no respiratory or pulse variations observable in the stream in the glass tube.

Volkmann found the **velocity** to be in the carotid (dog) = 205 to 357 mm.; carotid (horse) = 306; maxillary (horse) = 232; metatarsal = 56 mm. per second.

(2) C. Ludwig and Dogiel (1867) devised a "**stromuhr**" or **rheometer** for measuring the amount of blood which passed through an artery in a given time (Fig. 112).

It consists of two glass bulbs, A and B, of exactly the same capacity. These bulbs communicate with each other above, their lower ends being fixed by means of the tubes, *c* and *d*, to the metal disk, *e*, e_1. This disk rotates round the axis, X, Y, so that, after a complete revolution, the tube *c* communicates with *f*, and *d* with *g*; *f* and *g* are provided with horizontally placed cannulæ, *h* and *k*, which are tied into the ends of the divided artery. The cannula *h* is fixed in the central

FIG. 113.



I. Vierordt's hæmatachometer. A, glass; *e*, entrance; *a*, exit cannula; *p*, pendulum. II. Dromograph. A, B, tube inserted in artery; C, lateral tube connected with a manometer; *b*, index moving in a caoutchouc membrane, *a*; G, handle. III. Curve obtained by dromograph.

end, and *k* in the peripheral end of the artery (*e. g.*, carotid); the bulb, A, is filled with oil, and B with defibrinated blood; at a certain moment the communication through *h* is opened, the blood flows in, driving the oil before it, and passes into B, while the defibrinated blood flows through *k* into the peripheral part of the artery. As soon as the oil reaches *m*—a moment which is instantly noted, or, what is better, inscribed upon a revolving cylinder—the bulbs, A, B, are rotated upon the axis, X, Y, so that B comes to occupy the position of A. The same experiment is repeated, and can be continued for a long time. The quantity of blood which passes in the unit of time (1 sec.) is calculated from the time necessary to fill the bulb with blood. Important results are obtained by means of this instrument.

[Suppose 50 c.cm. of blood are delivered in 100 secs., then 1 c.cm. flows through in 2 secs. Suppose the sectional area of the artery to be 3¼ mm. As the velocity is measured by the ratio of the quantity to the sectional area, then $\frac{5000}{3.14} = 159$ mm. per second.]

[As peptone injected into the blood prevents it from coagulating (dog), this fact has been turned to account in using the rheometer.]

(3) **Vierordt's Hæmatachometer** (1858) consists of a small metal box (Fig. 113, I) with parallel glass sides. To the narrow sides of the box are fitted an inlet, *e*, and an exit cannula, *a*. In its interior is suspended, against the entrance opening, a pendulum, *p*, whose vibrations may be

read off on a curved scale. [This instrument, as well as Volkmann's apparatus, has only an historical interest.]

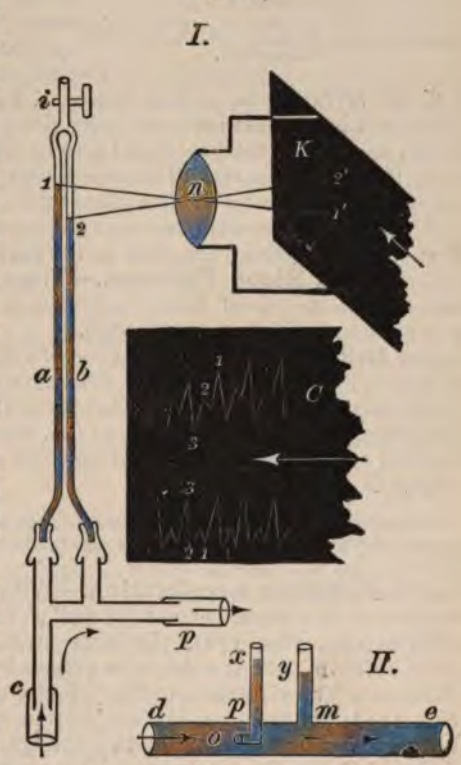
(4) **Chauveau** and **Lortet's Dromograph** (1860) is constructed on the same principle. A tube A, B (Fig. 113), of sufficient diameter, with a side tube fixed to it, C, which can be placed in connection with a manometer, is introduced into the carotid artery of a horse. At *a* a small piece is cut out and provided with a covering of gutta-percha which has a small hole in it; through this a light pendulum, *a*, *b*, with a long index, *b*, projects into the tube, *i. e.*, into the blood current, which causes the pendulum to vibrate, and the extent of the vibrations can be read off on a scale, S, S. G is an arrangement to permit the instrument to be held. Both this and the former instrument are tested beforehand with a stream of water sent through them with varying velocities.

(5) **Cybulski's Photohæmatachometer.**—When fluid flows into a tube (Fig. 114, II, *de*) in the direction of the arrow, the fluid stands higher in the manometer *p* than in *m*. The tube *my* indicates the lateral pressure, but *px* gives this *plus* the velocity of the fluid (p. 132). The velocity of the current may be estimated from the difference in the level in the two tubes.

Pitot's tube as used by *Cybulski* is bent at a right angle (I, *cp*), the end *c* being inserted and tied into the central, and *p* into the peripheral, part of a divided artery. As the blood flows through the tube, the blood rises higher in *a* than *b*.

To avoid having the manometers *a* and *b* too long, they are connected with each other by a capillary tube filled with air and provided above with a stop-cock *i*. The blood is allowed to rise to the height of 1 and 2, the stop-cock *i* is closed, and practically an air manometer is made, which shows a marked difference in the level of the blood of the two tubes. The level of the blood in 1 and 2 is continually changed by the movements of the heart and those of respiration, and these variations are photographed by means of a camera *n* with a rapidly moving plate *k*.

FIG. 114.



I. Scheme of the photohæmatachometer; II. Pitot's tube.

Fig. 114, C, shows a curve obtained from the carotid of a dog. The velocity of the current at $1_1 - 1 = 238$ mm., in the phase $2_1 - 2 = 225$ mm., and at $3_1 - 3 = 177$ mm. The velocity is greatest at the end of inspiration and the beginning of expiration. Asphyxia increases it at first. Paralysis of the sympathetic increases it, while stimulation of this nerve diminishes it. Section of the vagi increases the velocity, while stimulation diminishes it.

The curve of the velocity may be written off on a smoked glass plate, moving parallel with the index *b*. The dromograph curve, Fig. 113, III, shows the primary elevation, P, and the dicrotic elevation R.

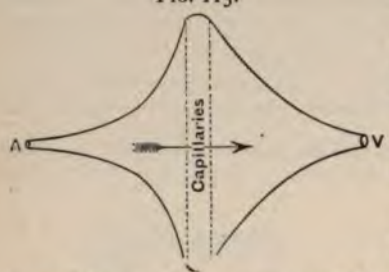
90. **VELOCITY OF THE BLOOD.—Division of Vessels—Arteries.**—In estimating the velocity of the blood, it is important to remember that the sectional area of all the branches of the aorta becomes greater as we proceed from the aorta toward the capillaries, so that the capillary area is 700 times greater than the sectional area of the aorta. As the veins join and form larger trunks, the venous area gradually becomes smaller, but the sectional area of the venous orifices at the heart is greater than that of the corresponding arterial orifices. [We may represent the result as two cones placed base to base (Fig. 115), the bases meeting in the capillary area. The sectional

area of the venous orifice (V) is represented larger than that of the arterial (A). The **increased sectional area** influences the **velocity** of the blood current, while the resistance affects the pressure.]

The common iliacs are an exception; the sum of their sectional areas is less than that of the aorta; the sections of the four pulmonary veins are together less than that of the pulmonary artery.

(2) **Sectional Area.**—*An equal quantity of blood* must pass through every section of the circulatory system, through the pulmonic as well as through the systemic circulation, so that the same amount of blood must pass through the pulmonary artery and aorta, notwithstanding the very unequal blood pressure in these two vessels.

FIG. 115.



Scheme of the sectional area. A, arterial, and V, venous orifice.

(3) **Lumen.**—The velocity of the current, therefore, in various sections of the vessels, must be inversely as their lumen.

(4) **Capillaries.**—Hence, the velocity must diminish very considerably as we pass from the root of the aorta and the pulmonary artery toward the capillaries, so that the **velocity in the capillaries** of mammals = 0.8 millimetre per sec.; frog = 0.53 mm. (*E. H. Weber*); man = 0.6 to 0.9 (*C. Vierordt*). According to A. W. Volkmann, the blood in mammalian capillaries flows 500 times slower than the blood in the aorta, so that the total sectional area of all the capillaries must be 500 times greater than that of the aorta. Donders found the velocity of the stream in the small afferent arteries to be 10 times faster than in the capillaries.

Veins.—The current becomes accelerated in the veins, but in the larger trunks it is 0.5 to 0.75 times less than in the corresponding arteries.

(5) **Mean Blood Pressure.**—The velocity of the blood does not depend upon the *mean* blood pressure, so that it may be the same in congested and in anæmic parts (*Volkmann, Hering*).

(6) **Difference of Pressure.**—On the other hand, the velocity in any section of a vessel is dependent on the difference of the pressure which exists at the commencement and at the end of that particular section of a blood vessel; it depends, therefore, on (1) the *vis a tergo* (*i.e.*, the action of the heart), and (2) on the amount of the resistance at the periphery (dilatation or contraction of the small vessels).

Corresponding to the smaller difference in the arterial and venous pressure in the fœtus (§ 85), the velocity of the blood is less in this case (*Cohnstein and Zuntz*).

(7) **Pulsatory Acceleration.**—With *every pulse beat* a corresponding acceleration of the blood current (as well as of the blood pressure) takes place in the arteries (pp. 169, 176). In large vessels, Vierordt found the increase of the velocity during the systole to be greater by ¼ to ½ than the velocity during the diastole. The variations in the velocity caused by the heart beat are recorded in Fig. 113, obtained by Chauveau's dromograph from the carotid of a horse. The velocity curve corresponds with a sphygmogram—P represents the primary elevation and R the dicrotic wave. This acceleration, as well as the pulse, disappears in the capillaries. A pulsatory acceleration, more rapid during its first phase, is observable in the small arteries, although the arteries themselves are not distended thereby.

(8) **Respiratory Effect.**—Every *inspiration retards* the velocity in the arteries, every *expiration aids* it somewhat; but the value of these agencies is very small.

If we compare what has already been said regarding the effect of the respiration on the contraction and dilatation of the heart and on the blood stream (§ 60), it is clear that **respiration favors the blood stream**, and so does artificial respiration. When artificial respiration is interrupted, the blood stream becomes slower (*Dogiel*). If the suspension of respiration lasts somewhat longer, the current is again accelerated on account of the dyspnœic stimulation of the vasomotor centre (*Heidenhain*) (§ 371, I).

(9) **Modifying Conditions.**—Many circumstances affect the velocity of the blood in the veins. (1) There are *regular* variations in the large veins near the heart due to the *respiration and the movements of the heart* (§§ 50 and 60). (2) *Irregular* variations due to *pressure*, *e. g.*, from contracting muscles (§ 87), *friction* on the skin in the direction or against the direction of the venous current; the *position* of a limb or of the body. The pump-like action of the veins of the groin on moving the leg has been referred to (§ 87). When the lower limb is extended and rotated outward, the femoral vein in the iliac fossa collapses, owing to an internal negative pressure; when the thigh is flexed and raised, it fills under a positive pressure (*Braune*). A similar condition obtains in walking.

91. **CAPACITY OF THE VENTRICLES.**—Vierordt calculated the capacity of the left ventricle from the velocity of the blood stream, and the amount of blood discharged per second by the right carotid, right subclavian, the two coronary arteries, and the aorta below the origin of the innominate artery. He estimated that with every systole of the heart, 172 cubic centimetres (equal to 180 grammes) of blood were discharged into the aorta; this, therefore, must be the capacity of the left ventricle (compare § 83).

92. **THE DURATION OF THE CIRCULATION.**—The time required by the blood to make a **complete circuit** through the course of the circulation was first determined by Hering (1829), in the horse. He injected a 2 per cent. solution of potassium ferrocyanide into a special vein, and ascertained (by means of ferric chloride) when this substance appeared in the blood taken from the corresponding vein on the *opposite* side of the body. The ferrocyanide may also be injected into the central or cardiac end of the jugular vein, and the time noted at which its presence is detected in the blood of the peripheral end of the same vein. Vierordt (1858) improved this method by placing under the corresponding vein of the opposite side a rotating disk, on which was fixed a number of cups at regular intervals. The first appearance of the potassium ferrocyanide is detected by adding ferric chloride to the serum which separates from the samples of blood after they have stood for a time. The duration of the circulation is as follows:—

Horse, ... 31.5 seconds.	Hedgehog, . . . 7.61 seconds.	Duck, ... 10.64 seconds.
Dog, ... 16.7 "	Cat, ... 6.69 "	Buzzard, . . 6.73 "
Rabbit, ... 7.79 "	Goose, ... 10.86 "	Fowl, ... 5.17 "

Results.—When these numbers are compared with the frequency of the normal pulse beat in the corresponding animals, the following deductions are obtained:—

(1) The mean time required for the circulation is accomplished during 27 heart beats, *i. e.*, for man = 32.2 seconds, supposing the heart to beat 72 times per minute.

(2) Generally, the mean time for the circulation in two warm-blooded animals is inversely as the frequency of the pulse beats.

Modifying Conditions.—The time is influenced by the following factors:—

1. **Long vascular channels** (*e. g.*, from the metatarsal vein of one foot to the other foot) require a longer time than short channels (as between the jugulars). The difference may be equal to 10 per cent. of the time required to complete the entire circuit.

2. In **young animals** (with shorter vascular channels and higher pulse rate) the time is shorter than in old animals.

3. **Rapid and energetic** cardiac contractions (as during muscular exercise) diminish the time. Hence rapid and at the same time less energetic contractions (as after section of both vagi), and slow but vigorous systoles (*e. g.*, after slight stimulation of the vagus), have no effect.

C. Vierordt estimated the **quantity of blood** in a man, in the following manner: In all warm-blooded animals, 27 systoles correspond to the time for completing the circulation. Hence, the

total mass of the blood must be equal to 27 times the capacity of the ventricle, *i. e.*, in man, 187.5 grms. × 27 = 5062.5 grms. This is equal to $\frac{1}{13}$ of the body weight in a person weighing 65.8 kilos. (compare § 49.)

It is not to be forgotten that the salt used is to some extent poisonous, but Hermann uses the corresponding innocuous soda salt (25 per cent.).

Pathological.—The duration of the circulation seems to be increased during septic fever (*E. Wolff*).

93. WORK OF THE HEART.—The **left ventricle** expels 0.188 kilo. of blood with each systole, and in doing so it overcomes the pressure in the aorta, which is equal to a column of blood 3.21 metres in height. [The amount of blood expelled from each ventricle during the systole is about 180 grms. (6 oz.). It is forced out against a pressure of 250 mm. Hg. = 3.21 metres of blood.] The work of the heart at each systole is 0.188 × 3.21 = 0.604 kilogramme-metre. If the number of beats = 75 per minute, then the work of the left ventricle in 24 hours = (0.604 × 75 × 60 × 24) = 65,230 kilogramme-metres; while the "work" done by the *right* ventricle is about one-third that of the left, and therefore = 21,740 kilogramme-metres. Both ventricles do work equal to 86,970 kilogramme-metres. A workman during eight hours produces 300,000 kilogramme-metres, *i. e.*, about four times as much as the heart. As the whole of the work of the heart is consumed in overcoming the resistance within the circulation, or rather is converted into heat, the body must be partly warmed thereby—(425.5 gramme-metres are equal to 1 heat unit, *i. e.*, the force required to raise 425.5 grammes to the height of 1 metre may be made to raise the temperature of 1 cubic centimetre of water 1° C.). So that 204,000 "heat units" are obtained from the transformation of the kinetic energy of the heart.

One gramme of coal when burned yields 8080 heat units, so that the heart yields as much energy for heating the body as if about 25 grammes of coal were burned within it to produce heat.

§ 94. BLOOD CURRENT IN THE SMALLER VESSELS.—Methods.—The most important observations for this purpose are made by means of the **microscope** on transparent parts of living animals. Malpighi was the first to observe the circulation in this way in the lung of a frog (1661).

The following parts have been employed: The tails of tadpoles and small fishes; the web, tongue, mesentery, and lungs of curarized frogs; the wing of the bat; the third eyelid of the pigeon or fowl; the mesentery; the vessels of the liver of frogs and newts, pia mater of rabbits, the skin on the belly of the frog, the mucous membrane of the inner surface of the human lip (*Hüter's* Cheilangioscope, 1879); the conjunctiva of the eyeball and eyelids. All these may be examined by *reflected* light.

[**Holmgren's Method.**—In studying the circulation in the frog's lung, it must be inflated. A cannula with a bulge on its free end is placed in the larynx, while to the other end is fixed a piece of caoutchouc tubing. The lung is inflated and then the caoutchouc tube is closed, after which the lung is placed in a chamber with glass above and below, and examined microscopically.]

[**Entoptical appearances** of the circulation (*Purkinje*, 1815). Under certain conditions a person may detect the movement of the blood corpuscles within the blood vessels of his own eye. The best method is that of Rood, viz., to look at the sky through a dark blue glass, or through several pieces of cobalt glass placed over each other (*Helmholtz*).]

Form and Arrangement of Capillaries.—Regarding the form and arrangement of the capillaries, we find that—

1. The *diameter* which, in the finest, permits only the passage of single corpuscles in a row—one behind the other—may vary from 5 μ to 2 μ, so that 2 or more corpuscles may move abreast when the capillary is at its widest.

2. The *length* is about 0.5 mm. They terminate in small veins.

3. The *number* is very variable, and the capillaries are most numerous in those tissues where the metabolism is most active, as in lungs, liver, muscles—less numerous in the sclerotic and in the nerve trunks.

4. They form numerous *anastomoses*, and give rise to **networks**, whose form and arrangement are largely determined by the arrangement of the tissue elements themselves. They form *simple loops* in the skin, and polygonal networks in the serous membranes, and on the surface of many gland tubes; they occur in the form of elongated networks, with short connecting branches in

muscle and nerve, as well as between the straight tubules of the kidney; they converge *radially* toward a central point in the lobules of the liver, and form *arches* in the free margins of the iris, and on the limit of the sclerotic and cornea.

[**Direct Termination of Arteries in Veins.**—Arteries sometimes terminate directly in veins, without the intervention of capillaries, *e.g.*, in the ear of the rabbit, in the terminal phalanges of the fingers and toes in man and some animals, in the cavernous tissue of the penis. They may be regarded as secondary channels which protect the circulation of adjacent parts, and they may also be related to the heat-regulating mechanisms of peripheral parts (*Hoyer*).]

In connection with the termination of arteries in capillaries, it is important to ascertain if the arterioles are **terminal arteries**, *i.e.*, if they do not form any further anastomoses with other similar arterioles, but terminate directly in capillaries, and thus only communicate by capillaries with neighboring arterioles—or the arteries may anastomose with other arteries just before they break up into capillaries. This distinction is important in connection with the nutrition of parts supplied by such arteries (*Cohnheim*).

Capillary Circulation.—On observing the capillary circulation, we notice that the **red corpuscles** move only in the axis of the current (axial current), while the lateral transparent plasma current flowing on each side of this central thread is free from these corpuscles. [The axial current is the more rapid.] This plasma layer or "**Poiseuille's space**" is seen in the smallest arteries and veins, where $\frac{3}{5}$ are taken up with the axial current, and the plasma layer occupies $\frac{1}{5}$ on each side of it (Fig. 116). A great many, but not all, of the colorless corpuscles move in this layer. It is much less distinct in the capillaries. Rud. Wagner stated that it is absent in the finest vessels of the lung and gills [although Gunning was unable to confirm this statement]. The colored corpuscles move in the smallest capillaries in *single file*, one after the other; in the larger vessels, several corpuscles may move abreast, with a *gliding* motion, and in their course they may turn over and even be twisted if any obstruction is offered to the blood stream. As a general rule, in these vessels the movement is uniform, but at a sharp bend of the vessel it may partly be retarded and partly accelerated. Where a vessel divides, not unfrequently a corpuscle remains upon the projecting angle of the division, and is doubled over it so that its ends project into the two branches of the tube. There it may remain for a time, until it is dislodged, when it soon regains its original form on account of its elasticity. Not unfrequently we see a red corpuscle becoming bent where two vessels meet, but on all occasions it rapidly regains its original form. This is a good proof of the elasticity of the colored corpuscles. The motion of the **colorless corpuscles** is quite different in character; they *roll* directly on the *vascular wall*, moistened on their peripheral zone by the plasma in Poiseuille's space, their other surface being in contact with the thread of colored corpuscles in the centre of the stream. Schklarewsky (1868) has shown by physical experiments, that the particles of least specific gravity in all capillaries (*e.g.*, of glass) are pressed toward the wall, while those of greater specific gravity remain in the middle of the stream. [Graphite and particles of carmine were supended in water, and caused to circulate through capillary tubes placed under a microscope, when the graphite kept the centre of the stream, and the carmine moved in the layer next the wall of the tube.]

When the colorless corpuscles reach the wall of the vessel, they must roll along, partly on account of their surface being *sticky*, whereby they readily adhere to the vessel, and partly because one surface is directed toward the axis of the vessel where the movement is most rapid, and where they receive impulses directly from the rapidly moving colored blood corpuscles (*Donders*). The rolling motion is not always uniform, not unfrequently it is retrograde in direction, which seems to be due to an irregular adhesion to the vascular wall. Their *slower* movement (10 to 12 times slower than the red corpuscles) is partly due to their stickiness, and partly to the fact that, as they are placed near the wall, a large part of their surface lies in the peripheral threads of the fluid, which, of course, move more slowly (in fact the layer of fluid next the wall is passive—p. 133).

[D. J. Hamilton finds that, when a frog's web is examined in a vertical position, by far the

greater proportion of leucocytes float on the *upper* surface, and only a few on the lower surface, of a small blood vessel. In experiments to determine why the colored corpuscles float or glide exclusively in the axial stream, while a great many, but not all, of the leucocytes roll in the peripheral layers, Hamilton ascertained that the nearer the suspended body approaches to the specific gravity of the liquid in which it is immersed, the more it tends to occupy the centre of the stream. He is of opinion that the phenomenon of the separation of the blood corpuscles in the circulating fluid is due to the colorless corpuscles being specifically lighter, and the colored either of the same or of very slightly greater specific gravity, than the blood plasma. Hamilton controverts the statement of Schklarewsky, and he finds that it is the relative specific gravity of a body which ultimately determines its position in a tube. These experiments point to the immense importance of a due relation subsisting between the specific gravity of the blood plasma and that of the corpuscles.]

In the vessels first formed in the incubated egg, as well as in young tadpoles, the movement of the blood from the heart occurs in jerks (*Spallanzani*, 1768).

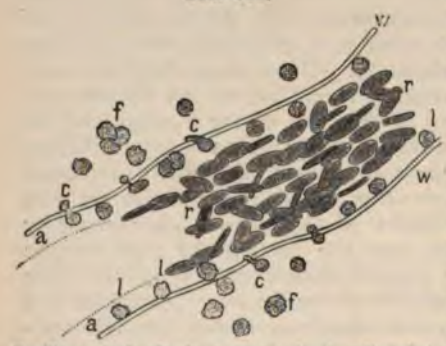
The velocity of the blood stream is influenced by the *diameter of the vessels*, which undergo periodic changes of calibre. This change occurs not only in vessels provided with muscular fibres, but also in the capillaries, which vary in diameter, owing to the contraction of the cells composing their walls (p. 138).

The amount of *water in the blood* is of importance; when it is increased, the circulation is facilitated and accelerated (§ 62).

The velocity of the blood is greater in the **pulmonary** than in the systemic capillaries; so that the total sectional area of the pulmonary capillaries is less than that of all the systemic capillaries.

95. **DIAPEDESIS.**—If the circulation be studied in the vessels of the mesentery, we may observe **colorless corpuscles** passing out of the vessels in greater or less numbers (Fig. 116). The mere contact with the air suffices to excite slight inflammation. At first, the colorless corpuscles in the plasma space move more slowly; several accumulate near each other, and adhere to the walls—soon they bore into the wall, ultimately they pass quite through it, and may wander for a distance into the perivascular tissues. It is doubtful whether they pass through the so-called "**stomata**" which exist between the endothelial cells, or whether they simply pass through the cement substance between the endothelial cells (p. 136). This process is called **diapedesis**, and consists of several acts: (*a*) The adhesion of lymph cells or colorless corpuscles to the inner surface of the vessel (after moving more slowly along the wall up to this point). (*b*) They send processes into and through the vascular wall. (*c*) The body of the cell is drawn after or follows the processes, whereby the corpuscle appears constricted in the centre (Fig. 116, *c*). (*d*) The complete passage of the corpuscle through the wall, and its further motion in virtue of its own amœboid movements. Hering observed that in large vessels with perivascular lymph spaces, the corpuscles passed into the spaces, hence cells are found in lymph before it has passed through lymphatic glands. The **cause** of the diapedesis is partly due to the independent locomotion of the corpuscles, and it is partly a physical act, viz., a filtration of the colloid mass of the cell under the force of the blood pressure (*Hering*)—in the latter respect depending upon the intravascular pressure and the velocity of the blood stream. Hering regards this process, and even the passage of the colored corpuscles through the vascular wall, as a normal process. The **red corpuscles** pass out of the vessels when the venous outflow is obstructed, which also causes the transudation of plasma through the vascular wall. The plasma carries the colored corpuscles along with it, and at the moment of their passage through the wall they assume extraordinary shapes, owing to the tension put upon them, regaining their shape as soon as they pass out (*Cohnheim*). This remarkable phenomenon was described by Waller in 1846. It was re-described by Cohnheim, and according to him the out-wandering is a sign of inflammation, and the colorless corpuscles which accumulate in the tissues are to be regarded as true **pus corpuscles**, which may undergo further increase by division.

FIG. 116.



Small vessel of a frog's mesentery showing diapedesis. *w*, *w*, vascular walls; *a*, *a*, Poiseuille's space; *r*, *r*, red corpuscles; *l*, *l*, colorless corpuscles adhering to the wall, and *c*, *c*, in various stages of extrusion; *f*, *f*, extruded corpuscles.

Stasis.—When a strong stimulus acts on a vascular part, hyperæmic *redness* and *swelling* occur.

Microscopic observation shows that the capillaries and the small vessels are dilated and *overfilled* with blood corpuscles; in some cases, a temporary narrowing precedes the dilatation; simultaneously the velocity of the stream changes, rarely there is a temporary acceleration, *more frequently it becomes slower*. If the action of the stimulus or irritant be continued, the retardation becomes considerable, the stream moves in jerks, then follows a **to-and-fro movement** of the blood column—a sign that stagnation has taken place in other vascular areas. At last the blood stream comes completely to a stand-still—**stasis**—and the blood vessels are plugged with blood corpuscles. Numerous colorless blood corpuscles are found in the stationary blood. While these various processes are taking place, the colorless corpuscles—more rarely the red—pass out of the vessels. Under favorable circumstances the stasis may disappear. The swelling which occurs in the neighborhood of inflamed parts is chiefly due to the **exudation** of plasma into the surrounding tissues.

96. MOVEMENT OF THE BLOOD IN THE VEINS.—In the smallest veins coming from the capillaries, the blood stream is more rapid than in the capillaries themselves, but less so than in the corresponding arteries. The stream is uniform, and if no other conditions interfered with it, the venous stream toward the heart ought to be uniform, but many circumstances affect the stream in different parts of its course. Among these are: (1) The relative *laxness*, great *distensibility*, and the ready *compressibility* of the walls, even of the thickest veins. (2) The *incomplete filling* of the veins, which does not amount to any considerable distention of their walls. (3) The numerous and free *anastomoses* between adjoining veins, not only between veins lying in the same plane, but also between superficial and deep veins. Hence, if the course of the blood be obstructed in one direction, it readily finds another outlet. (4) The presence of numerous **valves** which permit the blood stream to move only in a centripetal direction. They are absent from the smallest veins, and are most numerous in those of middle size.

Position of Valves.—The venous valves always have two pouches, and are placed at definite intervals, which correspond to the 1, 2, 3, or n^{th} power of a certain "fundamental distance," which is = 7 mm. for the lower extremity and 5.5 mm. for the upper. Many of the original valves disappear. On the proximal side of every valve a lateral branch opens into the vein, while on the distal side of each branch lies a valve. The same is true for the lymphatics (*K. Bardeleben*).

Effect of Pressure.—As soon as pressure is applied to the veins, the next lowest valves close, and those immediately above the seat of pressure open and allow the blood to move freely toward the heart. The *pressure* may be exerted from *without*, as by anything placed against the body; the thickened, *contracted* muscles, especially the muscles of the limbs, compress the veins. That the blood flows out of a divided vein more rapidly when the muscles contract, is shown during venesection. If the muscles are kept contracted, the venous blood passing out of the muscles collects in the passive parts, *e.g.*, in the cutaneous veins. The pulsatile pressure of the arteries accompanying the veins favors the venous current. From a hydrostatic point of view the valves are of considerable importance, as they serve to divide the column of blood into segments (*e.g.*, in the crural vein in the erect attitude), so that the fine blood vessels in the foot are not subjected to the whole amount of the hydrostatic pressure in the veins.

The **velocity** of the venous blood has been measured directly (with the hæmadromometer and the rheometer—§ 89). Volkmann found it to be 225 mm. per sec. in the jugular vein. Reil observed that 2½ times more blood flowed from an arterial orifice than from a venous orifice of the same size. The velocity of the venous current obviously depends upon the sectional area of the vessel. Borelli estimated the capacity of the venous system to be 4 times greater than that of the arterial; while, according to Haller, the ratio is 9 to 4.

Large Veins.—As we proceed from the small veins toward the venæ cavæ, the sectional area of the veins, taken as a whole, becomes less, so that the *velocity of the current increases* in the same ratio. The velocity of the current in the venæ cavæ may be about half of that in the aorta (*Haller*). As the **pulmonary veins** are narrower than the pulmonary artery, the blood moves more rapidly in the former.

97. **SOUNDS WITHIN ARTERIES.**—The sounds produced within arteries are, speaking strictly from a physical point of view, only noises or bruits. Still, following Skoda's lead, they are spoken of by physicians as "tones." Clinically, there is no sharp distinction between "tones," sounds, noises, or bruits. In four-fifths of all healthy men two sounds—corresponding in duration and other characters to the two heart sounds—are heard in the carotid (*Conrad, Weil*). Sometimes only the second heart sound is distinguishable, as its place of origin is near to the carotid. They are not true arterial sounds, but are simply "**propagated heart sounds.**" Sometimes the sound of the pulmonary artery can be heard in this way (*Weil, Bettelheim*). These murmurs, sounds, or bruits occur either *spontaneously*, or are produced by the *application of external pressure*, whereby the lumen of the vessel is diminished. Hence one distinguishes: (1) **Spontaneous Murmurs**, and (2) **Pressure Murmurs.**

Arterial Sounds or murmurs are readily produced by pressing upon a strong artery, *e.g.*, the crural in the inguinal region, so as to leave only a narrow passage for the blood ("**stenosal murmur**"). A fine blood stream passes with great rapidity and force through this narrow part, into a wider portion of the artery lying behind the point of compression. Thus arises the "pressure stream" (*P. Niemeyer*), or the "**fluid vein**" ("veine fluide" of Chauveau). The particles of the fluid are thrown into rapid *oscillation*, and undergo *vibratory* movements, and by their movements produce the sound within the peripheral dilated portion of the tube. A sound is produced in the fluid by pressure (*Corrigan*). The sounds are not caused by vibrations of the vascular wall, as supposed by Bouillaud.

A murmur of this sort is the "**sub-clavicular murmur**" (*Roser*), occasionally heard during systole in the subclavian artery; it occurs when the two layers of the pleura adhere to the apex of the lung (especially in tubercular diseases of the lungs), whereby the subclavian artery undergoes a local constriction due to its being made tense and slightly curved (*Friedreich*). This result is indicated in a diminution or absence of the pulse wave in the radial artery (*Weil*).

It is obvious that arterial murmurs will occur in the human body—(*a*) When, owing to pathological conditions, the arterial tube is *dilated at one part*, into which the blood current is forcibly poured from the normal narrow tube. Dilatations of this sort are called **aneurisms**, in which murmurs are generally audible. (*b*) When **pressure** is exerted *upon an artery*, *e.g.*, by the pressure of the greatly enlarged arteries during pregnancy, or by a large tumor pressing upon a large artery.

Spontaneous Murmurs.—In cases where no source of external pressure is discoverable, and when no aneurism is present, the spontaneously occurring sounds are favored, when at the moment of arterial rest (cardiac systole) the arterial walls are distended to the slightest extent, and when during the movement of the pulse (cardiac diastole) the tension is most rapid (*Traube, Weil*), *i. e.*, when the low systolic minimum tension of the arterial wall passes rapidly into the high maximum tension. This is especially the case in insufficiency of the aortic valves, in which case the sounds in the arteries are audible over a wide area. If the minimum tension of the arterial wall is relatively great, even during diastole, the sounds in the arteries are greatly diminished.

Arterial murmurs are **favored** by (1) Sufficient delicacy and elasticity of the arterial walls. (2) Diminished peripheral resistance, *e. g.*, an easy outflow of the fluid at the end of the stream. (3) Accelerated current in the vascular system generally. (4) A considerable difference of the pressure in the narrow and wide portions of the tube. (5) Large calibre of the arteries.

In normal pulsating arteries, sounds may be heard especially at an acute bend of the artery. Murmurs of this sort are loudest where several large arteries lie together; hence, during pregnancy, we hear the *uterine murmur*, or **placental bruit**, or *souffle* in the greatly dilated uterine arteries. It is much less distinct in the umbilical arteries of the cord (umbilical murmurs). Similar sounds are heard through the thin walls of the head of infants, and a murmur is sometimes heard in the enlarged spleen in ague (*Maissurianz*).

Auscultation of the Normal Pulse.—On auscultating the radial artery under favorable circumstances, and especially in old, thin persons with wide arteries and dicrotic pulse, one may hear two sounds corresponding to the primary and dicrotic waves.

In **insufficiency of the aortic valves**, characteristic sounds may be heard in the crural artery. If pressure be exerted upon the artery, a double blowing murmur is heard; the first one is due to a large mass of blood being propelled into the artery synchronously with the heart beat, the second to the fact that a large quantity of blood flows back into the heart during diastole. If no pressure be exercised two sounds are heard, and these seem to be due to a wave propagated into the arteries by the auricles and ventricles respectively—compare § 73, Fig. 86, III. In atheroma a double sound may sometimes be heard (§ 73, 2).

98. VENOUS MURMURS.—I. **Bruit de Diable.**—This sound is heard above the clavicles in the furrow between the two heads of the sterno-mastoid, most frequently on the right side, and in 40 per cent. of all persons examined. It is either a continuous or a rhythmical murmur, occurring during the diastole of the heart or during inspiration; it has a whistling or rushing character, or even a musical quality, and arises within the bulb of the common jugular vein. When this sound is heard without pressure being exerted by the stethoscope, it is a pathological phenomenon. If, however, pressure be exerted, and if, at the same time, the person examined turn his head to the opposite side, a similar sound is heard in nearly all cases. The pathological *bruit de diable* occurs especially in anæmic persons, in lead poisoning, in syphilitic and scrofulous persons, sometimes in young persons, and less frequently in elderly people. Sometimes a *thrill* of the vascular wall may be felt.

Causes.—It is due to the vibration of the blood flowing in from the relatively narrow part of the common jugular vein into the wide bulbous portion of the vessel, and seems to occur chiefly when the walls of a thin part of the vein lie close to each other, so that the current must purl through it. It is clear that pressure from without, or lateral pressure, as by turning the head to the opposite side, must favor its occurrence. Its *intensity* will be increased when the velocity of the stream is increased, hence *inspiration* and the *diastolic* action of the heart (both of which assist the venous current) increase it. The erect attitude acts in a similar manner. A similar bruit is sometimes, though rarely, heard in the subclavian, axillary, thyroid, facial, innominate and crural veins, and superior cava.

II. Regurgitant Murmurs.—On making a sudden effort, a murmur may be heard in the crural vein during expiration, which is caused by a centrifugal current of blood, owing to the incompetence or absence of the valves in this region. If the valves at the jugular bulb are not tight, there may be a bruit with expiration (*expiratory* jugular vein bruit—*Hamernjk*), or during the cardiac systole (*systolic* jugular vein bruit—*v. Bamberger*).

III. Valvular Sounds in Veins.—When the tricuspid valve is incompetent, during the ventricular systole, a large volume of blood is propelled backward into the venæ cavæ. The venous valves are closed suddenly thereby and a sound produced. This occurs at the bulb or dilatation on the jugular vein (*v. Bamberger*), and in the crural vein at the groin (*N. Friedreich*), *i. e.*, only as long as the valves are competent. Forced expiration may cause a valvular sound in the crural vein. No sound is heard in the veins under perfectly normal circumstances.

99. THE VENOUS PULSE—PHLEBOGRAM.—Methods.—A tracing of the movements of a vein, taken with a lightly weighted sphygmograph, has a characteristic form, and is called a **phlebogram** (Fig. 117). In order to interpret the various events of the phlebogram, it is most important to record simultaneously the events that take place in the heart. The auricular contraction (compare Fig. 39) is synchronous with *a b*; *b c*, with the ventricular systole, during which time the first sound occurs, while *a b* is a presystolic movement. The carotid pulse coincides nearly with the apex of the cardiogram, *i. e.*, almost simultaneously with the descending limb of the phlebogram (*Riegel*).

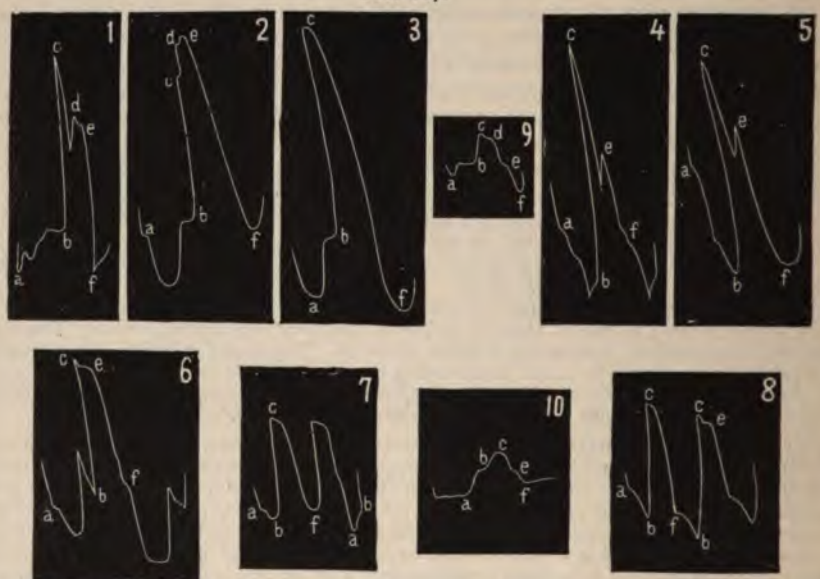
Occasionally in healthy individuals a pulsatile movement, synchronous with the action of the heart, may be observed in the common jugular vein. It is either confined to the lower part of the vein, the so-called bulb, or extends further up along the trunk of the vein. In the latter case, the valves above the bulb are insufficient, which is by no means rare, even in health. The wave motion passes from below upward, and is most obvious when the person is in the passive horizontal position, and it is more frequent on the right side, because the right vein lies nearer the heart than the left. It is propagated more slowly than the arterial pulse wave. The venous pulse resembles very closely the tracing of the cardiac impulse. Compare Fig. 117, 1, with Fig. 39.

It is obvious that, as the jugular vein is in direct communication with the right auricle, and as the pressure within it is low, the systole of the right auricle must cause a positive wave to be propagated toward the peripheral end of the jugular vein. Fig. 117, 9 and 10, are venous pulse tracings of a healthy person with insufficiency of the valves of the jugular vein. In these curves, the part *a b* cor-

responds to the contraction of the auricle. Occasionally this part consists of two elevations, corresponding to the contraction of the atrium and auricle respectively. As the blood in the right auricle receives an impulse from the sudden tension of the tricuspid valve, *synchronous with the systole of the right ventricle*, there is a positive wave in the jugular vein in Fig. 117, 9 and 10, indicated by *b*, *c*. Lastly, the sudden closure of the pulmonary valves may even be indicated (*e*). As the aorta lies in direct relation with the pulmonary artery, the sudden closure of its valves may also be indicated (Fig. 91, 9, at *d*). During the diastole of the auricle and ventricle, blood flows into the heart, so that the vein partly collapses and the lever of the recording instrument descends.

Sinus and Retinal Pulse.—The blood in the sinuses of the *brain* also undergoes a pulsatile movement, owing to the fact that during cardiac diastole much blood flows into the veins (*Mosso*). Under favorable circumstances, this movement may be propagated into the veins of the *retina*, constituting the *venous retinal pulse* of the older observers (*Helfreich*).

FIG. 117.



Venous pulses (*Friedreich*). 1–8, from insufficiency of the tricuspid; 9, 10, pulse of the jugular vein of a healthy person. In all the curves, *a b* = contraction of the right auricle; *b c*, of the right ventricle; *d*, closure of the aortic valves; *e*, closure of the pulmonary valves; *e*, *f*, diastole of the right ventricle.

Pathological Jugular Vein Pulse.—The venous pulse in the jugular vein is far better marked in *insufficiency of the tricuspid valve*, and the vein may pulsate violently, but if its valves be perfect, the pulse is not propagated along the vein, so that *a pulse in the jugular vein is not necessarily a sign of insufficiency of the tricuspid valve*, but only of insufficiency of the valve of the jugular vein (*Friedreich*).

Liver Pulse.—The ventricular systole is propagated into the valveless inferior vena cava, and causes the *liver pulse*. With each systole blood passes into the hepatic veins, so that the liver undergoes a *systolic swelling and injection*.

Fig. 117, 2–8, are curves of the pulse in the common jugular vein. Although at first sight the curves appear to be very different, they all agree in this, that the various events occurring in the heart during a cardiac revolution are indicated more or less completely. In all the curves, *a b* = auricular contraction. The auricle, when it contracts, excites a positive wave in the veins. The elevation, *b c*, is caused by the large blood wave produced in the veins, owing to the emptying of the ventricle. It is always greater, of course, in insufficiency of the tricuspid valves than under normal circumstances (Fig. 117, 9 and 10). In the latter case, the closure of the tricuspid valve causes only a slight wave motion in the auricle. The apex, *c*, of this wave may be higher or lower, accord-

ing to the tension in the vein and the pressure exerted by the sphygmograph. As a general rule, at least one notch (4, 5, 6, *e*) follows the apex, due to the prompt closure of the valves of the pulmonary artery. The closure of the closely adjacent aortic valves may cause a small secondary wave near to *e* (as in 1 and 2, *d'*). The curve falls toward *f*, corresponding to the diastole of the heart.

A well-marked venous pulse occurs when the *right auricle is greatly congested*, as in cases of insufficiency of the mitral valve or stenosis of the same orifice. In rare cases, in addition to the pulse in the common jugular vein, the external jugular, the facial, thyroid, external thoracic veins, or even the veins of the upper and lower extremities may pulsate. A similar pulsation must occur in the pulmonary veins in mitral insufficiency, but of course the result is not visible.

On rare occasions, a pulse occurs in the **veins** on the back of the **hand** and **foot**, owing to the arterial pulse being propagated through the capillaries into the veins. This may occur under normal circumstances, when the peripheral ends of the arteries become dilated and relaxed (*Quincke*), or when the blood pressure within these vessels rises rapidly and falls as suddenly, as in **insufficiency of the aortic valves.**

In progressive effusion into the pericardium the carotid pulse at first becomes smaller and the venous pulse larger; beyond a certain stage of pressure the latter ceases (*Riegel*).

100. DISTRIBUTION OF THE BLOOD.—In the rabbit, one-fourth of the total amount of the blood is found in each of the following: *a*, in the passive muscles; *b*, in the liver; *c*, in the organs of the circulation (heart and vessels); *d*, in all other parts together.

Methods.—The methods adopted do not give exact results. J. Ranke ligatured the parts during life, removed them, and investigated the amount of blood while the tissues were still warm.

Influencing Conditions.—The amount of blood is influenced by (1) the anatomical distribution of the vessels (vascularity or the reverse) as a whole; (2) the diameter of the vessels, which depends upon physiological causes (*a*) on the blood pressure within the vessels; (*b*) on the condition of the vasomotor or vaso-dilator nerves; (*c*) on the condition of the tissues themselves, *e.g.*, the vessels of the intestine during absorption; by the vessels of muscle during muscular contraction; of vessels in inflamed parts.

The most important factor, however, is the state of **activity of the organ** itself; hence, the saying, "ubi irritatio, ibi affluxus." We may instance the congestion of the salivary glands and the gastric mucous membrane during digestion, and the increased vascularity of muscles during contraction. As the activity of organs varies at different times, the *amount of blood in the part or organ goes hand in hand with the variations in its states of activity*. When some organs are congested, others are at rest; during digestion, there is muscular relaxation and less mental activity: violent muscular exertion retards digestion—during great congestion of the cutaneous vessels the activity of the kidneys diminishes. Many organs (heart, muscles of respiration, certain nerve centres) seem always to be in a nearly uniform state of activity and vascularity. During the *activity of an organ*, the amount of blood in it may be increased 30 per cent., nay, even 47 per cent. The motor organs of young muscular persons are relatively more vascular than those of old and feeble persons (*J. Ranke*). In the condition of increased activity a *more rapid renewal* of the blood seems to occur; after muscular exertion the duration of the circulation diminishes (*Vierordt*).

During a condition of mental activity, the carotid is dilated, the dicrotic wave in the carotid curve is increased (the radial shows the opposite condition), and the pulse is increased in frequency (*Gley*).

Age.—The *development of the heart and large vessels* determines a different distribution of the blood in the child from that which obtains in the adult. The heart is relatively small from infancy up to puberty, the vessels are relatively large; while after puberty the heart is large, and the vessels are relatively smaller. Hence it follows that the blood pressure in the arteries of the systemic circulation must be lower in the child than in the adult. The pulmonary artery is relatively wide in the child, while the aorta is relatively small; after puberty both vessels have nearly the same size. Hence, it follows that the blood pressure in the pulmonary vessels of the child is relatively higher than that in the adult (*Beneke*).

101. PLETHYSMOGRAPHY.—In order to estimate and register the amount of blood in a limb Mosso devised an instrument (Fig. 118), which he termed a **plethysmograph.**

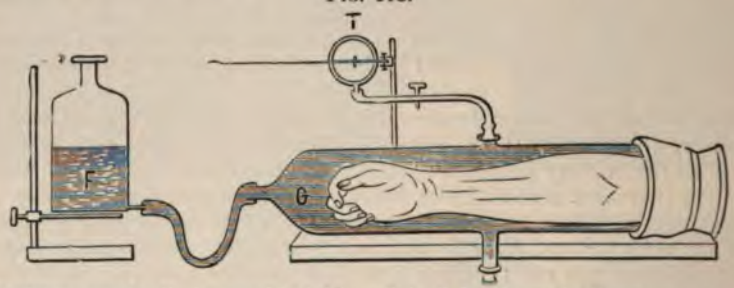
It consists of a long cylindrical glass vessel, G, suited to accommodate a limb. The opening through which the limb is introduced is closed with caoutchouc, and the vessel is filled with water. There is an opening in the side of the vessel in which a manometer tube, filled to a certain height with water, is fixed. As the arm is enlarged owing to the increased supply of arterial blood passing into it at each pulse beat, of course the water column in the manometer is raised. Fick placed a float upon the surface of the water, and thus enabled the variations in the volume of the fluid to be inscribed on a revolving cylinder. The curve obtained resembled the pulse curve; it was even dicrotic. In Fig. 118 the movement of the fluid is represented as conveyed to a Marey's tambour, T, similar to the recording apparatus employed in Brondgeest's pansphygmograph (Fig. 76).

The cylinder C may be filled with air. Kries fills it with gas and connects the tube leading to T to a gas burner. The variations in the gas flame are then photographed.

Results.—(1) Pulsatile Variations in the Volume.—As the venous current is regarded as uniform in the passive limb, every increase of the volume curve indicates a greater velocity of the arterial current toward the periphery, and *vice versâ* (*Fick*). The curves registered by the apparatus are **volume pulses**, and they resemble the curve of the dromograph (Fig. 113, III). The ascent of the curve indicates a greater, the descent a diminished inflow of arterial blood.

At first sight the plethysmograph curve (volume pulse, § 90, 7) is very like the pulse curve (pressure pulse); both are dicrotic. But there are differences; the volume pulse curve beyond the apex falls more rapidly. This rapid fall, which is not accompanied by a corresponding fall of the pressure, is attributed by v. Kries to peripheral reflexion. The dicrotic wave occurs sooner in the volume pulse than in the pulse curve.

FIG. 118.



Mosso's plethysmograph. G, glass vessel for holding a limb; F, flask for varying the water pressure in G; T, recording apparatus.

(2) The **respiratory undulations** correspond to similar variations in the blood pressure tracing (§ 85, *f*). Vigorous respiration and cessation of the respiration cause a diminution of the volume. The limb swells during straining and coughing, but diminishes during sighing. (3) Certain **periodic undulations** occur, due to the regular periodic contractions of the small arteries. (4) Other undulations, due to various accidental causes, affect the blood pressure: changes of the position of a limb acting hydrostatically, and dilatation or contraction of the vessels in other vascular regions. (5) Movement of the muscles of the limb under observation causes diminution of volume, as the venous current is accelerated, the musculature is also very slightly diminished in volume, even when the intra-muscular vessels are dilated. (6) *Mental exercise* causes a diminution in the volume of the limb, and so does sleep (*Mosso*). *Music* influences the blood pressure in dogs, the pressure rising or falling under different conditions. The stimulation of the auditory nerve is transmitted to the medulla oblongata, where it acts so as to cause acceleration of the action of the heart (*Dogiel*). (7) *Compression of the afferent artery* causes a decrease, and *compression of the vein* an increase in the volume of the limb (*Mosso*). (8) Stimulation of the vasomotor nerves causes a decrease, that of the vaso-dilators an increase in the volume (*Bowditch and Warren*).

102. TRANSFUSION OF BLOOD.—Transfusion is the introduction of blood from one animal into the vascular system of another animal.

(*a*) The **red corpuscles** are the most important elements in connection with the restorative powers of the blood. They seem to preserve their functions even in blood which has been defibrinated outside the body (§ 4, A).

(*b*) With regard to the **gases** present in the blood, arterial blood never acts injuriously; but venous blood overcharged with carbonic acid ought only to be transfused when the respiration is sufficient to oxygenate the blood as it passes through the pulmonary capillaries, whereby venous is transformed into arterial blood. If the respiratory movements have ceased, or are imperfectly performed, the blood becomes rapidly richer in carbonic acid, and in this condition reaches the heart; thence it is propelled into the blood vessels of the medulla oblongata, where it acts as a powerful stimulus of the respiratory centre, causing dyspnœa, convulsions, and death.

(*c*) The **fibrin**, and the substances from which it is formed, do not seem to play any part in connection with the restorative powers of the blood; hence defibrinated blood performs all the functions of non-defibrinated blood within the body (*Panum, Landois*).

(*d*) The investigations of Worm Müller showed that an **excess** of 83 per cent. of blood may be transfused into the vascular system of an animal (dog) without producing any injurious effects. Hence it follows that the vascular system has the power of accommodating large quantities of blood within it. That the vascular system can accommodate itself to a diminished amount of blood has been known for a long time (§ 85, *c*). [It is very important to observe that the transfusion of a large quantity of blood does not materially or permanently raise the blood pressure.]

When Employed.—The transfusion of blood is used (1) in **acute anæmia** (§ 41, I), *e.g.*, after copious hemorrhage. New blood (150 to 500 c. c.), from the *same species* of animal, is introduced directly into the vessels, to supply the place of the blood lost by the hemorrhage.

(2) In cases of **poisoning**, where the blood has been rendered useless by being mixed with a poisonous substance, and hence is unable to support life. In such cases remove a considerable quantity of the blood, and replace it by fresh blood. Carbonic oxide is a poison of this kind, and its effects on the body have already been described (§ 16). A similar practice is indicated in poisoning with ether, chloral, chloroform, opium, morphia, strychnine, cobra poison, and such substances as dissolve the blood corpuscles, *e.g.*, potassic chlorate.

(3) Under certain **pathological conditions**, the blood may become so altered in quality as to be unable to support life. The morphological elements of the blood may be altered, and so may the relative proportion of its other constituents. Among these conditions may be cited the pathological condition of uræmia, due, it may be, to the accumulation of urea or the products of its decomposition within the blood; accumulation of the biliary constituents in the blood, and great increase of the carbonic acid. All these three conditions, when very pronounced, may cause death. In these cases, part of the impure blood may be replaced by normal human blood.

Among conditions where the *morphological constituents* of the blood are altered qualitatively or quantitatively are: hydræmia (excessive amount of water in the blood, § 41, 1); oligocythæmia (abnormal diminution of red blood corpuscles). When these conditions are highly developed, more especially in pernicious anæmia (§ 10, 2), healthy blood may be substituted. Transfusion is not suited for persons suffering from leukæmia (compare p. 59).

After-Effects.—A quarter or half an hour after normal blood has been injected into the blood vessels of a man, there is a greater or less *febrile reaction*, according to the amount of blood transfused (Fever, § 220).

Operation.—The operative procedure to be adopted in the process of transfusion varies according as defibrinated or non-defibrinated blood is used. In order to defibrinate blood, some blood is withdrawn from a vein of a healthy man in the ordinary way, collected in an open vessel, and whipped or beaten with a glass rod until all the fibrin is completely removed from it. It is then filtered through an atlas filter, heated to the temperature of the body (by placing it in a vessel in warm water), and injected by means of a syringe into an artery opened for the purpose. A vein (*e.g.*, basilic or great saphenous) may be selected for the transfusion, in which case the blood is driven inward in the direction of the heart; if an artery is selected (radial or posterior tibial) the blood is injected toward the periphery (*Hüter*), or toward the heart (*Landois, Schäfer*).

If **non-defibrinated** human blood is used, the blood may be passed *directly* from the arm of the giver to the arm of the receiver by means of a flexible tube. The tube used must be filled with normal saline solution to prevent the entrance of air. [J. Duncan collects the blood shed during an operation in a 5 per cent. solution of sodic phosphate (*Pavy*), and injects the mixture especially where much blood has been lost previously.]

Dangers.—It is most important that **no air** be allowed to pass into the circulation, for if it be introduced in sufficient quantity it may cause death. When air enters the circulation it reaches the right side of the heart, where, owing to the movement of the blood, it forms air bubbles and makes a froth. The air-bubbles are pumped into the branches of the pulmonary artery, in which they become impacted, arrest the pulmonary circulation, and rapidly cause death.

Peritoneal Transfusion.—Recently, the injection of defibrinated blood into the *peritoneal cavity* has been recommended. The blood so injected is absorbed (*Ponfick*). Even after twenty minutes the number of blood corpuscles in the blood of the recipient (rabbit) is increased, and the number is greatest on the first or second day. The operation, however, may cause death, and one fatal case, owing to peritonitis, is recorded (*Mosler*). It is evident that this method of transfusion is not applicable in cases where blood must be introduced into the circulation as rapidly as possible (*e.g.*, after severe hemorrhage or in certain cases of poisoning). [Blood has been injected into the subcutaneous cellular tissue of the abdomen in cases of great debility.]

Heterogeneous Blood.—*The blood of animals ought never to be transfused into the blood vessels of man.* It is to be remembered, however, that the blood corpuscles of the sheep are rapidly dissolved by human blood, so that the active constituents of the blood are rendered useless (*Landois*). As a general rule, the blood serum of some mammals dissolves the blood corpuscles of other mammals (§ 5, 5).

Solution of the Blood Corpuscles.—The serum of dog's blood is a powerful solvent, while that of the blood of the horse and rabbit dissolves corpuscles relatively slowly. The blood corpuscles of mammals vary very greatly with reference to their power to resist the solvent action of the serum of other animals. The red blood corpuscles of rabbits' blood are rapidly dissolved by the blood serum of other animals, while those of the cat and dog resist the solvent action much longer. Solution of the corpuscles occurs in defibrinated as well as in ordinary blood. When the blood of a rabbit or lamb is injected into the blood vessels of a dog, the red blood corpuscles are dissolved in a few minutes. If blood be withdrawn by pricking the skin with a needle, the partially dissolved corpuscles may be detected.

Liberation of Hæmoglobin and Hæmoglobinuria.—As a result of the solution of the colored corpuscles, the blood plasma is reddened by the liberated hæmoglobin. Part of the dissolved material may be used up in the body of the recipient, some of it for the formation of bile, but if the solution of the corpuscles has been extensive, the hæmoglobin *is excreted in the urine* (hæmoglobinuria), in less amount in the intestine, the bronchi, and the serous cavities. Bloody urine has been observed in man after the injection of 100 grammes of lamb's blood. Even some of the recipient's blood corpuscles are dissolved by the serum of the transfused blood, *e. g.*, on transfusing dog's blood into man. In the rabbit, whose corpuscles are readily dissolved, the transfusion of the *blood serum* of the dog, man, pig, sheep, or cat produces serious symptoms, and even death. The dog, whose corpuscles are more resistant, bears transfusion of other kinds of blood well.

Dangers.—When *foreign* or *heterogeneous* blood (*i. e.*, blood from a different species) is transfused, two phenomena which may be dangerous to life occur:—

(1) Before the corpuscles are dissolved, they usually run together and form sticky masses, consisting of 10 or 12 corpuscles, which are apt to occlude the capillaries. After a time they give up their hæmoglobin, leaving the stroma, which yields a sticky, fibrin-like mass that may occlude fine vessels (§ 31).

(2) The presence of a large quantity of dissolved hæmoglobin may cause extensive coagulation within the blood vessels. The injection of dissolved hæmoglobin causes extensive coagulations (*Naunyn and Francken*).

The coagulation occurs usually in the venous system and in the larger vessels, and may cause death either suddenly or after a considerable time.

Dissolved hæmoglobin seems greatly to increase the activity of the fibrin-ferment (§ 30), perhaps by accelerating the disintegration of the colorless corpuscles. Hæmoglobin exposed to the air

gradually loses this property; and the fibrin-ferment, when in contact with hæmoglobin, is either destroyed or rendered less active (*Sachssendahl*).

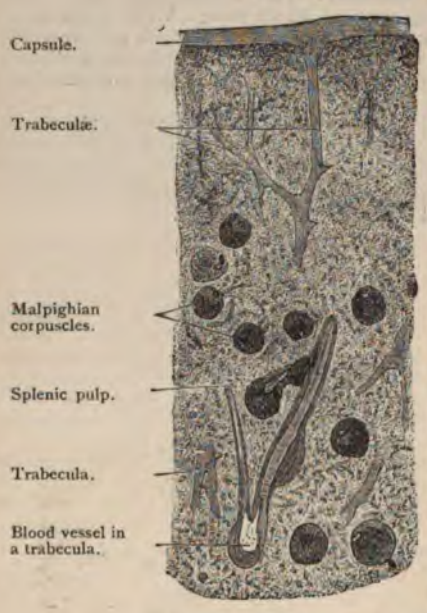
Vascular Symptoms.—As a result of the above-named causes of occlusion of the vessels, there are often signs of the circulation being impeded in various organs. In man, after transfusion of lambs' blood, the skin is bluish-red, in consequence of the stagnation of blood in the cutaneous vessels. Difficulty of breathing occurs from obstruction in the capillaries of the lung; while there may be rupture of small bronchial vessels, causing sanguineous expectoration. The dyspnœa may increase, especially when the circulation through the medulla oblongata—the seat of the respiratory centre—is interfered with. In the digestive tract, for the same reason, *increased peristalsis*, evacuation of the contents of the rectum, vomiting, and abdominal pain may occur. These phenomena are explained by the fact that disturbances of the circulation in the intestinal vessels cause increased peristaltic movements. Degeneration of the parenchyma of the *kidney* occurs as a result of the occlusion of some of the renal vessels. The uriniferous tubules become plugged with cylinders of coagulated albumin (*Ponfick*). Owing to the occlusion of numerous small muscular branches, the *muscles* may become stiff, or coagulation of their myosin may occur. Other symptoms, referable to the *nervous system*, *sense organs*, and *heart*, are all due to the interference with the circulation through them. An important symptom is the occurrence of a considerable amount of *fever* half an hour or so after the transfusion of heterogeneous blood (§ 200). When many vessels are occluded, rupture of some small blood vessels may take place. This explains the occurrence of slight, yet persistent hemorrhages, which occur on the free surfaces of the mucous and serous membranes, and in the parenchyma of organs, as well as in wounds. The blood coagulates with difficulty, and imperfectly.

Transfusion of other Fluids.—Other substances have been transfused. **Normal saline solution** (0.6 per cent. NaCl), or **serum** from the same species, aids the circulation in a purely mechanical way (*Goltz*), and it even excites the circulation (*Kronecker*). In severe anæmia this fluid cannot maintain life (*Eulenburg and Landois*). The injection of **peptone**, even in moderate amount, is dangerous to life, as it causes paralysis of the vessels (p. 73).

THE BLOOD GLANDS.

103.—**I. THE SPLEEN.—Structure.**—The spleen is covered by the peritoneum, except at the hilum. Under this **serous** covering there is a tough, thick, elastic, fibrous **capsule**, which closely invests the organ and gives a covering to the vessels which enter or leave it at the hilum, so that fibrous tissue is carried into the organ along the course of the vessels (Fig. 119). [The capsule cannot be separated without tearing the splenic pulp.] Numerous **trabeculæ** pass into the spleen from the deep surface of the capsule, where they branch and anastomose so as to produce a network of sustentacular tissue, which is continuous with the connective tissue, prolonged inward and surrounding the blood vessels (Fig. 120). Thus, the connective tissue in the spleen, as in other viscera, is continuous throughout the organ. In this way an irregular dense network is formed, comparable to the meshes of a bath sponge. [This network is easily demonstrated by washing out the pulp lying in its meshes by means of a stream of water, when a beautiful, soft, semi-elastic network or **framework** of rounded and flattened threads is obtained.] The **capsule** (Fig. 119) is composed of interlacing bundles of connective tissue mixed with numerous fine fibres of elastic tissue and some non-striped muscular fibres.

FIG. 119.



Section of human spleen × 10 times.

Reticulum.—Within the meshes of the trabecular framework there is disposed a very delicate network or reticulum of adenoid tissue, which, with the other colored elements that fill up the meshes, constitutes the splenic pulp (Fig. 121). The reticulum is continuous with the fibres of the trabeculæ. [If a fine section of the spleen be "penciled" in water, so as to remove the cellular elements, the preparation presents much the same characters as a section of a lymph gland similarly treated, viz., a very fine network of adenoid tissue, continuous with, and surrounding the walls of, the blood vessels. The spaces of this tissue are filled with lymph and blood corpuscles.]

The **pulp** is a dark, reddish-colored, semi-fluid material, which may be squeezed or washed out of the meshes in which it lies. It contains a large number of colored blood corpuscles, and becomes brighter when it is exposed to the action of the oxygen of the air.

Blood Vessels and Malpighian Corpuscles.—The large splenic artery, accompanied by a vein, splits up into several branches before it enters the spleen. Both vessels and their branches are enclosed in a fibrous sheath, which becomes continuous with the trabeculæ. The smaller branches of the artery gradually lose this fibrous investment, and each one ultimately divides into a group or pencil of arterioles or **penicilli**, *which do not anastomose with each other.* [Thus each branch is **terminal**—a condition which is of great importance in connection with the pathology of embolism or infarction of the vessels of the spleen.] At the points of division of the branches of the artery, or scattered along their course, are small oval or globular masses of adenoid tissue ($\frac{1}{15}$ to $\frac{1}{10}$ inch in diameter), the **Malpighian corpuscles.** [These bodies are visible to the naked eye as small, round, or oval white structures, about the size of millet seed, in a section of a fresh spleen. They are very numerous—[70,000 in man]—and are readily detected in the dark reddish pulp. One must be careful not to mistake sections of the trabeculæ for them. These corpuscles consist of adenoid tissue, whose meshes are filled with lymph corpuscles, and they present exactly the same structure as the solitary follicles of the intestine (§ 197). They are small lymphatic

accumulations around the arteries—**periarterial** masses of adenoid tissue similar to those masses that occur in a slightly different form in other organs, *e. g.*, the lungs. In a section of the spleen the artery may pass through the centre of the mass or through one side of it, and in some cases the tissue is collected unequally on opposite sides of the vessel, so that it is lop-sided. They are not surrounded by any special envelope. In some animals the lymphatic tissue is continued for some distance along the small arteries, so that to some extent it resembles a perivascular sheath of ade-

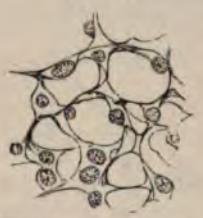
FIG. 121.



Adenoid reticulum of spleen of cat.

noid tissue. In a well-injected spleen, a few fine capillaries are to be found within these corpuscles. The capillaries distributed in the substance of the Malpighian corpuscle (Fig. 122) form a network, and ultimately pour their blood into the spaces in the pulp. According to Cadiat, the corpuscles are separated from the splenic pulp by a lymphatic sinus, which is traversed by efferent capillaries passing to the pulp (Fig. 122).]

Connection of Arteries and Veins.—It is very difficult to determine what is the exact mode of termination of the arteries within the spleen, more especially as it is extremely difficult to inject the blood vessels of the spleen. According to Stieda and others, the fine "capillary arteries" formed by the division of the small arteries do not open directly into the capillary veins, but the connection between the arteries and veins is by means of the "**intermediary intercellular spaces**" of the reticulum of the spleen, so that, according to this view, there is no continuous channel lined throughout by epithelium connecting these vessels one with another. Thus the blood of the spleen flows into the spaces of the adenoid reticulum just as the lymph stream flows through the spaces in a lymph gland. According to Billroth and Kölliker, a closed blood channel actually does exist between the capillary arteries and the veins, consisting of dilated spaces (similar to those of erectile tissue). These intermediary spaces are said to be completely lined by spindle-shaped epithelium, which abuts externally on the reticulum of the pulp. [According to Frey, owing to the walls of the terminal vessels being incomplete, there being clefts or spaces between the cells composing them, the blood passes freely into spaces of the adenoid tissue of the pulp "in the same way as the water of a river finds its way among the pebbles of its bed," these "**intermediary passages**" being bounded directly by the cells and fibres of the network of the pulp. From these passages the venous radicals arise. At first, their walls are imperfect and cribriform, and they often present peculiar transverse markings, due to the circular disposition of the elastic fibres of the reticulum. The small veins have at first a different course from the arteries. They anastomose freely, but they soon become ensheathed, and accompany the arteries in their course.]

FIG. 122.

Malpighian corpuscle of a cat's spleen injected. *a*, artery; *b*, meshes of the pulp injected; *c*, the artery of the corpuscle ramifying in the lymphatic tissue composing it.

Elements of the Pulp (Fig. 123.)—The morphological elements are very various—(1) Lymph corpuscles of various sizes, sometimes partly swollen, and at other times with granular contents. (2) Red blood corpuscles. (3) Transition forms between 1 and 2 [although this is denied by some observers (§ 7, C)]. (4) Cells containing red blood corpuscles and pigment granules. [These cells exhibit amœboid movements.] (Compare § 8.)

[**Lymphatics** undoubtedly arise within the spleen, but they are not numerous. There are two systems—a superficial or capsular, and trabecular system; and a perivascular set. The **superficial** lymphatics in the capsule are rather more numerous. Some of them seem to communicate with the lymphatics within the organ (*Tomsa Kölliker*). In the horse's spleen they communicate with the lymphatics in the trabeculæ, and with the perivascular lymphatics. The exact mode of origin of the **perivascular** system is unknown, but in part at least it begins in the spaces of the adenoid tissue of the Malpighian corpuscles and perivascular adenoid tissue, and runs along the arteries toward the hilum. There seem to be no afferent lymphatics in the spleen such as exist in a lymphatic gland.

The **nerves** of the spleen are composed for the most part of non-medullated nerve fibres, and run along with the artery. Their exact mode of termination is unknown, but they probably go to the blood vessels and to the muscular tissue in the capsule and trabeculæ. [They are well seen in the spleen of the ox, and in their course very small ganglia, placed wide apart, have been found by Remak and W. Stirling.]

FIG. 123.

Elements of human splenic pulp. 1, colorless cells; 2, endothelium; 3, colored blood corpuscles; 4, cells containing granules, the upper one with a colorless blood corpuscle, *b*, enclosed.

Chemical Composition.—Several of the more highly oxidized stages of albuminous bodies exist in the spleen. Besides the ordinary constituents of the blood, there exist leucin, tyrosin, xanthin, hypoxanthin; lactic, butyric, acetic, formic, succinic, and uric acids, and perhaps glycero-phosphoric acid (*Salkowski*); cholesterin, a gluten-like body, inosit, a pigment containing iron, and even free iron oxide (*Nasse*). The ash is rich in phosphoric acid and iron (p. 195)—poor in chlorine compounds. The splenic juice is alkaline in reaction; the specific gravity of the spleen = 1059–1066.

The **functions** of the spleen are obscure, but we know some facts on which to form a theory. [The spleen differs from other organs in that no very apparent effect is produced by it, so that we must determine its uses in the economy from a consideration of such facts as the following: (1) The effects of its removal or extirpation. (2) The changes which the blood undergoes as it passes through it. (3) Its chemical composition. (4) The results of experiments upon it. (5) The effects of diseases.]

(1) **Extirpation.**—The spleen may be removed from an animal—old or young—without the organism suffering any very obvious change (*Galen*). The human spleen has been successfully removed by *Köberle*, *Péan*, and others. As a result (compensatory?) the lymphatic glands enlarge, but not constantly, while the blood-forming activity of the red marrow of bone is increased. Small brownish-red patches were observed in the intestines of frogs after extirpation of the spleen. These new formations are regarded by some observers as compensatory organs. Tizzoni asserts that new splenic structures are formed in the omentum (horse, dog) after the destruction of the parenchyma and blood vessels of the spleen. The spleen is absent extremely seldom.

[The weight of the animal (dog) diminishes after the operation, but afterward increases. The number of red blood corpuscles is lessened, reaching its minimum about the 150th to the 200th day, while the colorless corpuscles are increased in number. The lymphatic glands (especially the internal, and those in the neck, mesentery, and groin) enlarge, while on section the cortical substance of these structures is redder, owing to the great number of red corpuscles, many of them are nucleated in the lymph spaces (*Gibson*). The marrow of all the long bones (those of the foot excepted), becomes very red and soft, with the characters of embryonic bone-marrow. Such animals withstand hemorrhage (to ⅓ of the total amount of blood) without any specially bad results (*Tizzoni, Winogradow*). Schindeler observed that animals after extirpation of the spleen became very ravenous.]

[**Regeneration.**—After entire removal of the spleen, nodules of splenic tissue are reproduced (fox); while new adenoid tissue is formed in the lymphatic glands, and in Peyer's patches, the parenchyma of the former coming to resemble splenic tissue (*Tizzoni, Eternod.*)]

(2) According to Gerlach and Funke the spleen is a **blood-forming gland.** The blood of the splenic vein contains far more colorless corpuscles than the blood of the splenic artery (p. 55). Many of these corpuscles undergo fatty degeneration, and disappear in the blood stream. That colorless blood corpuscles are formed within the spleen seems to be proved by the enormous number of these corpuscles which are found in the blood in cases of leukæmia (*Bennett* (1852), *Virchow*). Bizzozero and Salvioli found that, several days after severe hemorrhage, the spleen became enlarged, and its parenchyma contained numerous red nucleated hæmatoblasts.

(3) Other observers (*Kölliker and Ecker*) regard the spleen as an organ in which **colored blood corpuscles are destroyed,** and they consider the large protoplasmic cells containing pigment granules as a proof of this (p. 53). According to the observations of Kusnetzow, these structures are merely lymph corpuscles, which, in virtue of their amœboid movements, have entangled colored blood corpuscles. [Such corpuscles exhibit similar properties when placed upon a warm stage.] Similar cells occur in extravasations of blood. The colored blood corpuscles within the lymph cells gradually become disintegrated, and give rise to the production of granules of hæmatin and other derivatives of hæmoglobin. [The spleen contains so much free iron that a section of this organ, especially from a young animal, when treated with Tizzoni's fluid, *i. e.*, with potassic ferrocyanide and hydrochloric acid, gives a distinct blue color (§ 174, 4).] Hence, the spleen contains more *iron* than corresponds to the amount of blood present in it. When we consider that the spleen contains a large number of extractives derived from the decomposition of proteids, it is very probable that colored blood corpuscles are destroyed in the spleen. Further, the juice of the spleen contains salts similar to those that occur in the red blood corpuscles.

The blood from the spleen is said to have undergone other changes, but the following statement must be accepted with caution: The blood of the **splenic vein** contains more water and fibrin, its red blood corpuscles are smaller, brighter, less flattened, more resistant, and do not form rouleaux; its hæmoglobin crystallizes more easily, and there is a large proportion of O during digestion.

[The spleen has therefore very direct relations to the blood; in it colored blood corpuscles undergo disintegration, it produces colorless corpuscles, and it is said to transform white corpuscles into red.]

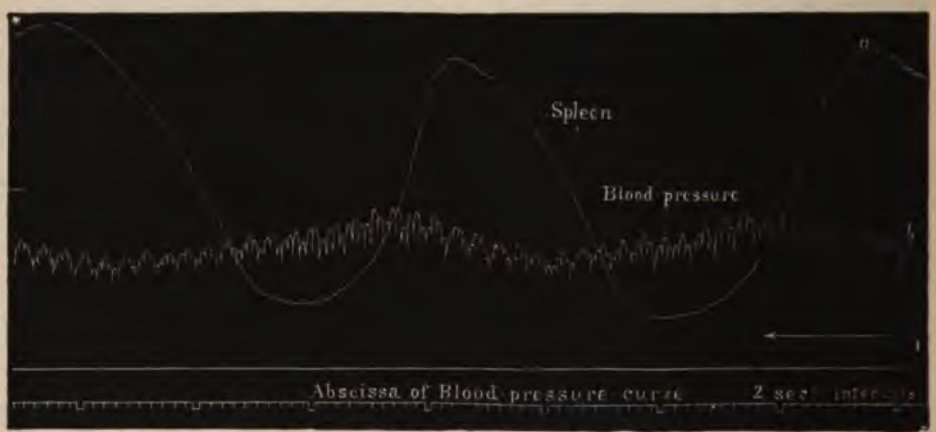
(4) **Contraction.**—In virtue of the plain muscular fibres in its capsule and trabeculæ, the spleen undergoes variations in its volume. Stimulation of the spleen or its nerves, by cold, electricity, quinine, eucalyptus, ergot of rye, and other "**splenic reagents**" causes it to contract, whereby it becomes paler, and its surface may even appear granular. *After a meal*, the spleen increases in size, and it is usually largest about five hours after digestion has begun, *i. e.*, at a time when the digestive organs have almost finished their work, and have again become less vascular. After a time it regains its original volume. For this reason the spleen was formerly regarded as an apparatus for regulating the amount of blood in the digestive organs. [The congestion of the spleen after a meal is more probably related to the formation of new colorless corpuscles than to the destruction of red corpuscles. It may be, however, that some of the products of digestion are partially acted upon in the spleen, and undergo further change in the liver.] There is a relation between the size of the spleen and that of the liver, for it is found that when the spleen contracts—*e. g.*, by stimulation of its nerves—the liver becomes enlarged, as if it were injected with more blood than usual (*Drosdow and Botschetschkarow*).

[**Oncograph.**—Botkin, and more recently Roy, have studied various conditions which affect the size of the spleen. Roy enclosed the spleen of a dog in a box with rigid walls, the oncograph (ὄγκος, volume), and filled with oil after the manner of the plethysmograph (§§ 101, 276). Any variations in the size of the organ caused a variation in the amount of oil within the box, and these variations were

recorded. The blood pressure was recorded at the same time. The circulation through the spleen is peculiar, and is not due to the blood pressure within the arteries, but is carried on chiefly by a rhythmical contraction of the muscular fibres of the capsule and trabeculæ. The spleen undergoes very regular rhythmical contractions (**systole**) and dilatations (**diastole**). This alternation of systole and diastole may last for hours, and the two events together occupy about one minute (Fig. 124). Changes in the arterial blood pressure have comparatively little influence on the volume of the spleen. The rhythmical contractions, although modified, still go on after section of the splenic nerves. This would seem to indicate that the spleen has an independent (nervous) mechanism within itself, causing its movements.]

[**Influence of Nerves.**—Section of the splenic nerves is followed by an increase in the size of the spleen. The nerves have their centre in the medulla oblongata. Stimulation of the medulla oblongata, either directly or by means of asphyxiated blood, causes contraction of the spleen, hence the spleen is "small and contracted" in death from asphyxia. The fibres proceed down the cord,

FIG. 124.



Tracing of a splenic curve, reduced one-half, taken with the oncograph. The upper line with large waves is the splenic curve; each ascent corresponds to an increase, and each descent to a diminution in the volume of the spleen. The curve beneath is a blood-pressure tracing from the carotid artery. The lowest line indicates the time, the interruptions of the marker occurring every two seconds. The vertical lines, *a* and *b*, give the relative positions of the lever point of the oncograph, and of the point of the recording style of the kymograph respectively (*Roy*).

and leaving it in the dorsal region, enter the left splanchnic, pass through the semilunar ganglion, and thus reach the splenic plexus. Stimulation of the peripheral ends of these nerves causes contraction of the spleen, and so does cold applied to the spleen directly or over the region of the organ. In the last case the result is brought about reflexly. Botkin found that the application of the induced current to the skin over the spleen, in a case of leukæmia, caused well-marked contraction of the spleen in all its dimensions, and the result lasted some time. After every stimulation the number of colorless corpuscles in the blood increased, and the condition of the patient improved.]

[There is a popular notion that the spleen is influenced by the condition of the nervous system. Botkin found that depressing emotions increased its size, while exhilarating ideas diminished it. The **causes** of these changes are referable not only to changes in the amount of blood in the spleen, but also to the greater or less degree of contraction of its muscular tissue. And it would appear that, like the small arteries, the muscular tissue of the spleen is in a state of **tonic con-**

traction. The size of the spleen may be influenced **reflexly.** Thus, Tarchanoff found that stimulation of the *central* end of the vagus, when the splanchnics were intact, caused contraction of the spleen, while stimulation of the *central* end of the sciatic also caused contraction, but to a less degree. It is quite certain that all the phenomena are not due to the action of vasomotor nerves on the splenic blood vessels. There is a certain amount of independent action of the muscular fibres of the organ, and it is not improbable that the innervation of the spleen is similar to the innervation of arteries, and that it has a motor centre in the cord capable of being influenced reflexly by afferent nerves, while it also sends out efferent impulses.]

[Stimulation of (1) the central end of a sensory nerve; (2) of the peripheral ends of both splanchnics; (3) of the peripheral ends of both vagi, causes contraction of the spleen. But even after section of the splanchnics and vagi, stimulation of a sensory nerve still causes contraction, so that there must be some other channel as yet unknown (*Roy*). Bochefontaine found that electrical stimulation of certain parts of the cortex cerebri produced contraction of the spleen.] *Sensory* nerves seem to occur only in the peritoneum covering the spleen.

Pressure on the splenic vein causes enlargement of the spleen, hence, increased pressure in this vein (congestion of the portal vein, cessation of hæmorrhoidal and menstrual discharges) also causes its enlargement. With regard to the action of "**splenic reagents,**" such as **quinine,** on the contraction of the spleen, Binz is of opinion that this drug retards the formation of the colorless blood corpuscles, so that its chief function is interfered with and the organ becomes less vascular. It is not definitely decided, however, whether it is contraction or dilatation of the spleen that alters the proportion of red and white corpuscles in the blood.

Splenic Tumors.—The increase in size of the spleen in various diseases early attracted the attention of physicians. The healthy spleen undergoes several variations in volume during the course of a day, corresponding with the varying activity of the digestive organs. In this respect the spleen resembles the arteries. In many fevers the spleen becomes greatly enlarged, probably due to paralysis of its nerves. It is greatly increased in intermittent fever or ague, and often during the course of typhus. When it becomes abnormally enlarged, and remains so after repeated attacks of the ague, it is greatly hypertrophied, and constitutes "**ague cake.**" In cases of splenic leukæmia it is greatly enlarged, and at the same time there is a great increase in the number of colorless corpuscles in the blood and also a decrease of the colored ones (§ 10).

FIG. 125.

Section of the thymus gland of a cat, with one complete lobule with a cortical part *a*, and a centre, *b*. *a*, lymphoid tissue; *c*, blood vessels injected; *d*, connective tissue.

II. The Thymus.—During fœtal life this gland is largely developed, and it increases during the first two or three years of life, remaining stationary until the tenth or fourteenth year, when it

FIG. 126.

Elements of the thymus (× 300). *a*, lymph corpuscles; *b*, concentric corpuscle of Hassall.

begins to atrophy and undergo fatty degeneration. [The degeneration begins at the outer part of each lobule and progresses inward (*His*).]

Structure.—"It consists of an aggregation of lymph follicles (resembling the glands of Peyer) or masses of adenoid tissue held together by a framework of connective tissue which contains blood vessels, lymphatics, and a few nerves (Fig. 125). The **framework** of connective tissue gives off septa which divide the gland into **lobes,** these being further subdivided by finer septa into **lobules,** the lobules being separated by fine intra-lobular lamellæ of connective tissue into **follicles** (0.5–1.5

mm.). These follicles make up the gland substance, and they are usually polygonal when seen in a section. Each follicle consists of a **cortical** and a **medullary** part, and the matrix or framework of both consists of a fine adeniod reticulum whose meshes are filled with lymph corpuscles" (Fig. 126, *a*).] Many of these corpuscles exhibit various stages of disintegration. In the medulla are found the **concentric corpuscles of Hassall.** ["They consist of a central granular part, around which are disposed layers of flattened, nucleated, endothelial cells arranged concentrically. When seen in a section they resemble the 'cell nests' of epithelioma (Fig. 126, *b*). They have also been compared to similar bodies which occur in the prostate. They are most numerous when the gland undergoes its retrograde metamorphosis." Sig. Mayer finds that the thymus of the frog contains structures, with transverse markings, identical with the stripes of striped muscular fibres. The structures are identical with those called "**sarcoplasts**" by Margo and Paneth, and "**sarcolytes**" by Sig. Mayer. They also occur in large numbers in the tail of the larvæ of batrachians, when the tail is undergoing a retrograde metamorphosis.]

Simon, His, and others described a convoluted blind canal, the "**central canal,**" as occurring within the gland, and on it the follicles were said to be placed. Other observers, Jendrassik and Klein, either deny its existence or regard it merely as a lymphatic or an artificial product. Numerous fine **lymphatics** penetrate into the interior of the organ, and many are distributed over its surface, but their mode of origin is unknown. [They seem to be channels through which the lymph corpuscles are conveyed away from the gland.] Numerous **blood vessels** are also distributed to the septa and follicles (Fig. 125, *c*).

Chemical Composition.—Besides gelatin, albumin, soda albumin, there are sugar and fat, leucin, xanthin, hypoxanthin, formic, acetic, butyric, and succinic acids. Potash and phosphoric acid are more abundant in the *ash* than soda, calcium, magnesium (? ammonium), chlorine, and sulphuric acid.

Function.—As long as it exists, it seems to perform the functions of a true lymph gland. This view is supported by the fact that in reptiles and amphibians, which do not possess lymph glands, the thymus remains as a permanently active organ. [**Extirpation** gave few positive results, but chemical investigation shows that the parenchyma contains a large number of products indicating considerable metabolic activity (*Friedleben*).]

III. The Thyroid.—Structure.—The gland consists of **lobes** and **lobules** held together by connective tissue rich in cells. Each lobule is made up of numerous **completely closed sacs** (0.04 to 0.1 mm. in diameter), which in the embryo and the newly-born animal are composed of a membrana propria lined by a single layer of nucleated cells (Fig. 127). The sacs contain a transparent, viscid, albuminous fluid. [Not unfrequently the sacs contain many colored blood corpuscles (*Baber*).] Each sac is surrounded by a plexus of capillaries which do not penetrate the membrana propria. There are also numerous lymphatics. At an early period the sacs dilate, their cellular lining atrophies, and their contents undergo colloid degeneration. When the gland vesicles are greatly enlarged, "**goitre**" is produced.

FIG. 127.

Section of the thyroid gland. *a*, closed vesicles; *b*, distended by colloid masses and lined by low columnar epithelium; *c*, inter-vesicular connective tissue.

The **chemical composition** of this gland has not been much investigated. In addition to the ordinary constituents, leucin, xanthin, sarkin, lactic, succinic, and volatile fatty acids have been found.

[**Excision.**—The effects differ according to the animal operated on. This gland has been excised in the human subject in cases of goitre. Reverdin pointed out that a peculiar condition results, called **cachexia stumipriva**, and practically the human being becomas a cretin. This operation, therefore, is highly questionable when performed on man. **Rabbits** endure the operation well, and so do the sheep, calf, and horse. Of **dogs**, cats, and foxes, only a very small number survive, nearly all die. It appears therefore that herbivora bear the operation and suffer fewer after-effects than carnivora (*Sanquirico and Orecchia*). The immediate effects are fibrillar contractions, which ultimately influence the gait of the animals, convulsions, anæsthesia, great diminution of sensibility, loss of flesh, redness of the ears and intense heat of the skin (which disappear after several days), difficulty in seizing and eating food, kerato-conjunctivitis, and frequently disturbance of the rhythm of respiration with dyspnœa and spasms of the abdominal muscles (*Schiff*). The arterial blood contains about the same amount of O as venous blood. Certain parts of the peripheral nerves undergo a kind of degenera-

tion similar to that found after nerve stretching. There is albuminuria and fall of the blood pressure. Death usually occurs between the third and fourth day, the animals being comatose (*Wagner*). Schiff found that if one-half of the gland was excised at once, and the other half a month afterward, death did not occur; but Wagner denies this, for he asserts that the remaining half hypertrophies, and if it be excised, death occurs with the usual symptoms. In **monkeys**, five days after the operation, there are symptoms of nervous disturbance. The animals have lost their appetite, there are fibrillar contractions of the muscles of the face, hands, and feet, but the tremors disappear on voluntary effort. The appetite returns and is increased, but notwithstanding, the animal grows thin and pale; while the tremors increase and affect all the muscles of the body. These tremors are of *central* origin, because they disappear on dividing the nerve. Thus there is profound alteration of the motor powers. Among the outward symptoms are puffiness of the eyelids, swelling of the abdomen, increased hebetude, and dyspnœa, while afterward there is a fall of the temperature and imbecility; the tremors disappear, there is a pallor of the skin, and ultimately after five to seven weeks the animals die comatose. Thus there is a slow onset of hebetude, terminating in imbecility. Very remarkable changes occur in the blood. There is a steady fall of the blood pressure; a diminution of the red blood corpuscles, or rather profound anæmia; leucocythæmia, the colorless corpuscles being increased to the ratio of four to fourteen; and lastly **mucin** is present in the blood, although normally it is not so. The salivary glands are hypertrophied, owing to the presence of mucin, which is found even in the parotid, although this is normally a serous gland (§ 141). The swelling of the abdomen is due to hypertrophy of the great omentum. Mucin is found in the peritoneal fluid, and the spleen is also enlarged. Thus these symptoms present many features in common with those of **myxœdema** as described by Ord (*v. Horsley*).]

[**Stages.**—Horsley distinguishes three stages. In the first or **neurotic** stage the animals exhibit constant tremors, 8 per second, and young animals do not appear to survive this stage. In the second or **mucinoid** stage, mucin is deposited in the tissues and blood; this change, however, is only seen to perfection in monkeys. If these animals be kept at a high artificial temperature, their life is considerably prolonged. In the third, **atrophic**, or **marasmic** period, the animals die of marasmus, while they lose their excess of mucin. **Age** seems to exert an important influence in thyroidectomy; young dogs survive but a short time, while old dogs merely exhibit symptoms of indolence and incapacity; and, as a matter of fact, the activity of the gland seems to be most active when tissue metabolism is most active.]

[The following table, after Horsley, indicates the symptoms that follow **loss of the function of the thyroid gland**:—

Stages.	Duration.	Symptoms.	Remarks.
I. **Neurotic.**	1 to 2 weeks in dogs; 1 to 3 weeks in monkeys.	Tremors, rigidity, dyspnœa.	Young dogs and monkeys alike die in this stage.
II. **Mucinoid.**	½ to 1 week in dogs; 3 to 7 weeks in monkeys.	Commencing hebetude and mucinoid degeneration of the connective tissues.	Dogs survive only to the beginning of this stage; monkeys die at the end, if not treated.
III. **Atrophic.**	5 to 8 weeks in monkeys.	Complete imbecility and atrophy of all tissues, especially muscles.	Monkeys survive according to the temperature of the air-bath.]

Functions.—The functions of the thyroid gland are very obscure. Perhaps it may be an apparatus for regulating the blood supply to the head (?). It becomes enlarged in **Basedow's disease**, in which there is great palpitation, as well as protrusion of the eyeball or exophthalmos, which seem to depend upon a simultaneous stimulation of the accelerating nerve of the heart, and the sympathetic fibres of the smooth muscles in the orbital cavity and the eyelids, as well as of the inhibitory fibres of the vessels of the thyroid. In many localities it is common to find swelling of the thyroid constituting **goitre**, which is sometimes, but far from invariably, associated with idiocy and cretinism. [Horsley finds that its removal is the essential cause of myxœdema and cretinism. He regards it (1) as a **blood-forming gland**, so that it has a hæmapoietic function, but Gibson finds no grounds for supporting this view. During the anemia resulting from its removal, the blood of the thyroid vein contains 7 per cent. more red blood corpuscles than the corresponding artery (*Horsley*). (2) It seems to regulate the formation of **mucin** in the body. After its removal the normal metabolism is no longer maintained, and there is a corresponding increasingly defective condition of nutrition.]

In the Tunicata, this gland, represented by a groove, secretes a digestive fluid. In vertebrates, it is an organ which has undergone a retrograde change (*Gegenbaur*).

IV. The Suprarenal Capsules.—Structure.—These organs are invested by a thin **capsule** which sends processes into the substance of the organ. They consist of an outer (broad) or **cortical** layer and an inner (narrow) or **medullary** layer. The former is yellowish in color, firm and striated, while the latter is softer and deeper in tint. In the outermost zone of the **cortex** (Fig. 128, *b*), the trabeculæ form polygonal meshes, which contain the cells of the gland substance; in the broader middle zone the meshes are elongated, and the cells filling them are arranged in columns radiating outward. Here the cells are transparent and nucleated, often containing oil globules; in the innermost narrow zone the polygonal arrangement prevails, and the cells often contain yellowish-brown pigment. In the **medulla** (*c*), the stroma forms a reticulum containing groups of cells of very irregular shape. Numerous **blood vessels** occur in the gland, especially in the cortex. [The **nerves** are extremely numerous, and are derived from the renal and solar plexuses. Many of the fibres are medullated. After they enter the gland, numerous ganglionic cells occur in the plexuses which they form. Indeed, some observers regard the cells of the medulla as nervous. Undoubtedly, numerous *multipolar nerve cells* exist within the gland.]

Chemical Composition.—The suprarenals contain the constituents of connective and nerve tissue; also leucin, hypoxanthin, benzoic, hippuric, and taurocholic acids, taurin, inosit, fats, and a body which becomes pigmented by oxidation. Among inorganic substances potash and phosphoric acid are most abundant.

FIG. 128.

Section of a human suprarenal capsule. *a*, capsule; *b*, gland cells of the cortex arranged in columns; *c*, glandular network of the medulla; *d*, blood vessels.

The **function** of the suprarenal bodies is very obscure. It is noticeable, however, that in **Addison's disease** ("bronzed skin"), which is perhaps primarily a nervous affection, these glands have frequently, but not invariably, been found to be diseased. Owing to the injury to adjacent abdominal organs, **extirpation** of these organs is often, although not always, fatal; in dogs pigmented patches have been found in the skin near the mouth. Brown-Séquard thinks they may be concerned in preventing the over-production of pigment in the blood.

[**Spectrum.**—MacMunn finds that the medulla of the suprarenal bodies (in man, cat, dog, guinea pig, rat, etc.) gives the spectrum of hæmochromogen (§ 18), while the cortex shows that of what he calls **histohæmatin**, the latter being a group of respiratory pigments. He finds that hæmochromogen is only found in excretory organs (the bile, the liver), hence he regards the medulla as **excretory**, so that part of the function of the adrenals may be "to metamorphose effete hæmoglobin or hæmatin into hæmochromogen," and when they are diseased, the effete pigment is not removed, hence the pigmentation of the skin and mucous membranes. Taurocholic acid has been found in the medulla by Vulpian, and pyrocatechin by Krukenberg. MacMunn believes that "they have a large share in the downward metamorphosis of coloring matter."]

V. Hypophysis Cerebri—Coccygeal and Carotid Glands.—The **hypophysis cerebri**, or **pituitary body**, consists of an anterior lower or larger lobe, partly embracing the posterior lower or smaller lobe. These two lobes are distinct in their structure and development. The *posterior* lobe is a part of the brain, and belongs to the infundibulum. The nervous elements are displaced by the ingrowth of connective tissue and blood vessels. The *anterior* portion represents an inflected and much altered portion of ectoderm, from which it is developed. It contains gland-like structures, with connective tissue, lymphatics, and blood vessels, the whole being surrounded by a capsule. According to Ecker and Mihalkowicz, it resembles the suprarenal capsule in its structure, while, according to other observers, in some animals it is more like the thyroid. Its functions are entirely unknown. [**Excision.**—Horsley has removed this gland twice successfully in dogs, which lived from five to six months. No nervous or other symptoms were noticed, but when the cortex of the brain was exposed and stimulated, a great increase in the excitability of the motor regions was induced, even slight stimulation being followed by violent tetanus and prolonged epilepsy.]

Coccygeal and **Carotid Glands.**—The former, which lies on the tip of the coccyx, is composed to a large extent of plexuses of small, more or less cavernous, arteries, supported and enclosed by septa and a capsule of connective tissue (*Luschka*). Between these lie polyhedral granular cells arranged in networks. The carotid gland has a similar structure (p. 118). Their functions are quite unknown. Perhaps both organs may be regarded as the remains of embryonal blood vessels (*Arnold*).

104. **COMPARATIVE.**—The heart in **fishes** (Fig. 129, I), as well as in the larvæ of amphibians with gills, is a **simple venous heart**, consisting of an auricle and a ventricle. The ventricle propels the blood to the gills, where it is oxygenated (arterialized); thence it passes into the aorta to be distributed to all parts of the body, and returns through the capillaries of the body and the veins to the heart. The **amphibians** (frogs) have **two auricles** and **one ventricle** (Frog, II). From the latter there proceeds *one* vessel which gives off the pulmonary arteries, and as the aorta supplies the rest of the body with blood, the veins of the systemic circulation carry their blood to the right auricle, those of the lung into the left auricle. In fishes and amphibians there is a dilatation at the commencement of the aorta, the bulbus arteriosus, which is partly provided with strong muscles. The **reptiles** (III) possess two separate auricles, and two imperfectly separated ventricles. The aorta and pulmonary artery arise separately from the two latter chambers. The venous blood

FIG. 129.

III. *Saurians.*—I, right auricle, with the venæ cavæ; II, right ventricle; III, left auricle; IV, left ventricle. V, anterior common aorta; 1, pulmonary artery; 2, arch of the aorta; 3, carotid artery; 4, posterior common aorta; 5, cœliac, and 6, subclavian, arteries; 7, pulmonary veins; 8, lungs. IV. *Tortoise.*—I, right auricle with the venæ cavæ; II, right, and IV, left ventricles; III, left auricle; 1 and 2, right and left aortæ; 3, posterior common aorta; 4, cœliac; 5, subclavian; 6, carotid, and 7, pulmonary arteries; 8, pulmonary veins.

of the systemic and pulmonary circulations flows separately into the right and left auricles, and the two streams are mixed in the ventricle. In some reptiles the opening in the ventricular septum seems capable of being closed. The complete separation of the ventricle into two is seen in Fig. IV, in the tortoise. The lower vertebrates have valves at the orifices of the venæ cavæ, which are rudimentary in birds and some mammals. All **birds** and **mammals** have two completely separate auricles and two separate ventricles. In the halicore the apex of the ventricles is deeply cleft. Some animals have accessory hearts, *e.g.*, the eel in its caudal vein. They are very probably lymph hearts (*Robin*). The veins of the wing of the bat pulsate (*Schiff*). The lowest vertebrate, **amphioxus**, has no heart, but only a rhythmically pulsating vessel.

Among **blood glands**, the thymus and spleen occur throughout the vertebrata, the latter being absent only in amphioxus and a few fishes.

Among **invertebrata** a *closed vascular system*, with pulsatile movement, occurs here and there, *e.g.*, among **echinodermata** (star fishes, sea urchins, holothurians) and the higher **worms**. The **insects** have a pulsating "*dorsal vessel*" as the central organ of the circulation, which is a contractile tube provided with valves and dilated by muscular action; the blood being propelled rhythmically in one direction into the spaces which lie among the tissues and organs, so that these animals do not possess a closed vascular system. The **mollusca** have a heart with a lacunar vascular system. The **cephalopods** (cuttle fish) have three hearts—a simple arterial heart, and two venous simple gill hearts, each placed at the base of the gills. The vessels form a completely closed circuit. The *lowest animals* have either a pulsatile vesicle, which propels the colorless juice into the tissues (infusoria), or the vascular apparatus may be entirely absent.

105. **HISTORICAL RETROSPECT.**—The ancients held various theories regarding the movement of the blood, but they knew nothing of its *circulation*. According to Aristotle (384 B.C.), the heart, the acropolis of the body, prepared in its cavities the blood, which streamed through the arteries as a nutrient fluid to all parts of the body, but never returned to the heart. With Herophilus and Erasistratus (300 B.C.), the celebrated physicians of the Alexandrian school, originated the erroneous view that the arteries contain air, which was supplied to them by the respiration (hence the name *artery*). They were led to adopt this view from the empty condition of the arteries after death. By experiments upon animals, Galen disproved this view (131–201 A.D.)—"Whenever I injured an artery," he says, "blood always flowed from the wounded vessel. On tying part of an artery between two ligatures, the part of the artery so included is always filled with blood."

Still, the idea of a single *centrifugal* movement of the blood was retained, and it was assumed that the right and left sides of the heart communicated directly by means of openings in the septum of the heart, until Vesalius showed that there are no openings in the septum. Michael Servetus (a Spanish monk, burned at Geneva, at Calvin's instigation, in 1553) discovered the pulmonary circulation. Cesalpinus confirmed this observation, and named it "Circulatio." Fabricius ab Aquapendente (Padua, 1574) investigated the valves in the veins more carefully (although they were known in the 5th century to Theodoretus, Bishop in Syria), and he was acquainted with the *centripetal* movement of the blood in the veins. Up to this time it was imagined that the veins carried blood from the centre to the periphery, although Vesalius was acquainted with the centripetal direction of the blood stream in the large venous trunks. At length **William Harvey**, who was a pupil of Fabricius (1604), demonstrated the complete circulation (1616–1619), and published his great discovery in 1628. [For the history of the discovery of the circulation of the blood, see the works of Willis on "W. Harvey," "Servetus and Calvin," those of Kirchner, and the various Harveian orations.]

According to Hippocrates, the heart is the origin of all the vessels; he was acquainted with the large vessels arising from the heart, the valves, the chordæ tendineæ, the auricles, and the closure of the semilunar valves. Aristotle was the first to apply the terms aorta and venæ cavæ; the school of Erasistratus used the term carotid, and indicated the functions of the venous valves. In Cicero a distinction is drawn between arteries and veins. Celsus mentions that if a vein be struck below the spot where a ligature has been applied to a limb, it bleeds, while Aretaeus (50 A.D.) knew that arterial blood was bright and venous dark. Pliny (†79 A.D.) described the pulsating fontanelle in the child Galen (131–203 A.D.) was acquainted with the existence of a bone in the septum of the heart of large animals (ox, deer, elephant). He also surmised that the veins communicated with the arteries by fine tubes. The demonstration of the **capillaries**, however, was only possible by the use of the **microscope**, and employing this instrument, Malpighi (1661) was the first to demonstrate the capillary circulation. Leuwenhoek (1674) described the capillary circulation more carefully, as it may be seen in the web of the frog's foot and other transparent membranes. Blancard (1676) proved the existence of capillary passages by means of injections. William Cooper (1697) proved that the same condition exists in warm-blooded animals, and Ruysch made similar injections. Stenson (born 1638) established the muscular nature of the heart, although the Hippocratic and Alexandrian schools had already surmised the fact. Cole proved that the sectional area of the blood stream became wider toward the capillaries (1681). Joh. Alfons Borelli (1608–1679) was the first to estimate the amount of work done by the heart.

PHYSIOLOGY OF RESPIRATION.

The **object** of respiration is to supply the oxygen necessary for the oxidation processes that go on in the body, as well as to remove the carbon dioxide formed within the body. The most important organs for this purpose are the **lungs.** There is an **outer** and an **inner respiration**—the former embraces the exchange of gases between the external air and the blood gases of the respiratory organs (lungs and skin)—the latter, the exchange of gases between the blood in the capillaries of the systemic circulation and the tissues of the body.

[The pulmonary apparatus consists of (1) an immense number of small sacs—the **air vesicles**—filled with air, and covered externally by a very dense plexus of capillaries; (2) **air passages**—the nose, pharynx, larynx, trachea, and bronchi communicating with (1); (3) the **thorax** with its muscles, acting like a pair of bellows, and moving the air within the lungs.]

106. STRUCTURE OF THE AIR PASSAGES AND LUNGS.—The lungs are compound tubular glands, which separate CO_2 from the blood. Each lung is provided with an excretory duct (bronchus) which joins the common respiratory passage of both lungs—the trachea.

Trachea.—The trachea and extra-pulmonary bronchi are similar in structure. The basis of the trachea consists of 16–20 **C**-shaped incomplete cartilaginous hoops placed over each other. These rings consist of hyaline cartilage, and are united to each other by means of tough fibrous tissue containing much elastic tissue, the latter being arranged chiefly in a longitudinal direction. The **function of the cartilages** is to keep the tube open under varying conditions of pressure. Pieces of cartilage having a similar function occur in the bronchi and their branches, but they are absent from the bronchioles, which are less than 1 mm. in diameter. In the smaller bronchi, the cartilages are fewer and scattered more irregularly. [In a transverse section of a large **intra-pulmonary bronchus**, two, three, or more pieces of cartilage, each invested by its perichondrium, may be found.] At the points where the bronchi subdivide, the cartilages assume the form of irregular plates embedded in the bronchial wall.

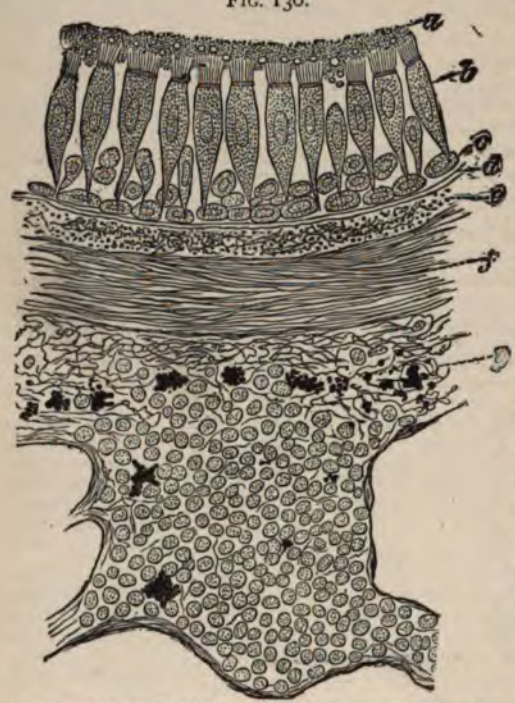
An *external fibrous layer* of connective tissue and elastic fibres covers the trachea and the extra-pulmonary bronchi externally. Toward the œsophagus, the elastic elements are more numerous, and there are also a few bundles of plain muscular fibres arranged longitudinally. Within this layer there are bundles of *non-striped muscular fibres* which pass transversely between the cartilages behind, and also in the intervals between the cartilages. [These pale reddish fibres constitute the **trachealis muscle**, and are attached to the inner surfaces of the cartilages at a little distance from their free ends. The arrangement varies in different animals—thus, in the cat, dog, rabbit, and rat the muscular fibres are attached to the *external* surfaces of the cartilages, while in the pig, sheep, and ox they are attached to their *internal* surfaces (*Stirling*).] Some muscular fibres are arranged longitudinally external to the transverse fibres. The **function** of these muscular fibres is to prevent too great distention when there is great pressure within the air passages.

The mucous membrane consists of a basis of very fine connective tissue, containing much adenoid tissue with numerous lymph corpuscles. Numerous elastic fibres are arranged chiefly in a longitudinal direction under the basement membrane. They are also abundant in the deep layers of the posterior part of the membrane opposite the intervals between the cartilages. A small quantity of loose **submucous** connective tissue containing the large blood vessels, glands, and lymphatics unites the mucous membrane to the perichondrium of the cartilages. The **epithelium** consists of a layer of columnar ciliated cells with several layers of immature cells under them. [The superficial layer of cells is columnar and **ciliated** (Fig. 130, *b*), while those lying under them present a variety of forms, and below all is a layer of somewhat flattened squames, *c*, resting on the basement membrane, *d*. These squames constitute a layer quite distinct from the basement membrane, and they form the layer described as **Débove's membrane.** They are active germinating cells, and play a most important part in connection with the regeneration of the epithelium, after the superficial layers have been shed, in such conditions as bronchitis. Not unfrequently a little viscid

mucus (*a*) lies on the free ends of the cilia. In the intermediate layer, the cells are more or less pyriform or battledore-shaped, with their long tapering process inserted among the deepest layer of squames. According to Drasch, this long process is attached to one of these cells and is an outgrowth from it, the whole constituting a "foot cell."]

Under the epithelium is the homogeneous **basement membrane**, through which fine canals pass, connecting the cement of the epithelium with spaces in the mucosa. [This membrane is well marked in the human trachea, where it plays an important part in many pathological conditions, *e.g.*, bronchitis. It is stained bright red with picrocarmine.] The cilia act so as to carry any secretion toward the larynx. Goblet cells exist between the ciliated columnar cells. Numerous small compound tubular **mucous glands** occur in the mucous membrane, chiefly between the cartilages. Their ducts open on the surface by means of a slightly funnel-shaped aperture, into which the ciliated epithelium is prolonged for a short distance. [The acini of some of these glands lie outside the trachealis muscle. The acini are lined by cubical or columnar secretory epithelium. In some animals (dog) these cells are clear, and present the usual characters of a mucus-secreting gland; in man, some of the cells may be clear, and others "granular," but the appearance of the cells depends upon the physiological state of activity.] These glands secrete the mucus, which entangles particles inspired with the air, and is carried toward the larynx by ciliary action. [Numerous **lymphatics** exist in the mucous and submucous coat, and not unfrequently small aggregations of adenoid tissue occur (especially in the cat) in the mucous coat, usually around the ducts of the glands. They are comparable to the solitary follicles of the alimentary tract. The **blood vessels** are not so numerous as in some other mucous membranes. [A plexus of **nerves** containing numerous ganglionic cells at the nodes exists on the posterior surface of the trachealis muscle. The fibres are derived from the vagus, recurrent laryngeal, and sympathetic (*C. Frankenhauser, W. Stirling, Kandarazi*).]

FIG. 130.



Transverse section of part of a human bronchus (× 450). *a*, precipitated mucus; *b*, ciliated columnar epithelium; *c*, deep germinal layer of cells (Dêbove's membrane); *d*, elastic basement membrane; *e*, elastic fibres divided transversely (inner fibrous layer); *f*, bronchial muscle; *g*, outer fibrous layer with leucocytes and pigment granules (black); below a mass of adenoid tissue.

[The **mucous membrane of the trachea and extra-pulmonary bronchi**, therefore, consists of the following layers from within outward:—

(1) Stratified columnar ciliated epithelium.
(2) A layer of flattened cells (Dêbove's membrane).
(3) A clear homogeneous basement membrane.
(4) A basis of areolar tissue, with adenoid tissue and blood vessels, and outside this a layer of longitudinal elastic fibres.

Outside this, again, is the **submucous coat**, consisting of loose areolar tissue, with the larger vessels, lymphatics, nerves, and mucous glands.]

[The **Bronchi.**—In structure the **extra-pulmonary bronchi** resemble the trachea. As they pass into the lung they divide very frequently, and the branches do not anastomose. In the **intra-pulmonary bronchi** the subdivisions become finer and finer, the finest branches being called **terminal bronchi**, or **bronchioles**, which open separately into clusters of air vesicles.]

[**Eparterial and Hyparterial Bronchi.**—As the bronchi proceed, one main trunk passes into the lung, running toward its base, and from it are given off branches dorsally and ventrally, and these branches again subdivide. In man one main branch comes off from the right bronchus and proceeds to the upper right lobe, *above* the place where the pulmonary artery crosses the bronchus. Such branches are called *eparterial*, and they are more numerous in birds. In man, all the branches, both on the right and left side, come off below the point where the pulmonary artery crosses the bronchus, and are called *hyparterial bronchi* (*C. Aeby*).]

[In the middle-sized **intra-pulmonary bronchi**, the usual characters of the mucous membrane are retained, only it is thinner; the cartilages assume the form of irregular plates situated in the outer wall of the bronchus; while the muscular fibres are disposed in a complete circle, constituting the **bronchial muscle** (Fig. 130, *f*). When this muscle is contracted, or when the bronchus as a whole is contracted, the mucous membrane is thrown into longitudinal folds, and opposite these folds the elastic fibres form large elevations. This muscle is particularly well developed in the smaller microscopic bronchi. Numerous elastic fibres, *e*, disposed longitudinally, exist under the basement membrane, *d*. They are continuous with those of the trachea, and are prolonged onward into the lung. The mucous membrane of the larger **intra-pulmonary bronchi** consists of the following layers from within outward :—

(1) Stratified columnar ciliated epithelium (Fig. 130, *b*).
(2) Dèbove's membrane (Fig. 130, *c*).
(3) Transparent homogeneous basement membrane (Fig. 130, *d*).
(4) Areolar tissue with longitudinal elastic fibres (Fig. 130, *e*).
(5) A continuous layer of non-striped muscular fibres disposed circularly (*bronchial muscle*, Fig. 130, *f*).

Outside this is the **submucous coat**, consisting of areolar tissue mixed with much adenoid tissue (Fig. 130, *g*), sometimes arranged in the form of cords, the **lymph-follicular cords.** It also contains the acini of the numerous **mucous glands**, blood vessels, and lymphatics. The ducts of the glands perforate the muscular layer, and open on the free surface of the mucous membrane. The submucous coat is connected by areolar tissue with the perichondrium of the **cartilages.** Outside the cartilages are the **nerves** and **nerve ganglia** accompanying the bronchial vessels. The branches of the pulmonary artery and of the pulmonary vein usually lie on opposite sides of the bronchus, while there are several branches of the bronchial arteries and veins. **Fat cells** also occur in the peribronchial tissue.]

In the **small bronchi** the cartilages and glands disappear, but the circular muscular fibres are well developed. They are lined by lower columnar ciliated epithelium, containing goblet cells.

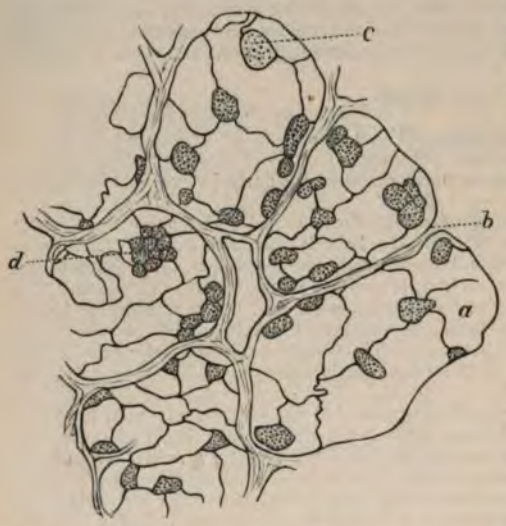
Bronchioles.—After repeated subdivision, the bronchi form the "*smallest bronchi*" (about 0.5 to 1 mm.) or *lobular bronchial tubes*. Each tube is lined by a layer of ciliated epithelium, but the glands and cartilages have disappeared. These tubes have a few lateral **alveoli** or **air cells** communicating with them. Each smallest bronchus ends in a "respiratory bronchiole (*Kölliker*), which gradually becomes beset with more air cells, and in which squamous epithelium begins to appear between the ciliated epithelial cells. [Each bronchiole opens into several wider *alveolar* or **lobular passages.** Each passage is completely surrounded with air cells, and from it are given off several similar but wider blind branches, the **infundibula**, which, in their turn, are beset on all sides with *alveoli* or *air cells*. Several infundibula are connected with each bronchiole, and the former are wider than the latter. Each bronchiole, with its alveolar passages, infundibula, and air vesicles, is termed a **lobule**, whose base is directed outward, and whose apex may be regarded as a terminal bronchus. The lung is made up of an immense number of these lobules, separated from each other by septa of connective tissue, the **interlobular septa** (Fig. 133, *e*) which are continuous on the one hand with the sub-pleural connective tissue, and on the other with the peribronchial connective tissue.]

[There is an alteration in the structure of the bronchi, as we proceed from the larger to the smaller tubes. The cartilages and glands are the first structures to disappear. The circular bronchial muscle is well developed in the smaller bronchi and bronchioles, and exists as a continuous thin layer over the alveolar passages, but it is not continued over and between the air cells. Elastic fibres, continuous, on the one hand, with those in the smaller bronchi, and on the other with those in the walls of the air cells, lie outside the muscular fibres in the bronchioles and infundibula. In the respiratory bronchioles, the ciliated epithelium is reduced to a single layer, and is mixed with the stratified form of epithelium, while, where the alveolar passages open into the air cells or alveoli, the epithelium is non-ciliated, low, and polyhedral.]

Alveoli or Air Cells.—The form of the cells, which are 250 μ ($\frac{1}{100}$ inch) in diameter, may be more or less spherical, polygonal, or cup-shaped. They are disposed around and in communication with the alveolar passages. Their form is determined by the existence of a nearly structureless membrane, composed of slightly fibrillated connective tissue containing a few corpuscles. This is surrounded by numerous fine elastic fibres, which give to the pulmonary parenchyma its well-marked elastic characters (Fig. 132, *e*, *e*). These fibres often bifurcate, and are arranged with reference to the alveolar wall. They are very resistant, and in some cases of lung disease may be recognized in the sputum. A few non-striped muscular fibres exist in the delicate connective tissue between adjoining air vesicles. These muscular fibres sometimes become greatly developed in certain diseases (*Arnold, W. Stirling*). The air cells are lined by two kinds of cells; (1) large, transparent, clear, polygonal (nucleated?) **squames** or placoids (22–45 μ) lying over and between the capillaries in the alveolar wall (Fig. 131, *a*); (2) small, irregular, "**granular**," nucleated cells (7–15 μ) arranged singly or in groups (two or three) in the interstices between the capillaries. They are well seen in a cat's lung (Fig. 131, *a*). [When acted on with nitrate of silver the cement substance bounding the clear cells is stained, but the small cells become of a uniform brown, granular appearance, so

that they are readily recognized. Small holes or "**pseudo-stomata**" seem to exist in the cement substance, and are most obvious in distended alveoli. They open into the lymph-canalicular system of the alveolar wall (*Klein*), and through them the lymph corpuscles, which are always to be found on the surface of the air vesicles, migrate, and carry with them into the lymphatics particles of carbon derived from the air.] In the alveolar walls is a very dense plexus of fine **capillaries** (Fig. 132, *c*), which lie more toward the cavity of the air vesicle, being covered only by the epithelial lining of the air cells. Between two adjacent alveoli there is only a single layer of capillaries (man), and on the boundary line between two air cells the course of the capillaries is twisted, thus projecting sometimes into the one alveolus, sometimes into the other.

FIG. 131.



Air vesicles injected with silver nitrate. *a*, outlines of squamous epithelium; *b*, alveolar wall; *c*, young epithelium cell; *d*, aggregation of young epithelial cells germinating.

[The **number of alveoli** is stated to be about 725 millions, a result obtained by measuring the size of the air vesicles and ascertaining the amount of air in the lung after an ordinary inspiration, determining how much of this air is in the air vesicles and bronchi respectively. The superficial area of the air vesicles is about 90 square metres, or 100 times greater than the surface of the body (.8 to .9 sq. metre).]

The **Blood vessels** of the lung belong to two different systems: (A) **Pulmonary vessels** (lesser circulation). The branches of the pulmonary artery accompany the bronchi and are closely applied to them. [As they proceed they branch, but the branches do not anastomose, and ultimately they terminate in small arterioles, which supply several adjacent alveoli, each arteriole splitting up into capillaries for *several* air cells (Fig. 132, *v*, *c*). An efferent vein usually arises at the opposite side of the air cells, and carries away the purified blood from the capillaries. In their course these veins unite to form the *pulmonary veins*, which, again, are joined in their course by a few small bronchial veins. The veins usually anastomose in the earlier part of their course, while the corresponding arteries do not.] Although the capillary plexus is very fine and dense, its sectional area is less than the sectional area of the systemic capillaries, so that the blood stream in the pulmonary capillaries must be more rapid than that in the capillaries of the body generally. The pulmonary veins, unlike veins generally, are collectively narrower than the pulmonary artery (water is given off in the lung), and they have no valves. [The pulmonary artery contains venous blood, and the pulmonary veins pure or arterial blood.]

(B) The **bronchial vessels** represent the nutrient system of the lungs. They (1–3) arise from the aorta (or intercostal arteries) and accompany the bronchi without anastomosing with the branches of the pulmonary artery. In their course they give branches to the lymphatic glands at the hilum of the lung, to the walls of the large blood vessels (vasa vasorum), the pulmonary pleura, the bronchial walls, and the interlobular septa. The blood which issues from their capillaries is returned —*partly* by the pulmonary veins—hence, any considerable interference with the pulmonary circulation causes congestion of the bronchial mucous membrane, resulting in a catarrhal condition of that membrane. The greater part of the blood is returned by the *bronchial veins*, which open into the vena azygos, intercostal vein, or superior vena cava. The veins of the smaller bronchi (fourth order onward) open into the pulmonary veins, and the anterior bronchial also communicate with the pulmonary vein (*Zuckerkandl.*)

[The **Pleura.**—Each pleural cavity is distinct, and is a large serous sac, which really belongs to the lymphatic system of the lung. The pleura consists of two layers, **visceral** and **parietal**. The visceral pleura covers the lung; the parietal portion lines the wall of the chest, and the two layers of the corresponding pleura are continuous with one another at the root of the lung. The visceral pleura is the thicker, and may readily be separated from the inner surface of the chest. Structurally, the pleura resembles a serous membrane, and consists of a thin layer of fibrous tissue covered by a layer of endothelium. Under this layer, or the pleura proper, is a *deep* or *sub-serous* layer of looser areolar tissue, containing many elastic fibres. The layer of the pleura pulmonalis of some animals, as the guinea pig, contains a network of non-striped muscular fibres (*Klein*). Over the lung it is also continuous with the interlobular septa. The **interlobular septa** (Fig. 133, *e*) consist of bands

of fibrous tissue separating adjoining lobules, and they become continuous with the peribronchial connective tissue entering the lung at its hilum. Thus the fibrous framework of the lung is continuous throughout the lung, just as in other organs. The connection of the sub-pleural fibrous tissue with the connective tissue within the substance of the lung has most important pathological bearings. The interlobular septa contain lymphatics and blood vessels. The endothelium covering the parietal layer is of the ordinary squamous type, but on the pleura pulmonalis the cells are less flattened, more polyhedral, and granular. They must necessarily vary in shape with changes in the volume of the lung, so that they are more flattened when the lung is distended, as during inspiration. The pleura contains many lymphatics, which communicate by means of **stomata** with the pleural cavity.]

[The **Lymphatics** of the lung are numerous, and are arranged in several systems. The various air cells are connected with each other by very delicate connective tissue, and, according to J. Arnold, in some parts this interstitial tissue presents characters like those of adenoid tissue; so that the lung is traversed by a system of **juice canals** or "Saft-canälchen."] [In the deep layer of the pleura there is a (*a*) **sub-pleural** plexus of lymphatics partly derived from the pleura, but chiefly

FIG. 132.

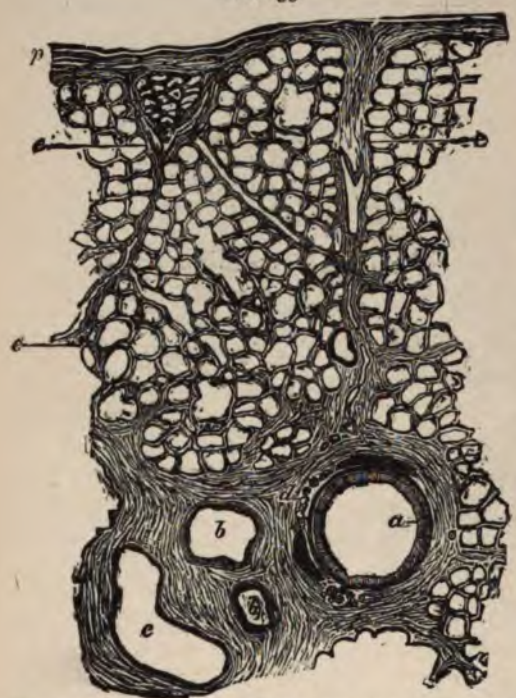
Semi-diagrammatic representation of the air vesicles of the lung. *v*, *v*, blood vessels at the margins of an alveolus; *c*, *c*, its blood capillaries; E, relation of the squamous epithelium of an alveolus to the capillaries in its wall; *f*, alveolar epithelium shown alone; *e*, *e*, elastic tissue of the lung.

from the lymph-canalicular system of the pleural alveoli. Some of these branches proceed to the bronchial glands, but others pass into the interlobular septa, where they join (*b*) the **perivascular** lymphatics which arise in the lymph-canalicular system of the alveoli. These trunks, provided with valves, run alongside the pulmonary artery and vein, and in their course they form frequent anastomoses. Special vessels arise within the walls of the bronchi, and occur chiefly in the outer coat of the latter, constituting (*c*) the **peri-bronchial** lymphatics, which anastomose with *b*. The branches of these two sets run toward the bronchial glands. Not unfrequently (cat) masses of adenoid tissue are found in the course of these lymphatics.] The lymph-canalicular system and the lymphatics become injected when fine-colored particles are inspired, or are introduced into the air cells artificially. The pigment particles pass through the semi-fluid cement substance into the lymph-canalicular system and thence into the lymphatics; or, according to Klein, they pass through actual holes or pores in the cement (p. 206).] [This pigmentation is well seen in coal-miner's lung or **anthracosis**, where the particles of carbon pass into and are found in the lymphatics. Sikorski and Küttner showed that pigment reached the lymphatics in this way during life. If pigment,

China ink, or indigo carmine be introduced into a frog's lung, it is found in the lymphatic system of the lung. Ruppert, and also Schotielius, showed that the same result occurred in dogs after the inhalation of charcoal, cinnabar, or precipitated Berlin blue, and von Ins after the inhalation of silica. Schestopal used China ink and cinnabar suspended in ¾ per cent. salt solution.] Excessively fine lymph canals lie in the wall of the alveoli in the interspaces of the capillaries, and there are slight dilatations at the points of crossing. According to Pierret and Renaut every air cell of the lung of the ox is surrounded by a large lymph space, such as occurs in the salivary glands. When a large quantity of fluid is injected into the lung, it is absorbed with great rapidity; even blood corpuscles rapidly pass into the lymphatics.

The **superficial** lymphatics of the pulmonary pleura communicate with the pleural cavity by means of free openings or **stomata**, and the same is true of the lymphatics of the parietal pleura, but these stomata are confined to limited areas over the diaphragmatic pleura. [The lymphatics in the costal pleura occur over the intercostal spaces and not over the ribs (*Dybkowski*).] The large arteries of the lung are provided with lymphatics which lie between the middle and outer coats. [The movements of the lung during respiration are most important factors in moving the lymph onward in the pulmonary lymphatics. The reflux of the lymph is prevented by the presence of valves.]

FIG. 133.



Human lung (× 50 and reduced ¼). *a*, small bronchus; *b*, *b*, pulmonary artery; *c*, pulmonary vein; *e*, interlobular septa, continuous with the deep layer of the pleura, *p*.

[The **nerves** of the lung are derived from the anterior and posterior pulmonary plexuses, and consist of branches from the vagus and sympathetic. They enter the lungs and follow the distribution of the bronchi, several sections of nerve trunks being usually found in a transverse section of a large bronchial tube. The nerves lie outside the cartilages, and are in close relation with the branches of the bronchial arteries. Medullated and non-medullated nerve fibres occur in the nerves, which also contain numerous small **ganglia** (*Remak*, *Klein*, *Stirling*). In the lung of the calf the ganglia are large. The exact mode of termination of the nerve fibres within the lung has yet to be ascertained in mammals, but some fibres pass to the bronchial muscle, others to the large blood vessels of the lung, and it is highly probable that the mucous glands are also supplied with nerve filaments. In the comparatively simple lungs of the frog, nerves with numerous nerve cells in their course are found (*Arnold*, *Stirling*), and in the very simple lung of the newt, there are also numerous nerve cells disposed along the course of the intra-pulmonary nerves. Some of these fibres terminate in the uniform layer of non-striped muscle which forms part of the pulmonary wall in the frog and newt, and others end in the muscular coat of the pulmonary blood vessels (*Stirling*). The functions of these ganglia are unknown, but they may be compared to the nerve plexuses existing in the walls of the digestive tract.]

The **Function** of the **non-striped muscle** of the entire bronchial system seems to be to offer a sufficient amount of resistance to increased pressure within the air passages; as in forced expiration, speaking, singing, blowing, etc. The vagus is the motor nerve for these fibres; and according to Longet, the "lung-tonus" during increased tension depends upon these muscles.

[**Effect of Nerves.**—By connecting the interior of a small bronchus with an oncograph (§ 103) in curarized dogs (the thorax being opened), Graham Brown and Roy found that **section** of one vagus causes a marked expansion of the bronchi of the corresponding lung, while **stimulation** of the peripheral end of a divided vagus causes a powerful contraction of the bronchi of *both* lungs.

Stimulation of the central end of one vagus, the other being intact, also causes a contraction (feebler) under the same circumstances. Especially in etherized dogs, expansion and not contraction results. If both vagi be divided, no effect is produced by stimulation of the central end of either vagus. It seems plain that the vagi contain centripetal or afferent fibres, which can cause both expansion and contraction of the bronchi. Asphyxia causes contraction provided the vagi are intact, but none if they are divided, although in etherized dogs expansion frequently occurs, while stimulation of the central end of other sensory nerves has very rarely any, or, if any, but a slight, effect on the calibre of the bronchi, so that in the dog the only connection between the cerebro-spinal centres and the bronchi is through the vagi.]

Pathological.—Stimulation of the smooth muscles, whereby a spasmodic narrowing of the smaller bronchi is produced, may excite asthmatic attacks. If the expiratory blast be interfered with, acute emphysema may take place (*Biernier*).

Chemistry.—In addition to connective, elastic, and muscular tissue, the lungs contain lecithin, inosit, uric acid (taurin and leucin in the ox), guanin, xanthin (?), hypoxanthin (dog)—soda, potash, magnesium, oxide of iron, much phosphoric acid, also chlorine, sulphuric and silicic acids—in diabetes sugar occurs—in purulent infiltration glycogen and sugar—in renal degeneration urea, oxalic acid, and ammonia salts; and in diseases where decomposition takes place, leucin and tyrosin.

[**Physical Properties of the Lungs.**—The lungs, in virtue of the large amount of elastic tissue which they contain, are endowed with **elasticity**; and when the chest is opened they collapse. If a cannula with a small lateral opening be tied into the trachea of a rabbit's or sheep's lungs, the lungs may be inflated with a pair of bellows, or elastic pump. After the artificial inflation, the lungs, owing to their elasticity, collapse and expel the greater part of the air. As much air remains within the light spongy tissue of the lungs, even after they are removed from the body, a healthy lung floats in water. If the air cells are filled with pathological fluids or blood, as in certain diseased conditions of the lung (pneumonia), then the lungs or parts thereof may sink in water. The lungs of the fœtus, before respiration has taken place, sink in water, but after respiration has been thoroughly established in the child, the lungs float. Hence, this **hydrostatic test** is largely used in medico-legal cases, as a test of the child's having breathed. If a healthy lung be squeezed between the fingers, it emits a peculiar and characteristic fine crackling sound, owing to the air within the air cells. A similar sound is heard on cutting the vesicular tissue of the lung. The **color** of the lungs varies much; in a young child it is rose-pink, but afterward it becomes darker, especially in persons living in towns or a smoky atmosphere, owing to the deposition of granules of carbon. In coal miners the lungs may become quite black.]

[**Excision of the Lung.**—Dogs recover after the excision of one entire lung, and they even survive the removal of portions of lung infected with tubercle (*Biondi*).]

107. **MECHANISM OF RESPIRATION.**—The mechanism of respiration consists in an alternate dilatation and contraction of the chest. The dilatation is called **inspiration**, the contraction **expiration**. As the whole external surfaces of both elastic lungs are applied directly, and in an air-tight manner, by their smooth, moist, pleural investment, to the inner wall of the chest, which is covered by the parietal pleura, it is clear that the lungs must be distended with every dilatation of the chest, and diminished by every contraction thereof. The **movements of the lungs**, therefore, are entirely **passive**, and are dependent on the thoracic movements.

On account of their complete elasticity and their great extensibility, the lungs are able to accommodate themselves to any variation in the size of the thoracic cavity, without the two layers of the pleura becoming separated from each other. As the capacity of the non-distended chest is greater than the volume of the collapsed lungs after their removal from the body, it is clear that the lungs, even in their natural position within the chest, are distended, *i. e.*, they are in a certain state of **elastic tension** (§ 60). The tension is greater the more distended the thoracic cavity, and *vice versâ*. As soon as the pleural cavity is opened by perforation from without, the lungs, in virtue of their elasticity, collapse, and a space

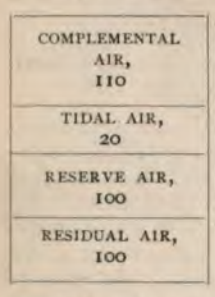
filled with air is formed between the surface of the lungs and the inner surface of the thoracic wall (**pneumothorax**), The lungs so affected are rendered useless for respiration; hence a double pneumothorax causes death.

Pneumothorax.—It is also clear that, if the pulmonary pleura be perforated from within the lung, air will pass from the respiratory passages into the pleural sac, and also give rise to pneumothorax. [Not unfrequently the surgeon is called on to open the chest, say by removing a portion of a rib, to allow of the free exit of pus from the pleural cavity. If this be done with proper precautions, and if the external wound be allowed to heal, after a time the air in the pleural cavity becomes absorbed, the collapsed lung tends to reign its original form, and again becomes functionally active.]

Estimation of Elastic Tension.—If a manometer be introduced through an intercostal space into the pleural cavity, in a dead subject, we can measure, by means of a column of mercury, the amount of the elastic tension required to keep the lung in its position. This is equal to 6 mm. in the dead subject, as well as in the condition of expiration. If, however, the thorax be brought into the position of inspiration by the application of traction from without, the elastic tension may be increased to 30 mm. Hg (*Donders*).

If the glottis be closed and a deep inspiration taken, the air within the lungs must become rarefied, because it has to fill a greater space. If the glottis be suddenly opened, the atmospheric air passes into the lungs until the air within the lungs has the same density as the atmosphere. Conversely, if the glottis be closed, and if an expiratory effort be made, the air within the chest must be compressed. If the glottis be suddenly opened, air passes out of the lungs until the pressure outside and inside the lung is equal. As the glottis remains open during ordinary respiration, the equilibration of the pressure within and without the lungs will take place gradually. During tranquil inspiration there is a slight negative pressure; during expiration, a slight positive pressure in the lungs; the former = 1 mm., the latter 2–3 mm. Hg in the human trachea (measured in cases of wounds of the trachea).

108. QUANTITY OF GASES RESPIRED.—As the lungs within the chest never give out all the air they contain, it follows that only a part of the air of the lungs is changed during inspiration and expiration. The volume of this air will depend upon the depth of the respirations.



Hutchinson defined the following:—

(1) **Residual air** is the volume of air which remains in the chest *after the most complete expiration*. It is = 1230–1640 c. c. [100–130 cubic inches].

(2) **Reserve or supplemental air** is the volume of air which can be expelled from the chest *after* a normal quiet expiration. It is = 1240–1800 c. c. [100 cubic inches].

(3) **Tidal air** is the volume of air which is taken in and given out at each respiration. It is = 500 cubic centimetres [20 cubic inches].

(4) **Complemental air** is the volume of air that can be forcibly inspired over and above what is taken in at a normal respiration. It amounts to about 1500 c. c. [100–130 cubic inches].

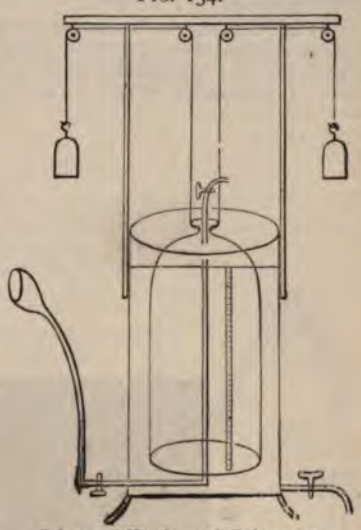
(5) **Vital Capacity** is the term applied to the volume of air which can be forcibly expelled from the chest after the deepest possible inspiration. It is equal to 3772 c. c. (or 230 cubic inches) for an Englishman (*Hutchinson*), and 3222 for a German (*Haeser*).

Hence, after every quiet inspiration, both lungs contain (1 + 2 + 3) = 3000 to 3900 c. cm. [220 cubic inches]; after a quiet expiration (1 + 2) = 2500 to 3400 c. cm. [200 cubic inches]. So that about $\frac{1}{6}$ to $\frac{1}{7}$ of the air in the lungs is subject to renewal at each ordinary respiration.

Donders calculated that the entire bronchial system and the trachea contain about 500 c. c. of air.

Estimation of Vital Capacity.—This was formerly thought to be of great utility, but at the present time not much importance is attached to it, nor is it frequently measured in cases of disease. It is estimated by means of the **spirometer** of Hutchinson (Fig. 134), which consists of a graduated cylinder filled with water and inverted like a gasometer over water, and balanced by means of a counterpoise. Into the cylinder a tube projects, and this tube is connected with a mouth-piece. The person to be experimented upon takes the deepest possible inspiration, closes his nostrils, and breathes forcibly into the mouth-piece of the tube. After doing so the tube is closed. The cylinder is raised by the air forced into it, and after the water inside and outside the cylinder is equalized, the height to which the cylinder is raised indicates the amount *of air expired*, or the vital or respiratory capacity. In a man of average height, 5 feet 8 inches, it is equal to 230 cubic inches.

FIG. 134.



Scheme of Hutchinson's Spirometer.

The following circumstances affect the vital capacity:—

(1) The **Height.**—Every inch added to the height of persons between 5 and 6 feet gives an increase of the vital capacity = 130 c. c. [8 cubic inches].

(2) The **Body weight.**—When the body weight exceeds the normal by 7 per cent. there is a diminution of 37 c. c. of the vital capacity for every kilo. of increase.

(3) **Age.**—The vital capacity is at its maximum at 35; there is an annual decrease of 23.4 c. c., from this age onward to 65, and backward to 15 years of age.

(4) **Sex.**—It is less in women than men, and even where there is the same circumference of chest, and the same height in a man and a woman, the ratio is 10 : 7.

(5) **Position** and **Occupation.**—More air is respired in the erect than in the recumbent position.

(6) **Disease.**—Abdominal and thoracic diseases diminish it.

109. **NUMBER OF RESPIRATIONS.**—In the **adult,** the number of respirations varies from 16 to 24 per minute, so that about 4 pulse beats occur during each respiration. The number of respirations is influenced by many conditions:—

(1) The **Position of the Body.**—In the adult, in the horizontal position, Guy counted 13, while sitting 19, while standing 22, respirations per minute.

(2) **Age.**—Quetelet found the mean number of respirations in 300 individuals to be:—

Year.	Respirations.		Year.	Respirations.	
0 to 1,	44	Average	20 to 25,	18.7	Average
5,	26	Number per	25 to 30,	16	Number per
15 to 20,	20	Minute.	30 to 50,	18.1	Minute.

(3) The **State of Activity.**—Gorham counted in children of 2 to 4 years of age during standing 32, in sleep 24, respirations per minute. During bodily exertion the number of respirations increases before the heart beats. [Very slight *muscular* exertion suffices to increase the frequency of the respirations.]

[(4) The **Temperature** of the surrounding medium.—The respirations become more numerous the higher the surrounding temperature, but this result only occurs when the actual temperature of the blood is increased, as in fever.

(5) **Digestion.**—There is a slight variation during the course of the day, the increase being most marked after mid-day dinner (*Vierordt*).

(6) The **Will** can to a certain extent modify the number and also the depth of the respirations, but after a short time the impulse to respire overcomes the voluntary impulse.

(7) The **Gases of the Blood** have a marked effect, and so has the heat of the blood in fever.]

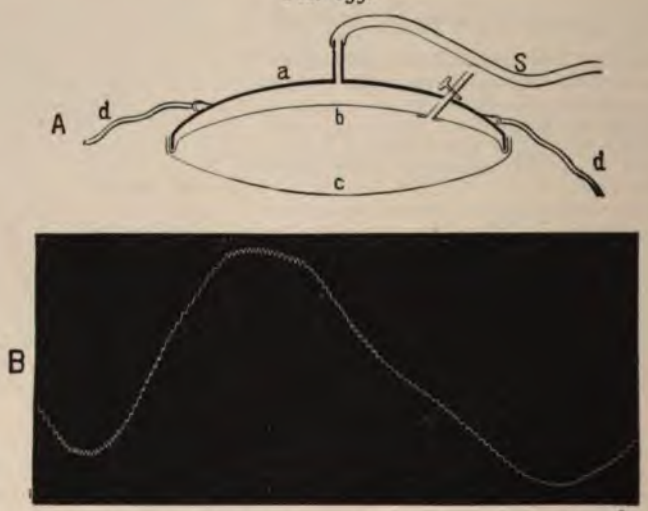
[(9) **In Disease.**—The number may be greatly **increased** from many causes, *e. g.*, in fever, pleurisy and pneumonia, some heart diseases, or in certain cases of alteration of the blood, as in anæmia; and **diminished** where there is pressure on the respiratory centre in the medulla, in coma. It is important to note the **ratio** of pulse beats to respirations.]

FIG. 135.



A, Brondgeest's tambour for registering the respiratory movements. *b*, *c*, inner and outer caoutchouc membranes; *a*, the capsule; *d*, *d*, cords for fastening the instrument to the chest; *S*, tube to the recording tambour. B, normal respiratory curve obtained on a vibrating plate (each vibration = 0.01613 sec.).

110. TIME OCCUPIED BY THE RESPIRATORY MOVEMENTS.—The time occupied in the various phases of a respiration can only be accurately ascertained by obtaining a curve or **pneumatogram** of the respiratory movements by means of recording apparatus.

Methods.—The graphic method can be employed in three directions: (1) *To record the movements of individual parts of the chest wall.*

(1) Vierordt and C. Ludwig transferred the movements of a part of the chest wall to a lever which inscribed its movements upon a revolving cylinder. Reigel (1873) constructed a "**double stethograph**" on the same principle. This instrument is so arranged that one arm of the lever may be applied in connection with the healthy side of a person's chest, and the other on the diseased side. In the case of animals placed on their backs, Snellon introduced a long needle vertically through the abdominal walls into the liver. Rosenthal opened the abdomen and applied a lever to the under surface of the diaphragm, and thus registered its movements (**Phrenograph**).

(2) An air tambour, such as is used in Brondgeest's pansphygmograph (Fig. 135, A) may be employed. It consists of a brass vessel, *a*, shaped like a small saucer. The mouth of the brass

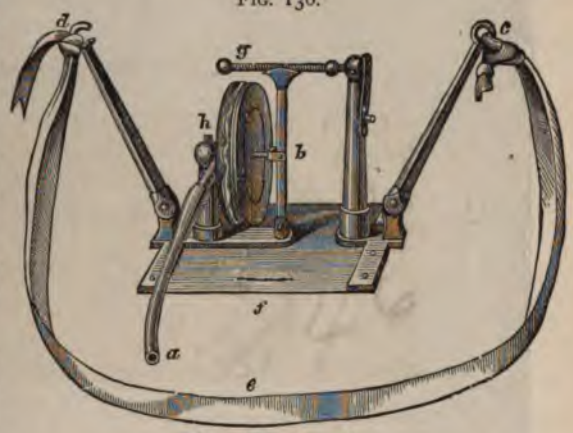
vessel is covered with a double layer of caoutchouc membrane, *b*, *c*, and air is forced in between the two layers until the external membrane bulges outward. This is placed on the chest, and the apparatus is fixed in position by means of the bands, *d*, *d*. The cavity of the tambour communicates by means of a caoutchouc tube, *s*, with a recording tambour, which inscribes its movements upon a revolving cylinder. Every dilatation of the chest compresses the membrane, and thus the air within the tambour is also compressed. [A somewhat similar apparatus is used by Burdon-Sanderson, and called a **"recording stethograph."** By it movements of the corresponding points on opposite sides of the chest can be investigated.] A cannula or œsophageal sound may be introduced into that portion of the œsophagus which lies in the chest, and a connection established with Marey's tambour (*Rosenthal*). [This method also enables one to measure the *intra-thoracic pressure*.]

Marey's Stethograph or Pneumograph.—[There are two forms of this instrument, one modified by P. Bert and the more modern form (Fig. 136). A tambour (*h*) is fixed at right angles to a thin elastic plate of steel (*f*). The aluminium disk on the caoutchouc of the tambour is attached to an upright (*b*), whose end lies in contact with a horizontal screw (*g*). Two arms (*d*, *c*) are attached to opposite sides of the steel plate, and to them the belt (*e*) which fastens the instrument to the chest is attached. When the chest expands, these two arms are pulled asunder, the steel plate is bent, and the tambour is affected, and any movement of the tambour is transmitted to a registering tambour by the air in the tube (*a*)].

(2) *To record variation in volume of the thorax or of the respired gases.*

For this purpose E. Hering secures the animal, and places it in a tight box provided with two openings in its side; one hole contains a tube, which is connected to a cannula tied into the transversely divided trachea of the animal, so that respiration can go on undisturbed. In the other orifice is fixed a water manometer provided with a swimmer arranged to write on a recording surface. Gad registered graphically the respired air by means of a special apparatus; the expired air raised a very light and carefully equipoised box placed over water. As it was raised, it moved a writing style. During inspiration the box sank.

FIG. 136.



Marey's Stethograph.

(3) *To record the rate at which the respiratory gases are exchanged.*

If the trachea of an animal, or the mouth of a man (the nostrils being closed), be connected with a tube like that of the dromograph (Fig. 113), then during inspiration and expiration the pendulum will be moved to and fro by the air, and the movements of the pendulum can be registered. [Some years ago, an instrument, called the "Anapnograph," was constructed on this principle.]

The curve (Fig. 135, B) was obtained by placing the tambour of a Brondgeest's pansphygmograph upon the xiphoid process, and recording the movement upon a plate attached to a vibrating tuning fork. The *inspiration* (ascending limb) begins with moderate rapidity, is accelerated in the middle, and toward the end again becomes slower. The *expiration* also begins with moderate rapidity, is then accelerated, and becomes much slower at the latter part, so that the curve falls very gradually.

Inspiration is slightly shorter than Expiration.—According to Sibson, the ratio for an adult is as 6 to 7; in women, children, and old people, 6 to 8 or 6 to 9. Vierordt found the ratio to be 10 to 14.1 (to 24.1); J. R. Ewald, 11 to 12. It is only occasionally that cases occur where inspiration and expiration are equally long, or where expiration is shorter than inspiration. When respiration proceeds quietly and regularly, there is usually *no pause* (complete rest of the chest walls) *between the inspiration and expiration*. The very flat part of the

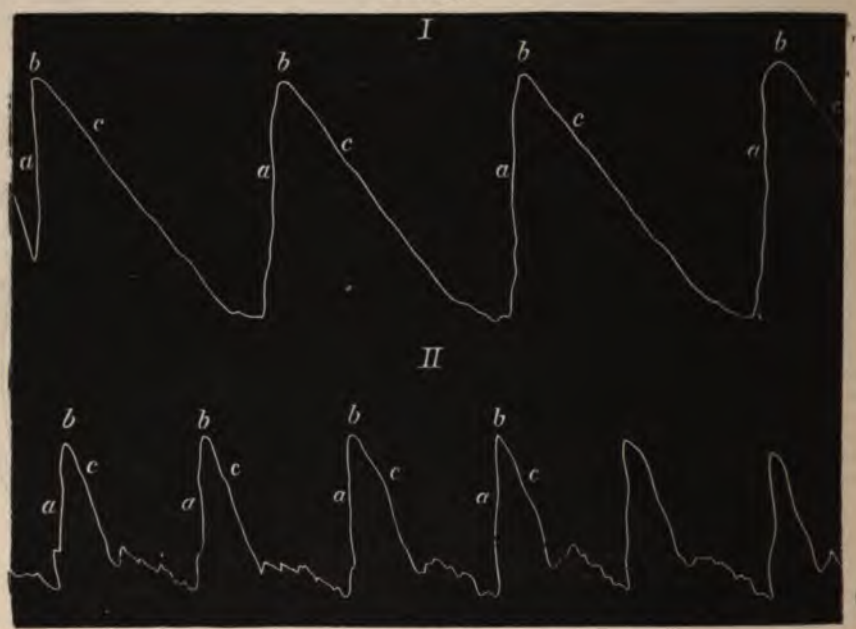
expiratory curve has been wrongly regarded as due to a pause. Of course, we may make a voluntary pause between two respirations, or at any part of a respiratory act.

Some observers, however, have described a pause as occurring between the end of expiration and the beginning of the next inspiration (expiration pause), and also another pause at the end of inspiration (inspiration pause). The latter is always of very short duration, and considerably shorter than the former. During very deep and slow respiration, there is usually an expiration pause, while it is almost invariably absent during rapid breathing. An inspiration pause is always absent under normal circumstances, but it may occur under pathological conditions.

In certain parts of the respiratory curve slight irregularities may appear, which are sometimes due to vibrations communicated to the thoracic walls by vigorous heart beats (Fig. 137).

The "**type**" of respiration may be ascertained by taking curves from various parts during the respiratory movements. Hutchinson showed that, in the female,

FIG. 137.



Pneumatograms obtained by means of Riegel's stethograph. I, normal curves; II, curve from a case of emphysema; *a*, ascending limb; *b*, apex; *c*, descending limb of the curve. The small elevations are due to the cardiac impulse.

the thorax is dilated chiefly by raising the sternum and the ribs (Respiratio costalis), while in man it is caused chiefly by a descent of the diaphragm (Respiratio diaphragmatica or abdominalis). In the former, there is the so-called "**costal type,**" in the latter the "**abdominal** or **diaphragmatic type.**"

This difference in the type of respiration in the sexes occurs only during normal quiet respiration. During deep and **forced respiration,** in both sexes the dilatation of the chest is caused chiefly by raising the chest and the ribs. In man, the epigastrium may be pulled in sooner than it is protruded. During **sleep,** the type of respiration in both sexes is thoracic, while at the same time the inspiratory dilatation of the chest precedes the elevation of the abdominal wall (*Mosso*). It is not determined whether the costal type of respiration in the female depends upon the constriction of the chest by corsets or other causes (*Sibson*), or whether it is a natural adaptation to the child-bearing function in women (*Hutchinson*). Some observers maintain that the difference of type is quite distinct, even in sleep, when all constrictions are removed, and that similar differences are noticeable in young children. This is denied by others, while a third class of observers hold that

the costal type occurs in children of both sexes, and they ascribe as a cause the greater flexibility of the ribs of children and women, which permits the muscles of the chest to act more efficiently upon the ribs.

III. **PATHOLOGICAL.—Examination of the Lungs.**—The same **methods** that are applicable to the heart, viz., I, Inspection; II, Palpation; III, Percussion; and IV, Auscultation, apply here also.]

[By **inspection** we may determine the presence of symmetrical or unilateral alterations in the shape of the chest, the presence of bulging or flattening at one part, and variations in the movement of the chest walls. By **palpation**, the presence or absence, character, seat, and extent of any movements are more carefully examined. But we may also study what is called **vocal fremitus** (§ 117). **Percussion** (§ 114), **Auscultation** (§ 116).]

[In investigating the respiratory movements, we should observe (1), the **frequency** (§ 109); (2), the **type** (§ 110); (3), the **nature**, character, and extent of the movements, noting also whether they are accompanied by **pain** or not (§ 110); (4), the **rhythm**.]

I. **Changes in the Mode of Movement.**—In persons suffering from disease of the respiratory organs, the dilatation of the chest may be diminished (to the extent of 5 or 6 cm.) on *both* sides or only on *one* side. In affections of the apex of the lung (in phthisis), the sub-normal expansion of the upper part of the wall of the chest may be considerable. *Retraction* of the soft parts of the thoracic wall, the xiphoid process, and the parts where the lower ribs are inserted, occurs in cases where air cannot freely enter the chest during inspiration, *e.g.*, in narrowing of the larynx; when this retraction is confined to the upper part of the thoracic wall, it indicates that the portion of the lung lying under the part so affected is less extensile and diseased.

Harrison's Groove.—In persons suffering from chronic difficulty of breathing, and in whom, at the same time, the diaphragm acts energetically, there is a slight groove, which passes horizontally outward from the xiphoid cartilage, caused by the pulling in of the soft parts and corresponding to the insertion of the diaphragm.

The **duration of inspiration** is lengthened in persons suffering from narrowing of the trachea or larynx; **expiration** is lengthened in cases of dilatation of the lung, as in emphysema, where all the expiratory muscles must be brought into action (Fig. 137, II).

II. **Variations in the Rhythm.**—When the respiratory apparatus is much affected, there is either an increase or a deepening of the respirations, or both. When there is great difficulty of breathing, this is called **dyspnœa**.

Causes of Dyspnœa.—(1) Limitation of the exchange of the respiratory gases in the blood due to (*a*) diminution of the respiratory surface (as in some diseases of the lungs); (*b*) narrowing of the respiratory passages; (*c*) diminution of the red blood corpuscles; (*d*) disturbances of the respiratory mechanism (*e.g.*, due to affections of the respiratory muscles or nerves, or painful affections of the chest wall); (*e*) impeded circulation through the lungs due to various forms of heart disease. (2) **Heat dyspnœa.**—The frequency of the respirations is increased in *febrile conditions*. The warm blood acts as a direct irritant of the respiratory centre in the medulla oblongata, and raises the number of respirations to 30–60 per minute ("Heat dyspnœa"). If the carotids be placed in warm tubes, so as to heat the blood going to the medulla oblongata, the same phenomena are produced (§ 368). [When a child sucks, it breathes exclusively through the nose, hence catarrhal conditions of the nasal mucous membrane are fraught with danger to the child.]

[**Orthopnœa.**—Sometimes the difficulty of breathing is so great that the person can only respire in the erect position, *i.e.*, when he sits or is propped up in bed. This occurs frequently toward the close of some heart affections, notably in mitral lesions; dropsical conditions, especially of the cavities, may be present.]

Cheyne-Stokes' Phenomenon.—This remarkable phenomenon occurs in certain diseases, where the normal supply of blood to the brain is altered, or where the quality of the blood itself is altered, *e.g.*, in certain affections of the brain and heart, and in uræmic poisoning. Respiratory pauses of one-half to three-quarters of a minute alternate with a short period (½–¾ min.) of increased respiratory activity, and during this time 20–30 respirations occur. The respirations constituting this "series" are shallow at first; gradually they become deeper and more dyspnœic, and finally become shallow or superficial again. Then follows the pause, and thus there is an alternation of pauses and series (or groups) of modified respirations. During the pause, the pupils are contracted and inactive; and when the respirations begin, they dilate and become sensible to light; the eyeball is moved as a whole at the same time. Hein observed that consciousness was abolished during the pause, and that it returned when respiration commmenced.

Causes.—Luciani and Rosenbach regard variations in the excitability of the respiratory centre as the cause of the phenomenon, which they compare with the periodic contraction of the heart (§ 58). The excitability of the respiratory centre is lowest during the pause. They observed this phenomenon after injury to the medulla oblongata above the respiratory centre, and after apnœa produced in animals deeply narcotized with opium, and in the last stages of asphyxia, during respiration in a closed space. During **hibernation**, this mode of respiration is normal in Myoxus, the hedgehog, and the caiman.

Periodic Respiration.—If frogs be kept under water, or if the aorta be clamped, after several hours, they become passive. If they be taken out of the water, or if the clamp be removed from the aorta, they gradually recover and always exhibit the Cheyne Stokes' phenomenon. In such frogs the blood current may be arrested temporarily, while the phenomenon itself remains (*Sokolow and Luchsinger*). If the blood current be arrested by ligature of the aorta, or if the frogs be bled, the respirations occur in groups. This is followed by a few single respirations, and then the respiration ceases completely. During the pause between the periods, mechanical stimulation of the skin causes the discharge of a group of respirations (*Siebert and Langendorff*).

Action of Drugs.—Muscarin, digitalin, curara, chloral, sulphuretted hydrogen, and the poison of many infectious diseases (typhus, diphtheria, scarlet fever) may also cause periodic respiration in frogs [which is not due to the action of these drugs on the heart].

Periodic respiration without any variation in the size of the individual respirations—the so-called "**Biot's respiration**"—occurs normally during sleep. While the nervous system as it were strives to rest, and thus forgets the respiration, the organism does not observe the short pauses (*Mosso*). [There is a periodic increase or decrease in the depth of the respiration, especially in old people and children, even to the extent of respiration becoming "remittent," or even "intermittent," for a period of 30 sec. during sleep. During periodic respiration the action of the several respiratory muscles does not coincide. As a rule, one respires more than is required by the organism. Mosso calls this "**luxus respiration.**"] Periodic irregularities in the respiration are often of reflex origin (*Knoll*).

112. GENERAL VIEW OF THE RESPIRATORY MUSCLES.

(A) Inspiration.

3. According to Garland, the pharynx is always narrowed.

(B) Expiration.

I. During Ordinary Respiration.

The thoracic cavity is diminished by the *weight* of the chest, the *elasticity* of the lungs, costal cartilages, and abdominal muscles.

II. During Forced Expiration.

The Abdominal Muscles.

1. The abdominal muscles [including the obliquus externus and internus, and transversalis abdominis] (*Nn. abdominis internis anteriores e nervis intercostalibus*, 8–12).

2. Mm. intercostales interni, so far as they lie between the osseous parts of the ribs, and the Mm. infracostales (*Nn. intercostales*).

3. M. triangularis sterni (*Nn. intercostales*).

4. M. serratus posticus inferior (*Ram. externi nerv. dorsalium*).

5. M. quadratus lumborum (*Ram. muscular e plexu lumbali*).

113. ACTION OF THE INDIVIDUAL RESPIRATORY MUSCLES.—(A) **Inspiration.**—(1) **The Diaphragm** arises from the cartilages and the adjoining osseous parts of the lower six ribs (costal portion), by two thick processes or crura, from the upper three or four lumbar vertebræ, and a sternal portion from the back of the ensiform process. It represents an *arched double cupola* or dome-shaped partition, directed toward the chest; in the larger concavity on the right side lies the liver, while the smaller arch on the left side is occupied by the spleen and stomach. During the passive condition, these viscera are pressed against the under surface of the diaphragm, by the elasticity of the abdominal walls, and by the intra-abdominal pressure, so that the arch of the diaphragm is pressed upward into the chest. The elastic traction of the lungs also aids in producing this result. The greater part of the upper surface of the central tendon of the diaphragm is united to the pericardium. The part on which the heart rests, and which is perforated by the inferior vena cava (foramen quadrilaterum) is the deepest part of the middle portion of the diaphragm during the passive condition.

Action of the Diaphragm.—When the diaphragm contracts, both arched portions become flatter, and the chest is thereby elongated from above downward. In this act, the lateral muscular parts of the diaphragm pass from an arched condition into a flatter form (Fig. 138), and during a forced inspiration the lowest lateral portions, which during rest are in contact with the chest wall, become separated from it. The middle of the central tendon where the heart rests (fixed by means of the pericardium and inferior vena cava) takes no share in this movement, especially in ordinary quiet breathing, but during the deepest inspiration it sinks somewhat.

Undoubtedly, the diaphragm is the most powerful agent in increasing the cavity of the chest. Brücke believes that in addition to increasing the length of the thoracic cavity from above downward, it also increases the transverse diameter of the lower part of the chest. It presses upon the abdominal viscera from above, and strives to press these outward, thus tending to push out the adjoining thoracic wall. If the contents of the abdomen are removed from a living animal, every time the diaphragm contracts the ribs are drawn inward. This, of course, hinders the chest from becoming wider below, hence the presence of the abdominal viscera seems to be necessary for the normal activity of the diaphragm. Every contraction of the diaphragm, by increasing the intra-abdominal pressure, favors the venous blood current in the abdomen toward the vena cava inferior.

FIG. 138.

Sagittal section through the second rib on the right side. When the arched muscular part of the diaphragm contracts, a wedge-shaped space, with its apex downward, is formed around the circumference of the lower part of the chest.

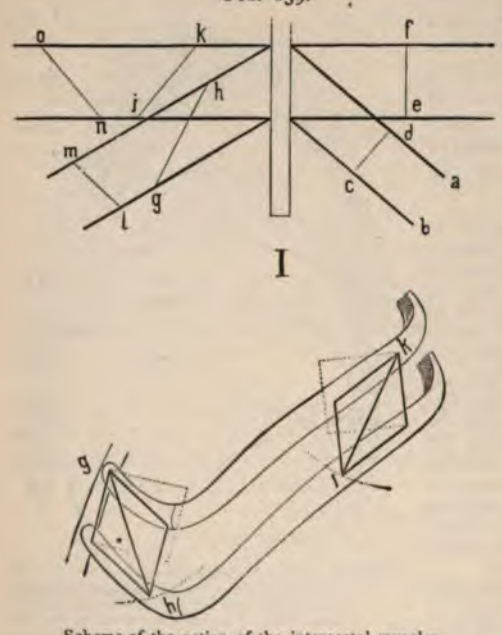
Phrenic Nerve.—The immense importance of the diaphragm as *the great inspiratory muscle* is proved by the fact that, after both phrenic nerves (third and fourth cervical nerves) are divided, death occurs. The phrenic nerve contains some sensory fibres for the pleura, pericardium, and a portion of the diaphragm. The contraction of the diaphragm is not to be regarded as a "simple muscular contraction," since it lasts 4 to 8 times longer than a simple

contraction; it is rather a short tetanic contraction, which we may arrest in any stage of its activity, without bringing into action any antagonistic muscles (*Kronecker and Marckwald*).

(2) **The Elevators of the Ribs.**—The ribs at their vertebral ends (which lie much higher than their sternal ends) are united by means of joints by their heads and tubercles to the bodies and transverse processes of the vertebræ. A horizontal axis can be drawn through both joints, around which the ribs can rotate upward and downward. If the axis of rotation of each pair of ribs be prolonged on both sides until they meet in the middle line, the angles so formed are greatest above (125°), and smallest below (88°). Owing to the ribs being curved, we can imagine a plane which, in the passive (expiratory) condition of the chest, has a slope from behind and inward to the front and outward. If the ribs move on their axis of rotation, this plane becomes more horizontal, and the thoracic cavity is increased in its transverse diameter. As the axis of rotation of the upper ribs runs in a more frontal, and that of the lower ribs in a more sagittal direction, the elevation of the upper ribs causes a greater increase from before backward, and the lower ribs from within outward (as the movements of ribs which are directed downward are vertical to the axis). The costal cartilages undergo a slight tension at the same time, which brings their elasticity into play.

Changes in the Chest.—*All "inspiratory muscles" which act directly upon the chest wall do so by raising the ribs:* (*a*) When the ribs are raised, the intercostal spaces are widened. (*b*) When the upper ribs are raised, all the lower ribs and the sternum must be elevated at the same time, because all the ribs are connected with each other by means of the soft parts of the intercostal spaces. (*c*) During inspiration, there is an elevation of the ribs and a dilatation of the intercostal spaces. (The lowest rib is an exception; during forced respiration, at least, it is drawn downward.) (*d*) If, on a preparation of the chest, the ribs be raised as in inspiration, we may regard all those muscles as elevators of the ribs, whose origin and insertion become approximated. Every one is agreed that the *scaleni* and *levatores costarum longi et breves*, the *serratus posticus superior*, are inspiratory muscles. These are the most important inspiratory muscles which act upon the ribs.

FIG. 139.



Scheme of the action of the intercostal muscles.

Intercostal Muscles.—With regard to the action of the intercostal muscles, there is a great difference of opinion. According to the above experiment, the external intercostals and the intercartilaginous parts of the internal intercostals act as inspiratory muscles, while the remaining portions of the internal intercostals (as far as they are covered by the external) are elongated when the ribs are raised, while they shorten when the chest wall descends. A muscle shortens only during its activity. The internal intercostals were regarded by Hamberger as depressors of the ribs or expiratory muscles.

In Fig. 139, I, when the rods, *a* and *b* (which represent the ribs), are raised, the intercostal space must be widened ($e\,f > c\,d$). On the opposite side of the figure, it is evident that when the rods are raised, the line, $g\,h$, is shortened ($i\,k < g\,h$, direction of the external intercostals), $l\,m$ is lengthened ($l\,m < o\,n$, direction of internal intercostals.) Fig. 139, II, shows, that when the ribs are raised, the intercartilaginei, indicated by $g\,h$, and the external intercostals indicated by $l\,k$, are shortened. When the ribs are raised, the position of the muscular fibres is indicated by the diagonal of the rhomb becoming shorter.

The mode of action of the intercostal muscles is an old story, Galen (131–203 A. D.) regarding

the externals as inspiratory, the internals as expiratory. Hamberger (1727) accepted this proposition, and considered the intercartilaginei also as inspiratory. Haller looked upon both the external and internal intercostals as inspiratory, while Vesalius (1540) regarded both as expiratory. Landerer, observing that the upper two or three intercostal spaces became narrower during inspiration, regarded both as active during inspiration and expiration. They keep one rib attached to the other, so that their action is to transmit any strain put upon them to the wall of the chest. On this view they will be in action, even when the distance between their points of attachment becomes greater. Landois regards the external intercostals and intercartilaginei as active *only* during inspiration, the internal intercostals *only* during expiration. [Martin and Hartwell exposed the internal intercostals, and observed whether they contracted along with the diaphragm, or whether the contractions of these two muscles alternate. As the result of their experiments, they conclude that "the internal intercostal muscles are expiratory throughout their whole extent, at least in the dog and cat; and that in the former animal they are almost "ordinary" muscles of respiration, while in the latter they are 'extraordinary' respiratory muscles."] Landois is of opinion that the *chief* action of these muscles is not to raise or depress the ribs, but rather that the external intercostals and the intercartilaginei offer resistance to the inspiratory dilatation of the intercostal spaces, and to the simultaneously increased elastic tension of the lungs. The internal intercostals act during powerful expiratory efforts (*e. g.*, coughing), and oppose the distention of the lungs and chest caused by this act. Unless muscles were present to resist the uninterrupted tension and pressure, the intercostal substance would become so distended that respiration would be impossible. [According to Rutherford, the internal intercostals are probably muscles of inspiration.]

The **Pectoralis minor and (? Serratus anticus major)** can only act as elevators of the ribs when the shoulders are fixed, partly by the rhomboidei, and partly by fixing the shoulder joint and supporting the arms, as is done instinctively by persons suffering from breathlessness.

(3) **Muscles acting on the Sternum, Clavicle, and Vertebral Column.**—When the head is fixed by the muscles of the neck, the sternocleidomastoid raises the manubrium sterni and the sternal end of the clavicle, so that the thorax is raised and thereby dilated. The scaleni also aid in this act. The clavicular portion of the trapezius may act in a similar although less energetic manner. When the *vertebral column is straightened*, it causes an elevation of the upper ribs, and a dilatation of the intercostal spaces which aid inspiration. During deep respiration, the straightening of the vertebral column takes place involuntarily.

(4) **Laryngeal Movements.**—During labored respiration, with every inspiration, the *larynx descends* and the glottis is opened. At the same time the palate is raised, so as to permit a free passage to the air entering through the mouth.

(5) **Facial Movements.**—During labored respiration, the facial muscles are involved; there is an inspiratory dilatation of the nostrils (well marked in the horse and rabbit). When the need for respiration is very great, the mouth is gradually widened, and the person, as it were, gasps for breath. During expiration, the muscles that are active during (4) and (5) relax, so that a position of equilibrium is established without there being any active expiratory movement to counteract the inspiratory movement. During inspiration the pharynx becomes narrow (*Garland*).

(B) **Expiration.**—Ordinary expiration occurs without the aid of muscles, owing to the **weight of the chest,** which tends to fall into its normal position from the position to which it was raised during inspiration. This is aided by the **elasticity** of the various parts of the chest. When the costal cartilages are raised, which is accompanied by a slight rotation of their lower margins from below forward and upward, their elasticity is called into play. As soon, therefore, as the inspiratory forces cease, the costal cartilages return to their normal position, *i.e.*, the position of expiration, and tend to untwist themselves; at the same time, the **elasticity of the distended lungs** draws upon the thoracic walls and the diaphragm. Lastly, the **tense and elastic abdominal walls,** which, in man chiefly, are stretched and pushed forward, tend to return to their non-distended passive condition when the **abdominal viscera** are relieved from the pressure of the contracted diaphragm. (When the position of the body is reversed, the action

of the weight of the chest is removed, but in place of it there is the weight of the viscera, which press upon the diaphragm.)

The **abdominal muscles** [obliquus internus and externus, transversalis abdominis and levator ani] are always active during labored respiration. They act by diminishing the abdominal cavity, and they press the abdominal contents upward against the diaphragm. When they act simultaneously, the abdominal cavity is diminished throughout its whole extent. The **triangularis sterni** depresses the sternal ends of the united cartilages and bones, from the third to sixth ribs downward; and the **serratus posticus inferior** depresses the lowest four ribs, causing the other to follow. It is aided by the **quadratus lumborum**, which depresses the last rib. According to Henle, the serratus posticus inferior fixes the lower ribs for the action of the slips of the diaphragm inserted into them, so that it acts during inspiration. According to Landerer, the downward movement of the ribs in the lower part of the thorax dilates the chest.

In the erect position, when the vertebral column is fixed, deep inspiration and expiration naturally alter the position of the **centre of gravity**, so that during inspiration, owing to the protrusion of the thoracic and abdominal walls, the centre of gravity lies somewhat more to the front. Hence, with each respiration there is an involuntary balancing of the body. During very deep inspiration, the accompanying straightening of the vertebral column and the throwing backward of the head compensate for the protrusion of the anterior walls of the trunk.

114. **RELATIVE DIMENSIONS OF THE CHEST.**—The diameter of the chest is ascertained by means of callipers; the circumference with a flexible centimetre or other measure.

In strong men, the **circumference** of the upper part of the chest (immediately under the arms) is 88 centimetres (34.3 inches), in females 82 centimetres (32 inches); at the level of the ensiform process 82 centimetres (32 inches) and 78 centimetres (30.4 inches) respectively. When the arms are placed horizontally, during moderate expiration, the circumference immediately under the nipple and the angles of the scapulæ is equal to half the length of the body; in man 82, and during deep inspiration 89 centimetres. The circumference at the level of the ensiform cartilage is 6 centimetres less. In old people, the circumference of the upper part of the chest is diminished, so that the lower part becomes the wider of the two. The right half of the chest is usually slightly larger than the left half, owing to the greater development of the muscles on that side. The **long diameter** of the chest—from the clavicle to the margin of the lowest rib—varies very much.

The **transverse diameter** in man, above and below, is 25 to 26 centimetres (9.7 to 10.1 inches), in females 23 to 24 centimetres (8.9 to 9.2 inches); above the nipple it is 1 centimetre more. The **antero-posterior** diameter (distance of anterior chest wall from the tip of a spinous process) in the upper part of the chest is = 17 (6.6 inches), in the lower 19 centimetres (7.4 inches). Valentin found that in a man, during the deepest inspiration, the chest on a level with the groove in the heart was increased about $\frac{1}{12}$ to $\frac{1}{7}$; while Sibson estimates the increase at the level of the nipple to be $\frac{1}{10}$.

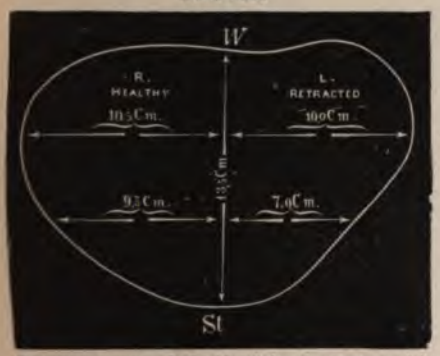
Thoracometer.—In order to obtain a knowledge of the degree of movement—rising or falling—of the chest wall during respiration, various instruments have been invented. The thoracometer (Fig. 141) measures the elevation in different parts of the sternum. It consists of two metallic bars placed at right angles to each other; one of them, A, is placed on the vertebral column. On B there is placed a movable transverse bar, C, which carries on its free end a toothed rod, Z, directed downward. The lower end of this rod is provided with a pad which rests on the sternum, while its toothed edge drives a small wheel, which moves an index, whose excursions are indicated on a circle with a scale attached to it.

The Cyrtometer of Woillez consists of a brass chain of movable links, to be applied in a definite direction to part of the chest wall, *e. g.*, transversely on a level with the nipple, or vertically upon the mammillary or axillary lines anteriorly. There are freely movable links at two parts, which permit the chain to be easily removed, so that as a whole it still retains its form. The chain is laid upon a sheet of paper, and a line drawn with a pencil around its inner margin gives the form of the thorax (Fig. 140). [A lead wire answers the same purpose.]

Limits of the Lungs.—The extent and boundaries of the lungs are ascertained in the living subject by means of **percussion**, which consists in lightly tapping the chest wall by means of a **hammer** (percussion hammer). A small ivory or bone plate or **pleximeter**, held in the left hand, is laid on the chest, and the hammer is made to strike this plate, whereby a sound is emitted, which sound varies with the condition of the subjacent lung tissue. Whenever the lung substance in contact with the chest wall contains air, a clear resonant tone or sound —such as is obtained by striking a vessel containing air, a clear percussion sound —is obtained. Where the lung does not contain air, a dull sound—like striking a limb—is obtained. If the parts containing air be very thin, or only partially filled with air, the sound is "muffled."

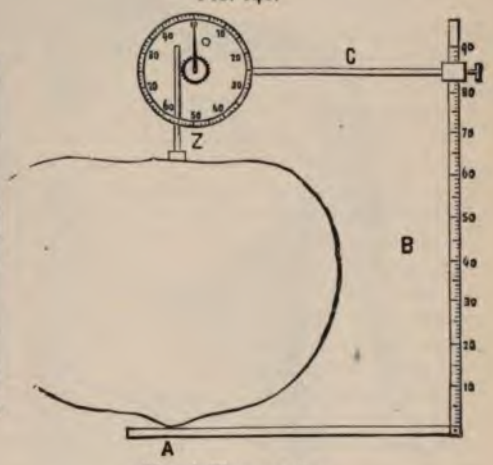
Fig. 142 indicates the relation of the lungs to the anterior surface of the chest. The *apices of the lungs reach* 3 to 7 centimetres (1.1 to 2.7 inches) above the clavicles anteriorly, while posteriorly they extend from the spines of the scapulæ as high as the seventh spinous process. The *lower margin* of the *right lung* in the passive position (moderate expiration) of the chest, commences at the *right* margin

FIG. 140.



Cyrtometer curve. Left side of the chest retracted in a girl aged twelve.

FIG. 141.



Sibson's Thoracometer.

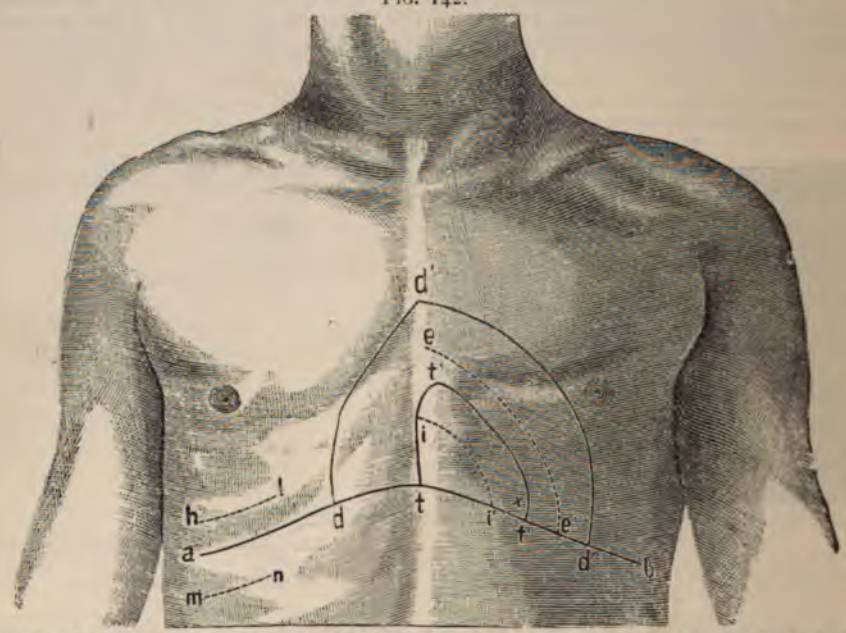
of the sternum at the insertion of the sixth rib, runs under the right nipple, nearly parallel to the upper border of the sixth rib, and descends a little in the axillary line, to the upper margin of the seventh rib. On the *left* side (apart from the position of the heart), the lower limit reaches as far down anteriorly as the right. In Fig. 142 the line *a*, *t*, *b* shows the lowest limit of the passive lungs. *Posteriorly* both lungs reach as far down as the tenth rib. During the *deepest inspiration*, the lungs descend anteriorly as far as between the sixth and seventh ribs, and posteriorly to the eleventh rib—whereby the diaphragm is separated from the thoracic wall (Fig. 143). During the *deepest expiration*, the lower margins of the lungs are elevated almost as much as they descend during inspiration. In Fig. 142, *m*, *n* indicates the margin of the right lung during deep inspiration; *h*, *l*, during deep expiration. [The part of the chest wall covered by the costal pleura is considerably larger than the circumference of the lung. This is specially marked at the lower margin of the lung, and where the left lung is incised over the heart. In these regions, during expiration, the surfaces of the visceral and parietal pleuræ are in contact, but during inspiration they are separated, and allow the thin margins of the lung to be insinuated between them. This available space is called

complemental space (*Gerhardt*), or "disposable" or **reserve pleural space** by Luschka (*Eichhorst*).]

It is important to observe the relation of the margin of the left lung to the heart. In Fig. 142 a somewhat triangular space, reaching from the middle of the point of insertion of the fourth rib to the sixth rib on the left side of the sternum, is indicated. In the passive chest, the heart lies in contact with the thoracic wall in this triangular area (§ 56). This area is represented by the triangle *t*, *t'*, *t''*, and percussion over it gives a dull sound (**superficial dullness**).

In the area of the larger triangle, *d*, *d'*, *d''*, where the heart is separated from the chest wall by the thin anterior margins of the lung, percussion gives a muffled sound, while further outward a clear lung percussion sound is obtained. During deep inspiration, the inner margin of the left lung reaches over the heart as far as

FIG. 142.



Topography of the lungs and heart. *h*, *l*, upward limit of margin of lung during deepest expiration; *m*, *n*, lower limit during deepest inspiration; *t*, *t'*, *t''*, triangular area where the heart is uncovered by lung, dull percussion sound; *d*, *d'*, *d''*, muffled percussion sound; *i*, *i'*, anterior margin of left lung reaches this line during deep inspiration, and during deep expiration it recedes as far as *e*, *e'*.

the insertion of the mediastinum, whereby the dull sound is limited to the smallest triangle, *t*, *i*, *i'*. Conversely, during very complete expiration, the margin of the lung recedes so far that the cardiac dullness embraces the space, *t*, *e*, *e'*.

115. PATHOLOGICAL PERCUSSION SOUNDS.—Abnormal Dullness.—The normal clear resonant percussion sound of the lungs becomes muffled when infiltration takes place into the lungs, so as to diminish the normal amount of air within them, or when the lungs are compressed from without, *e.g.*, by effusion of fluid into the pleura. The percussion sound becomes clearer when the chest wall is very thin, as in spare individuals, during very deep inspiration, and especially in emphysema, where the air vesicles of certain parts of the lung (apices and margins) become greatly dilated.

The pitch of the percussion sound ought also to be noted. It depends upon the greater or less tension of the elastic pulmonary tissue, and on the elasticity of the thoracic wall. The tension of the elastic tissue is increased during inspiration and diminished during expiration, so that even under physiological conditions, the pitch of the sound varies.

The sound is said to be **tympanitic** when it has a musical quality resembling in its timbre the sound produced on drums, and when it has a slight variation in pitch. If a caoutchouc ball be placed near the ear, on tapping it gently, a well-marked tympanitic sound is heard, and the sound is of higher pitch the smaller the diameter of the ball. A tympanitic sound is always produced on tapping the trachea in the neck. *A tympanitic sound produced over the chest is always indicative of a diseased condition.* It occurs in cases of cavities or vomicæ within the substance of the lung (the sound becomes deeper when the mouth, or better, the mouth and nose, are closed), when air is present in one pleural cavity, as well as in conditions where the tension of the pulmonary tissues is diminished. The tympanitic sound resembles the *metallic tinkling* which is heard in large pathological cavities in the lungs, or which occurs when the pleural cavity contains air, and when the conditions which permit a more uniform reflection of the sound waves within the cavity are present.

[When a cavity, freely communicating with a large bronchus, exists in the upper and anterior part of the lung, a peculiar "**cracked-pot sound**" is heard on percussing over the part. Some notion of this sound may be obtained by clasping the two hands so as to bring the palms nearly together, leaving an air space between, and then striking them on the knee. When percussion is made over a large cavity communicating with a bronchus, some of the air is expelled, and the sound thereby emitted is blended with the fundamental note of the air in the cavity itself, the combination of these two sounds thus producing the "cracked-pot" sound.]

Resistance.—When percussing a chest, we may determine whether the substance lying under the portion of the chest under examination presents great or small resistance to the blow, either of the percussion hammer or of the tips of the fingers, as the case may be [*e.g.*, in great pleuritic effusion exerting much pressure on, and so distending, the thoracic walls].

Phonometry.—If the stem of a vibrating tuning fork be placed on the chest wall, over a part containing air, its sound is intensified; but if it be placed over a portion of the lung which contains little or no air, its sound is enfeebled (*Von Baas*).

116. THE NORMAL RESPIRATORY SOUNDS.—If the ear directly, or through the medium of a **stethoscope**, be placed in connection with the chest wall, we hear over the entire area, where the lung is in contact with the chest, the so-called "**normal vesicular sound,**" which is audible *during inspiration*, and its typical characters may be studied by listening in the infra-scapular region in an adult. It is a fine sighing or breezy sound [which gradually increases in intensity until it reaches a maximum, and falls away before expiration begins]. It is said to be caused by the sudden dilatation of the air vesicles (hence "vesicular") during inspiration, and it is also ascribed to the friction of the current of air entering the alveoli. The sound has, at one time, a soft, at another, a sharper character; the latter occurs constantly in children up to 12 years of age. In their case the sound is sharper, because the air, in entering vesicles one-third narrower, is subjected to greater friction. This is followed by an *expiratory* sound, which may be absent during quiet breathing. It is a feeble sighing sound, of an indistinct, soft character, caused by the air passing out of the air vesicles, is three or four times shorter than the inspiratory, is loudest at first, and soon disappears, the latter part of the expiratory act giving rise to no audible sound. Its absence is not a sign of disease, but when it is prolonged and loud, suspicion is aroused.]

Bronchial Respiration.—Within the larger air passages—larynx, trachea, bronchi—during inspiration and expiration, there are loud, rough, harsh sounds like a sharp h or ch—the "*bronchial*"—the laryngeal, tracheal, or "tubular" sound, or breathing. [In normal bronchial breathing, as heard over the trachea, there is a pause between the inspiratory and expiratory sounds, which are of nearly equal duration and of about the same intensity throughout. These sounds are also heard between the scapulæ, at the level of the fourth dorsal vertebra (bifurcation of trachea), and they occur also during expiration, being slightly louder on the right side, owing to the slightly greater calibre of the right bronchus. At all other parts of the chest, the vesicular sound obscures the tubular or bronchial sound. If the air vesicles are deprived of their air, the tubular breathing becomes distinct.

Bronchial respiration is produced chiefly in the larynx, owing to the formation of air eddies in consequence of the narrowing of the respiratory part of the glottis. This "laryngeal stenosis sound" excites resonance of the tracheo-bronchial column

of air, and communicates to it the specific character of bronchial breathing which is heard over the large tubes of the bronchial system (*Dehio*).

It is asserted that, when lungs containing air are placed over the trachea, the tubular sound there produced becomes vesicular. In this case, we must suppose that the vesicular sound arises from the tubular breathing becoming weakened, and acoustically altered by being conducted through the lung alveoli. A sighing sound is often produced at the apertures of the nose and mouth during forced inspiration.

117. **PATHOLOGICAL RESPIRATORY SOUNDS.**—[The breath sounds heard in disease may be merely modifications of the normal vesicular or bronchial sounds, or new sounds, such as friction sounds, râles, or rhonchi.]

[**Puerile Breathing** is merely an exaggerated vesicular sound, so called because it resembles the louder vesicular sound heard in children. It occurs when some part of the lung is unable to act, and there is, as it were, extra work of the other parts to compensate, and thus the sound is exaggerated.]

(1) **Bronchial or Tubular Breathing** occurs over the entire area of the lung, either when the air vessels are *devoid of air*, which may be caused by the exudation of fluid or solid constituents, or when the lungs are compressed from without. In both cases vesicular sounds disappear, and the condensed or solidified lung tissue *conducts* the tubular sound of the large bronchi to the surface of the chest. [The sound heard over a hepatized lobe of the lung in pneumonia is a typical example.] It also occurs in large cavities, with resistant walls near the surface of the lung, provided these cavities communicate with a large bronchus. [In this case it is termed **cavernous breathing.**]

(2) **The amphoric sound** is compared to that produced by blowing over the mouth of an empty bottle. It occurs either when a *cavity*—at least the size of the fist—exists in the lung, which is so blown into during respiration that a peculiar amphoric-like sound, with a metallic timbre, called **metallic tinkling,** is produced; or when the lung still contains air, and is capable of expansion; as there is still air in the pleural cavity, it acts as a resonator, and causes an amphoric sound, simultaneous with the change of air in the lungs. [The amphoric sound or echo and metallic tinkling are the only certain signs of the existence of a cavity in the lung.]

(3) If **obstruction** occurs in the course of the air passages of the lungs, various results may accrue, according to the nature of the resistance: (*a*) owing to various causes, *e. g.*, in the apices of the lungs, there may be partial swelling of the walls of the air tubes, or infiltration into the air cells, which hinders the regular supply of air. In these cases parts of the lung are not supplied with air continuously; it only reaches them periodically, when a **cogwheel sound** occurs. A similar sound may be heard occasionally in a normal lung, when the muscles of the chest contract in a periodic spasmodic manner. (*b*) When the air entering large bronchi causes the formation of bubbles in the mucus which may have accumulated there "**mucous râles**" are produced. They also occur in small spaces when the walls are separated from their fluid contents by the air entering during inspiration, or when the walls, being adherent to each other, are suddenly pulled asunder. The râles are distinguished as *moist* (when the contents are fluid), or as *dry* (when the contents are sticky); they may be inspiratory, expiratory, or continuous, or they may be coarse or fine; further, there is the very fine crepitation, or crackling sound, and, lastly, the metallic tinkling caused in large cavities through resonance. [**Crepitation** or **vesicular râles** are fine crepitating sounds like those produced by rubbing a lock of hair between the fingers near one's ear; they occur only during inspiration, and are a proof that some air is entering the air vesicles. It is heard in its typical form during the first stage of pneumonia, and seems to be produced by the bursting of minute bubbles of air in a fluid.] (*c*) When the mucous membrane of the bronchi is greatly swollen, or is so covered with viscid mucus that the air must force its way through, deep sonorous **rhonchi** (rhonchi sonori) may occur in the large air passages, and clear, shrill sibilant sounds (rhonchi sibilantes) in the smaller ones. [Rhonchi are usually due to catarrh or to affections of the bronchial mucous membrane or bronchitis.] When there is extensive bronchial catarrh, not unfrequently we feel the chest wall vibrating with the râle sounds (**bronchial fremitus**).

(4) If fluid and air occur together in one pleural cavity in which the lung is collapsed, on shaking the person's thorax vigorously we hear a sound such as is produced when air and water are shaken together in a bottle. This is the **succussion sound** of Hippocrates. Much more rarely this sound is heard under similar conditions in large pulmonary cavities.

(5) **Pleural Friction.**—When the two opposed surfaces of the pleura are inflamed, have become soft, and are covered with exudation, they move over each other during respiration, and in doing so give rise to **friction sounds,** which can be felt (often by the patient himself), and can also be heard. The sound is comparable to the sound produced by bending new leather.

(6) **Pectoral Fremitus.**—When we speak or sing in a loud tone, the walls of the chest vibrate, because the vibration of the vocal cords is propagated throughout the entire bronchial ramifications. The vibration is, of course, greatest near the trachea and large bronchi. The ear cannot detect the sounds distinctly. If there be much exudation or air in the pleura, or great accumulation of mucus in the bronchi, the pectoral fremitus is diminished or altogether absent. [In health, when a person

speaks, the **vocal resonance** over the trachea, although loud, may be inarticulate; and on listening over the sternum the sound is diminished and quite inarticulate; while over the chest wall generally the sound, though distinct, is feeble.

All conditions which cause bronchial breathing increase the pectoral fremitus. Under normal circumstances, therefore, it is louder where bronchial breathing is heard normally. The ear hears an intensified sound, called **bronchophony** [which is a sound like that heard normally over the trachea or bronchi, but audible over the vesicular lung tissue. The conditions that cause it are the same as those on which bronchial breathing depends, so that it is heard in pneumonia and phthisis. If, through effusion into the pleura or inflammatory processes in the lung tissue, the bronchi are pressed flat, a peculiar bleating sound (**ægophony**) may be heard.]

118. PRESSURE IN THE AIR PASSAGES DURING RESPIRATION.—Respiratory Pressure.—If a manometer be tied into the trachea of an animal, so that the respiration goes on completely undisturbed, *i. e.*, **normal respiration,** during every inspiration there is a negative pressure (−3 mm. Hg) and during expiration a positive pressure. Donders placed the U-shaped manometer tube in one nostril, closed his mouth, leaving the other nostril open, and respired quietly. During every quiet inspiration the mercury showed a negative pressure of − 1 mm., and during expiration a positive pressure of 2–3 mm. (Hg).

Forced Respiration.—As soon as the air was inspired or expired with greater force, the variations in pressure became very much greater, *e. g.*, during speaking, singing, and coughing. The inspiratory pressure was = − 57 mm. (36–74), the greatest expiratory pressure + 87 (82–100) mm. Hg. The pressure of forced expiration, therefore, is 30 mm. greater than the inspiratory pressure (*Donders*).

Resistance to Inspiration.—Notwithstanding this, we must not conclude that the expiratory muscles act more powerfully than the inspiratory; for during inspiration a variety of resistances have to be overcome, so that after these have been met, there is only a residue of the force for the aspiration of the mercury. The resistances to be overcome by the inspiratory muscles are: (1) The *elastic tension of the lungs*, which during the deepest expirations = 6 mm.; during the deepest inspirations = 30 mm. Hg (§ 107). (2) The raising of the weight of the chest. (3) The *elastic torsion* of the costal cartilages. (4) The depression of the abdominal contents, and the elastic distention of the abdominal walls. All these not inconsiderable resistances, which the inspiratory muscles have to overcome, act during expiration, and aid the expiratory muscles. The forces concerned in inspiration are decidedly much greater than those of expiration.

Intra-thoracic Pressure.—As the lungs within the chest, in virtue of their elasticity, continually strive to collapse, necessarily they must cause a negative pressure *within the chest.* This amounts in dogs, during inspiration, to − 7.1 to − 7.5 mm. Hg, and during expiration to − 4 mm. Hg. The corresponding values for man have been estimated at − 4.5 mm. Hg and − 3 mm. Hg, by Hutchinson.

[We must distinguish between the **respiratory pressure** of the air *within the respiratory passages*, and the intra-thoracic pressure. The former is the same as the atmospheric pressure when the chest is passive, but less than it as the chest is being enlarged, and greater than it when it is being diminished in size. The **intra-thoracic pressure** is the pressure within the chest, but *outside the lungs*, *i. e.*, in the pleura, mediastinum, etc. It is negative, *i. e.*, less than the atmospheric pressure, and must vary with the degree of distention of the lungs.]

[**Method.**—A direct estimation was made by Adamkiewicz and Jacobson. A trocar with its stylet was forced into the fourth left intercostal space near the sternum and pushed into the pericardium (sheep). The stylet was then withdrawn, and the trocar connected with a manometer, and the negative pressure of − 3 to − 5 mm. Hg was obtained. During severe dyspnœa it was − 9 mm. Hg. Rosenthal introduced an œsophageal sound with an elastic ampulla on its lower end into the œsophagus, so that the ampulla came to lie opposite the posterior mediastinum. The sound was connected with a registering tambour or manometer. During inspiration the manometer fell, and during expiration it rose.]

Even the greatest inspiratory or expiratory pressure is always much less than the blood pressure in the large arteries; but if the pressure be calculated upon the entire respiratory surface of the thorax, very considerable results are obtained.

Pneumatometer.—This instrument of Waldenburg is merely a mercurial manometer fixed to a stand, and connected to an elastic tube with a suitable mouth-piece, which is fitted over the mouth and nose, while the variations of the Hg can be read off on a scale. [In the male, the expiratory pressure is 90–120 mm. Hg, and the respiratory 70–100. The relation of the pressures during expiration and inspiration is more important than the absolute pressure.] The inspiratory pressure is diminished in nearly all diseases where the expansion of the lung is impaired [phthisis], or the expiratory pressure is diminished, as in emphysema and asthma.

Effects of the first Respiration on the Thorax.—Until birth, the airless lungs are completely collapsed (atelectic) within the chest, and fill it, so that on opening the chest in a dead fœtus, pneumothorax does not occur (*Bernstein*). Supposing, however, respiration to have been fully established after birth, and air to have freely entered the lungs, if a manometer be placed in connection with the trachea, and the chest be opened, the manometer will register a pressure of 6 mm. Hg, due to the collapse of the elastic lungs. Bernstein supposes that the thorax assumes a new permanent form, due to the first respiratory distention; it is as if, owing to the respiratory elevation of the ribs, the thorax had become permanently too large for the lungs, which are, therefore, kept permanently distended, but collapse as soon as air passes into the pleura. When a lung has once been filled with air, it cannot be emptied by pressure from without, as the small bronchi are compressed before the air can pass out of the alveoli. The expiratory muscles cannot possibly expel all the air from the lungs, while the inspiratory muscular force is sufficient to distend the lungs beyond their elastic equilibrium. Inspiration distends the lungs, increasing their elastic tension, while expiration diminishes the tension without abolishing it.

119. APPENDIX TO RESPIRATION.—Nasal Breathing.—During quiet respiration we usually breathe—or ought to breathe—through the nostrils, the mouth being closed. The current of air passes through the pharyngo-nasal cavity—so that, in its course during inspiration, it is (1) *warmed* and rendered *moist*, and thus irritation of the mucous membrane of the air passages by the cold air is prevented; (2) small *particles of soot*, or other foreign substances in the air, adhere to, and become embedded in the mucus covering the somewhat tortuous walls of the respiratory passages, and are carried outward by the agency of the ciliated epithelium of the respiratory passages; (3) disagreeable odors and certain impurities are detected by the sense of smell.

If a lung be inflated, air constantly passes through the walls of the alveoli and trachea. This also occurs during violent expiratory efforts (cutaneous emphysema in whooping cough), so that pneumothorax may occur (*J. R. Ewald and Kobert*).

Pulmonary Œdema, or the exudation of lymph into the pulmonary alveoli, occurs (1) When there is very great resistance to the blood stream in the aorta or its branches, *e. g.*, by ligaturing all the arteries going to the head or the arch of the aorta, so that only one carotid remains pervious. (2) When the pulmonary veins are occluded. (3) When the left ventricle, owing to mechanical injury, ceases to beat, while the right ventricle goes on contracting (§ 47). These conditions produce at the same time anæmia of the vasomotor centre, which results in stimulation of that centre, and consequent contraction of all the small arteries. Thus the blood stream through the veins to the right heart is favored, and this in its turn favors the production of œdema of the lungs. [The injection of muscarin rapidly causes pulmonary œdema, due to the increase of pressure and slowing of the blood stream in the pulmonary capillaries. It is set aside by atropin (*Weinzweig, Grossmann*).]

120. MODIFIED RESPIRATORY MOVEMENTS.—(1) **Coughing** consists in a sudden violent expiratory explosion after a previous deep inspiration and closure of the glottis, whereby the glottis is forced open, and any substance, fluid, gaseous, or solid, in contact with the respiratory mucous membrane is violently ejected through the open mouth. It is produced voluntarily or reflexly; in the latter case, it can be controlled by the will only to a limited extent.

[**Causes.**—A cough may be discharged **reflexly** from a large number of surfaces: (1) A draught of cold air striking the *skin*, especially of the upper part of the body. This may cause congestion of blood in the air passages, this in turn exciting the cough. (2) More frequently it is discharged from the respiratory mucous membrane, especially of the larynx, the sensory branches of the vagus and the superior laryngeal nerve being the afferent nerves. A cough cannot be discharged from every part of the larynx: thus there is none from the true vocal cords, but only from the glottis respiratoria. All other parts of the larynx are inactive, and so is the trachea as far as the bifurcation, where stimulation excites cough (*Kohts*). (3) Sometimes an offending body, such as a pea or inspissated cerumen in the external auditory meatus, gives rise to coughing, the afferent nerve being the auricular branch of the vagus. (4) There seems to be no doubt that there may be a "*gastric or stomach cough*," produced by stimulation of the gastric branches of the vagus, especially in cases of indigestion, accompanied by irritation of the larynx and trachea. (5) Irritation of the costal pleura and even of the œsophagus (*Kohts*). (6) Irritation of some parts of the nose.

(7) Sometimes also from irritation of the pharynx, as by an elongated uvula. (8) In some diseases of the liver, spleen, and generative organs, when pressure is exerted on these parts.]

(2) **Hawking,** or clearing the throat. An expiratory current is forced in a continuous stream through the narrow space between the root of the tongue and the depressed soft palate, in order to assist in the removal of foreign bodies. When the act is carried out periodically, the closed glottis is suddenly forced open, and it is comparable to a voluntary gentle cough. This act can only be produced voluntarily.

(3) **Sneezing** consists in a sudden violent expiratory blast through the *nose*, for the removal of mucus or foreign bodies (the mouth being rarely open) after a simple or repeated spasm-like inspiration—the glottis remaining open. It is usually caused reflexly by stimulation of sensory nerve fibres of the nose [nasal branch of the fifth nerve], or by sudden exposure to a bright light [the afferent nerve is the optic]. This reflex act may be interfered with to a certain extent, or even prevented, by stimulation of sensory nerves, or firmly compressing the nose where the nasal nerve issues. The continued use of sternutatories, as in persons who take snuff, dulls the sensory nerves, so that they no longer act when stimulated reflexly.

[**Sternutatories or Errhines,** such as powdered ipecacuanha, snuff, and euphorbium, also increase the secretion from the nasal glands. The afferent impulses sent to the respiratory centre also affect the vasomotor centre, so that, even when sneezing does not occur, the blood pressure throughout the body is raised.]

(4) **Snoring** occurs during respiration through the open mouth, whereby the inspiratory and expiratory stream of air throws the uvula and soft palate into vibration. It is involuntary, and usually occurs during sleep, but it may be produced voluntarily.

(5) **Gargling** consists in the slow passage of the expiratory air current in the form of bubbles through a fluid lying between the tongue and the soft palate, when the head is held backward. It is a voluntary act.

(6) **Crying,** caused by emotional conditions, consists in short, deep inspirations, long expirations with the glottis narrowed, relaxed facial and jaw muscles, secretion of tears, often combined with plaintive inarticulate expressions. When crying is long continued, sudden and spasmodic involuntary contractions of the diaphragm occur, which cause the inspiratory sounds in the pharynx and larynx known as **sobbing.** This is an involuntary act.

(7) **Sighing** is a prolonged inspiration, usually combined with a plaintive sound, often caused involuntarily, owing to painful or unpleasant recollections.

(8) **Laughing** is due to short, rapid expiratory blasts through the tense vocal cords, which cause a clear tone, and there are characteristic inarticulate sounds in the larynx, with vibrations of the soft palate. The mouth is usually open, and the countenance has a characteristic expression, owing to the action of the M. zygomaticus major. It is usually involuntary, and can only be suppressed, to a certain degree, by the will (by forcibly closing the mouth and stopping respiration).

(9) **Yawning** is a prolonged deep inspiration occurring after successive attempts at numerous inspirations—the mouth, fauces, and glottis being wide open; expiration shorter—both acts often accompanied by prolonged characteristic sounds. It is quite involuntary, and is usually excited by drowsiness or ennui.

[(10) **Hiccough** is due to a spasmodic involuntary contraction of the diaphragm, causing an inspiration, which is arrested by the sudden closure of the glottis, so that a characteristic sound is emitted. Not unfrequently it is due to irritation of the gastric mucous membrane, and sometimes it is a very troublesome symptom in uræmic poisoning.]

121. **CHEMISTRY OF RESPIRATION—CARBON DIOXIDE, OXYGEN, and WATERY VAPOR GIVEN OFF.—1. Estimation of CO_2.**—1. The **volume** of CO_2 is estimated by means of the **anthracometer** (Fig. 143, II). The volume of gas is collected in a graduated tube, *r*, *r*, provided with a bulb at one end (previously filled with water and carefully calibrated, *i. e.*, the exact amount which each part of the tube contains is accurately measured), and the tube is closed. The lower end has a stop-cock, *h*, and to this is screwed a flask, *n*, completely filled with a solution of caustic potash; the stop-cock is then opened, the potash solution is allowed to ascend into the tube, which is moved about until all the CO_2 unites with the potash to form potassium carbonate. Hold the tube vertically and allow the potash to run back into the flask, close the stop-cock, and remove the bottle with the potash. Place the stop-cock under water, open it, and allow the water to ascend in the tube, when the space in the tube occupied by the fluid indicates the volume of CO_2 which is combined with the potash.

2. By **Weight.**—A large quantity of the mixture of gases which has to be investigated is made to pass through a Liebig's bulb filled with caustic potash. The potash apparatus having been carefully weighed beforehand, the increase of weight indicates the amount of CO_2 which has been taken up by the potash from the air passed through it.

3. By **Titration.**—A large volume of the air to be investigated is conducted through a known volume of a solution of barium hydrate. The CO_2 unites with the barium and forms barium carbonate. The fluid is neutralized with a standard solution of oxalic acid, and the more barium that has united with the CO_2 the smaller will be the amount of oxalic acid used, and *vice versâ*.

II. **Estimation of Oxygen.**—According to **volume** (*a*) By the union of the O with potassium pyrogallate. The same procedure is adopted as for the estimation of CO_2, only the flask, *n*, is filled with the pyrogallate solution instead of potash. (*b*) By explosion in an eudiometer (see *Blood Gases*, § 35).

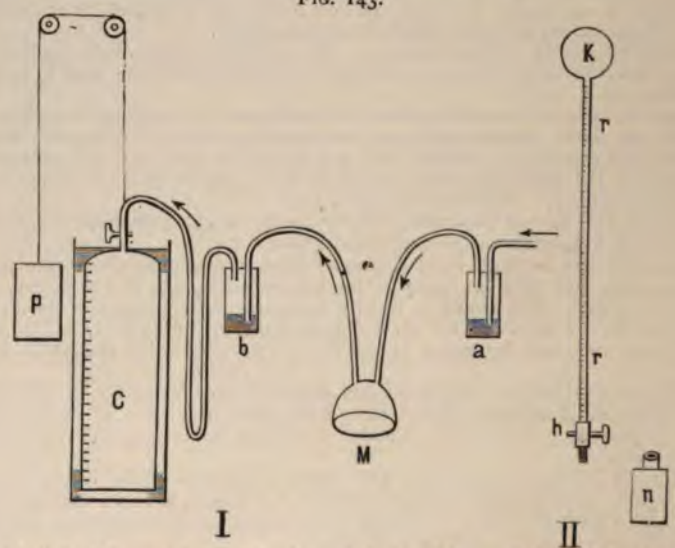
III. **Estimation of Watery Vapor.**—The air to be investigated is passed through a bulb containing *concentrated sulphuric acid*, or through a tube filled with pieces of *calcium chloride*. The amount of water is directly indicated by the increase of weight.

122. METHODS OF INVESTIGATION.—I. Collecting the Expired Air.—(1) The air expired may be collected in the cylinder of the spirometer, which is suspended in concentrated salt solution to avoid the absorption of CO_2 (§ 108).

Andral and Gavarret's Apparatus.—The operator breathed several times into a capacious cylinder (Fig. 143). A mouth-piece (M) was placed air-tight over the mouth, while the nostrils were closed. The direction of the respiratory current was regulated by two so-called "**Müller's Valves**" (mercurial), (*a* and *b*). With every inspiration the bottle or valve, *a* (filled below with Hg and hermetically closed above), permits the air inspired to pass to the lungs—during every expiration the expired air can pass only through *b* to the collecting cylinder C.

(2) If the gases given off by the **skin** are to be collected, a limb, or whatever part is to be investigated, is secured in a closed vessel, and the gases so obtained are analyzed.

FIG. 143.



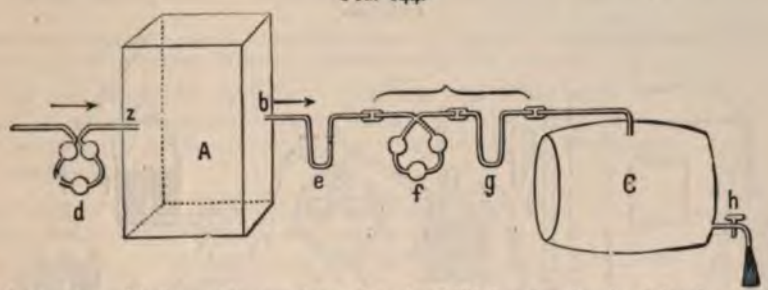
I. Apparatus of Andral and Gavarret for collecting the expired air. C, large cylinder to collect the air expired; P, weight to balance cylinder; *a*, *b*, two Müller's valves; M, mouth-piece. II. Anthracometer of Vierordt.

II. The most important apparatus for this purpose are those of (*a*) **Scharling** (Fig. 144), which consists of a closed box, A, of sufficient size to contain a man. It is provided with an inlet *s* and outlet *b*. The latter is connected with an aspirator, C, a large barrel filled with water. When the stop-cock, *h*, is opened and the water flows out of the barrel, fresh air will rush in continuously into the box, A, and the air mixed with the expired gases will be drawn toward C. A Liebig's bulb, *d*, filled with caustic potash, is connected with the entrance tube, *s*, through which the in-going air must pass, whereby it is completely deprived of CO_2, so that the person experimented on is supplied with air free from CO_2. The air passing out by the exit tube, *b*, has to pass first through *e*, where it gives up its watery vapor to sulphuric acid, whereby the amount of watery vapor is estimated by the increase of the weight of the apparatus, *e*. Afterward the air passes through a bulb, *f*, containing caustic potash, which absorbs all the CO_2, while the tube, *g*, filled with sulphuric acid, absorbs any watery vapor that may come from *f*. The increase in weight of *f* and *g* indicates the amount of CO_2. The total volume of air used is known from the capacity of C.

(*b*) **Regnault and Reiset's Apparatus** is more complicated, and is used when it is necessary to keep animals for some time under observation in a bell-jar. It consists of a globe, R, in which is placed the dog to be experimented on (Fig. 145). Around this is placed a cylinder,

g, g (provided with a thermometer, t), which may be used for calorimetric experiments. A tube, c, leads into the globe, R; through this tube passes a known quantity of pure oxygen (Fig. 145, O). To absorb any trace of CO_2, a vessel containing potash (Fig. 145, CO_2) is placed in the course of the tube. The vessel for measuring the O is emptied toward R, through a solution of calcium chloride from a large pan ($CaCl_2$) provided with large flasks. Two tubes, d and e, lead from R,

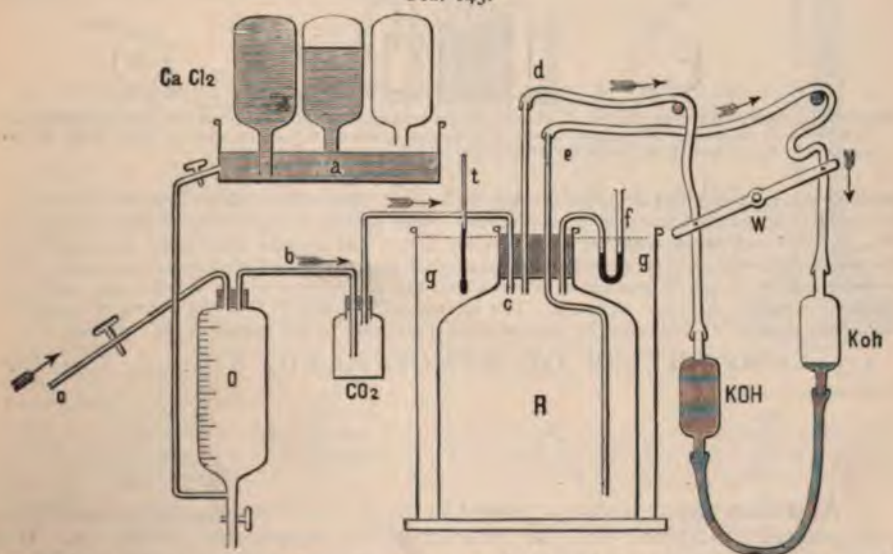
FIG. 144.



Scharling's apparatus. d, bulb containing caustic potash to absorb CO_2 from in-going air; A, box for animal experimented on; e and g, tubes containing sulphuric acid to absorb watery vapor; f, potash bulb to absorb CO_2 given off; C, vessel filled with water to aspirate air; h, stop-cock.

and are united by caoutchouc tubes with the potash bulbs (KOH, K*oh*), which can be raised or depressed alternately by means of the beam, W. In this way they aspirate alternately the air from R, and the caustic potash absorbs the CO_2. The increase in weight of these flasks after the experiment indicates the amount of CO_2 expired. The manometer, f, shows whether there is a difference of the pressure outside and inside the globe, R.

FIG. 145.

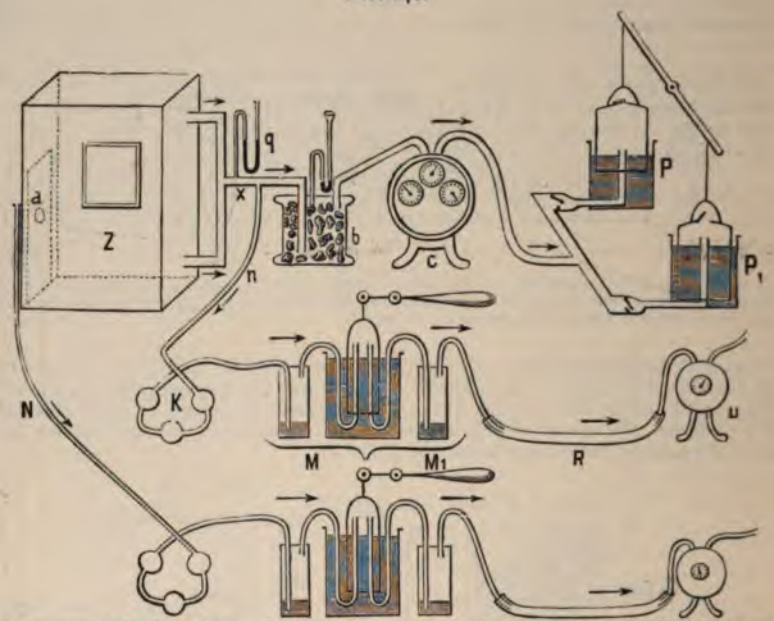


Scheme of the respiration apparatus of Regnault and Reiset. R, globe for animal; g, g, outer casing for R, provided with a thermometer, t; d and e, exit tubes to movable potash bulbs, KOH and K*oh*; O, in-going oxygen; CO_2, vessel to absorb any carbonic acid; $CaCl_2$, apparatus for estimating the amount of O supplied; f, manometer.

(*c*) **v. Pettenkofer** has invented the most complete apparatus (Fig. 146). It consists of a chamber, Z, with metallic walls, and provided with a door and a window. At a is an opening for the admission of air, while a large double suction pump, PP_1 (driven by means of a steam engine) continually renews the air within the chamber. The air passes into a vessel, b, filled with pumice-

stone saturated with sulphuric acid, in which it is dried; it then passes through a large *gas meter*, *c*, which measures the total amount of the air passing through it. After the air is measured, it is emptied outward by means of the pump, PP_1. From the chief exit tube, *x*, of the chamber, provided with a small manometer, *q*, a narrow laterally placed tube, *n*, passes, conducting a small secondary stream, which is chemically investigated. This current passes through the *suction apparatus*, MM_1 (constructed on the principle of Müller's mercurial valve, and driven by a steam engine). Before

FIG. 146.



Respiration apparatus of v. Pettenkofer. Z, chamber for person experimented on; *x*, exit tube with manometer, *q*; *b*, vessel with sulphuric acid; C, gas meter; PP_1, pump; *n*, secondary current, with, *k*, bulb; MM_1, suction apparatus; *u*, gas meter; N, stream for investigating air before it enters Z.

reaching this apparatus, the air passes through the bulb, K, filled with sulphuric acid, whose increase in weight indicates the amount of *watery vapor*. After passing through MM_1, it goes through the tube, R, filled with *baryta solution*, which takes up CO_2. The quantity of air which passes through the accessory current, *n*, is measured by the *small* gas meter, *u*, from which it passes outward. The *second accessory stream*, N, enables us to investigate the air before it enters the chamber, and it is arranged in exactly the same way as *n*. The increase of CO_2 and H_2O in the accessory stream, *n* (*i. e.*, more than in N), indicates the amount of CO_2 given off by the person in the chamber, Z.

123. COMPOSITION OF ATMOSPHERIC AIR.—1. **Dry Air** contains:—

Gas.	By Weight.	By Volume.
O,	23.015	20.96
N,	76.985	79.02
CO_2,		0.03–0.034

2. **Aqueous vapor** is always present in the air, but it varies greatly in amount, and generally increases with the increase of the temperature of the air. We distinguish (*a*) the *absolute moisture, i. e.*, the quantity of watery vapor which a volume of air contains in the form of vapor; and (*b*) the *relative moisture, i. e.*, the amount of watery vapor which a volume of air contains with respect to its temperature.

Experience shows that people generally can breathe most comfortably in an atmosphere which is not completely saturated with aqueous vapor according to its temperature, but is only saturated to the extent of 70 per cent. If the air be too dry, it irritates the respiratory mucous membrane; if

too moist, there is a disagreeable sensation, and if it be too warm, a feeling of closeness. Hence, it is important to see that the proper amount of watery vapor is present in the air of our sitting rooms, bedrooms, and hospital wards.

The **absolute amount** of moisture varies. In towns during the day it increases with increase of temperature, and diminishes when the temperature falls; it also varies with the direction of the wind, season of the year, and the height above sea level.

The **relative amount** of moisture is greatest at sunrise, least at midday; small on high mountains; greater in winter than in summer; larger with a south or a west wind than with a north or an east wind.

The air in midsummer contains absolutely three times as much watery vapor as in midwinter, nevertheless the air in summer is *relatively* drier than the air in winter.

3. The **air expands by heat.** Rudberg found that 1000 volumes of air, at 0°, expanded to 1365 when heated to 100° C.

4. The **density** of the air diminishes with increase of the height above the sea level.

FIG. 147.

124. COMPOSITION OF EXPIRED AIR.—1. The expired air contains **more CO_2**—in normal respiration = 4.38 vols. per cent. (3.3 to 5.5 per cent.), so that it contains nearly 100 times more CO_2 than the atmospheric air.

2. It contains **less O** (4.782 vols. per cent. less) than the atmospheric air. *i. e.*, it contains only 16.033 vols. per cent. of O.

3. **Respiratory Quotient.**—Hence, during respiration, more O is taken into the body from the air than CO_2 is given off; so that the volume of the expired air is ($\frac{1}{40}$ to $\frac{1}{50}$) smaller than the volume of the air inspired, both being calculated as dry, at the same temperature, and at the same barometric pressure. The relation of the O absorbed to the CO_2 given off is 4.38 : 4.782. This is expressed by the "respiratory quotient"—

$$\frac{CO_2}{O}\left(=\frac{4.38}{4.782}=\right) 0.906.$$

4. An excessively small quantity of **N** is added to the expired air (*Regnault and Reiset*). Segen found that all the N taken in with the food did not reappear in the excreta (urine and fæces), and he assumed that a small part of it was given off by the lungs.

5. During ordinary respiration the expired air is **saturated with watery vapor.** It is evident, therefore, that when the watery vapor in the air varies, the lungs give off different quantities of water from the body. The percentage of watery vapor falls during rapid respiration (*Moleschott*).

6. The expired air is **warmer** (36.3° C.). It is very near the temperature of the body, and although the temperature of the surrounding atmosphere be very variable, the temperature of the expired air still remains nearly the same.

Fig. 147 shows the instrument used by Valentin and Brunner to determine the temperature of the expired air. It consists of a glass tube, A, A., with a mouth-piece, B, and in it is a fine thermometer, C. The operator breathes through the nose and expires slowly through the mouth-piece into the tube.

Temperature of the Air.	Temperature of the Expired Air.
−6.3° C.,	+ 29.8° C.
+ 17–19° C.,	+ 36.2–37° C.
+ 44° C.,	+ 38.5° C.

7. The diminution of the **volume** of the expired air mentioned under (3) is far more than compensated by the warming which the inspired air undergoes in the respiratory passages, so that the volume of the expired air is one-ninth greater than the air inspired.

8. A very small quantity of **ammonia** is found in the expired air = 0.0204 grammes in 24 hours; it is probably derived from the blood.

9. Small quantities of **H** and **CH_4** are expired, both being absorbed from the intestine. In herbivora, Reiset found that 30 litres of CH_4 were expired in 24 hours.

125. QUANTITY OF GASES EXCHANGED.—As under normal circumstances more O is absorbed than there is CO_2 given off (equal volumes of O and CO_2 contain equal quantities of O), a part of the O must be used for other oxidation processes in the body. According to the extent of these latter processes, the ratio of the O taken into the CO_2 given out —

$$\left(\frac{CO_2}{O} = 0.906 \text{ normally}\right) \text{ must vary.}$$

The amount of CO_2 given off may be less than the "mean" above stated. The quantity of CO_2 alone is not a reliable indication of the entire exchange of gases during respiration; we must estimate simultaneously the amount of O absorbed and the CO_2 given off.

126. DAILY GASEOUS INCOME AND EXPENDITURE :—

Income in 24 hours.	Expenditure in 24 hours.
Oxygen—	**Carbonic Acid—**
744 grms. = 516.500 c. cmtr. (*Vierordt*).	900 grms. = 455500 c. cmtr. (*Vierordt*).
	36 grms. per hour (*Scharling*).
	32.8 to 33.4 grms. " (*Liebermeister*).
	34 grms. . . " . (*Panum*).
	31.5 to 33 grms. . " . (*Ranke*).
	Water.—640 grms. . " . (*Valentin*).
(At 0° C. and mean barometric pressure.)	330 " . " . (*Vierordt*).

127. CONDITIONS INFLUENCING THE GASEOUS EXCHANGES—The formation of CO_2, in all probability, consists of two distinct processes. First, compounds containing CO_2, which are *oxidation products* of substances containing carbon, seem to be formed in the tissues. The second process consists in the separation of this CO_2, which, however, takes place without the absorption of O. Both processes do not always occur simultaneously, and the one process may exceed the other in extent. The formation of CO_2 is affected by—

1. **Age.**—Until the body is fully developed, the CO_2 given off increases, but it diminishes as the bodily energies decay. Hence, in young persons the O absorbed is relatively greater than the CO_2 given off; at other periods both values are pretty constant. Example :—

Age—Years.	In 24 Hours.	
	CO_2, Gram. Excreted. = Carbon.	O Absorbed, Gram.
8	443 gram. = 121 Carbon	375 grammes.
15	766 " = 209 "	652 "
16	950 " = 259 "	809 "
18–20	1003 " = 274 "	854 "
20–24	1074 " = 293 "	914 "
40–60	889 " = 242 "	757 "
60–80	810 " = 221 "	689 "

The *absolute* amount of CO_2 given off is less in children than in adults; but if the CO_2 given off be calculated with reference to body weight, then, weight for weight, a child gives off twice as much CO_2 as an adult.

2. Sex.—Males, from the eighth year onward to old age, give off about one-third more CO_2 than females. This difference is more marked at puberty, when the difference may rise to one-half. After cessation of the menses, there is an increase, and in old age the amount of CO_2 given off diminishes. Pregnancy increases the amount, owing to causes which are easily understood (*Andral and Gavarret.*)

3. Constitution.—In general, muscular, energetic persons use more O and excrete more CO_2 than less active persons of the same weight.

4. Alternation of Day and Night.—The CO_2 given off is diminished about one-fourth during sleep, due to the constant heat of the surroundings (bed), darkness, absence of muscular activity, and the non-taking of food (see 5, 6, 7, 9). O is not stored up during sleep (*S. Lewin*). After awaking in the morning, the respirations are deeper and more rapid, while the amount of CO_2 given off is increased. It decreases during the forenoon, until dinner at mid-day causes another increase. It falls during the afternoon, and increases again after supper.

During **hibernation**, when no food is taken, and when the respirations cease, or are greatly diminished, the respiratory exchange of gases is carried out by diffusion and the cardio-pneumatic movements (§ 59). The CO_2 given off falls to $\frac{1}{75}$, the O taken in to $\frac{1}{11}$, of what they are in the waking condition. Much less CO_2 is given off than O taken in, so that the body weight may increase through the excess of O.

5. Temperature of the Surroundings.—Cold-blooded animals become warmer when the temperature of their environment is raised, and they give off more CO_2 in this condition than when they are cooler; *e.g.*, a frog with the temperature of the surroundings at 39° C. excreted three times as much CO_2 as when the temperature was 6° C. **Warm-blooded animals** behave quite differently when the temperature of the surrounding medium is changed. When the temperature of the animal is lowered thereby, there is a considerable decrease in the amount of CO_2 given off, as in cold-blooded animals, but if the temperature of the animal be increased (and also in fever), the CO_2 is increased (*C. Ludwig and Sanders-Ezn*). Exactly the reverse obtains when the temperature of the surroundings varies and the bodily temperature remains constant. As the cold of the surrounding medium increases, the processes of oxidation within the body are increased through some as yet unknown reflex mechanism; the number and depth of the respirations increase, whereby more O is taken in and more CO_2 is given out. A man in January uses 32.2 grammes O per hour; in July only 31.7 grammes. In animals, with the temperature of the surroundings at 8° C., the CO_2 given off was one-third greater than with a temperature of 38° C. When the temperature of the air increases—the body temperature remaining the same—the respiratory activity and the CO_2 given off diminish, while the pulse remains nearly constant. On passing suddenly from a cold to a warm medium the amount of CO_2 is considerably diminished; and conversely, on passing from a warm to a cold medium, the amount is considerably increased (§ 214).

6. Muscular exercise causes a considerable increase in the CO_2 given out, which may be three times greater during walking than during rest (*Ed. Smith*). Ludwig and Sczelkow estimated the O taken in and the CO_2 given off by a rabbit during rest, and when the muscles of the hind limbs were tetanized. During tetanus the O and CO_2 were increased considerably, but in tetanized animals more O was given off in the CO_2 expired than was taken up simultaneously during respiration. The passive animal absorbed nearly twice as much O as the amount of CO_2 given off (§ 294).

7. Taking of food causes a not inconsiderable increase in the CO_2 given off, which depends upon the quantity taken; the increase generally occurs about an hour after the chief meal—dinner. During **inanition**, the exchange of gases diminishes considerably until death occurs. At first the CO_2 given off diminishes more quickly than the O is taken up. The **quality** of the food influences the

CO_2 given off to this extent, that substances rich in carbon (carbohydrates and fats) cause a greater excretion of CO_2 than substances which contain less C (albumins). Regnault and Reiset found that a dog gave off 79 per cent. of the O inspired after a flesh diet, and 91 per cent. after a diet of starch. If easily oxidizable substances (glycerin or lactate of soda) are injected into the blood, the O taken in and the CO_2 given off undergo a considerable increase (*Ludwig and Scheremetjewsky*). Alcohols, tea, and ethereal oils diminish the CO_2 (*Prout, Vierordt*). [Ed. Smith divided foods, with reference to the excretion of CO_2, into two classes. The **respiratory excitants** include nitrogenous foods, rum, beer, sugar, stout, etc.; the **non-exciters** starch, fat, some alcoholic mixtures. The most powerful respiratory excitants, however, are tea, sugar, coffee, and rum, and the maximum effect is usually experienced within an hour. He also found that the effects produced by alcoholic drinks varied with the nature of the spirituous liquor. Thus brandy, whisky, and gin diminish the amount; while pure alcohol, rum, ale, and porter tend to increase it.

8. The **number and depth of the respirations** have practically no influence on the formation of CO_2 or the oxidation processes within the body, these being regulated by the tissues themselves, by some mechanism as yet unknown (*Pflüger*). They have a marked effect, however, upon the removal of the already formed CO_2 from the body. An increase in the *number* of respirations (their depth remaining the same), as well as an increase of their *depth* (the number remaining the same), causes an *absolute* increase in the amount of CO_2 given off, which, with reference to the total amount of gases exchanged, is *relatively* diminished. The following example from Vierordt illustrates this:—

No. of Resps. per Minute.	Volume of Air.	Amount of CO_2.	= per cent. CO_2.	Depth of Resps.	Amount of CO_2.	= per cent. CO_2
12	6000	258 c. cmtr.	= 4.3%	500	21 c. cmtr.	= 4.3%
24	12000	420 "	= 3.5 "	1000	36 "	= 3.6 "
48	24000	744 "	= 3.1 "	1500	51 "	= 3.4 "
96	48000	1392 "	= 2.9 "	2000	64 "	= 3.2 "
				3000	72 "	= 1.4 "

9. Exposure to **bright light** causes an increase in the CO_2 given off in frogs, in mammals and birds, even in frogs deprived of their lungs, or in those whose spinal cord has been divided high up. The consumption of O is increased at the same time. The same results occur in blind persons, although to a less degree. Bluish-violet light is almost as active as white light, while red light is less active.

10. The experiments of Gréhant, on dogs, seem to show that intense inflammation of the bronchial mucous membrane influences the CO_2 given off.

11. Among **poisons**, thebaia increases the CO_2 given off, while morphia, codeia, narcein, narcotin, papaverin, diminish it (*Fübini*).

128. DIFFUSION OF GASES WITHIN THE LUNGS.—The air within the air vesicles contains most CO_2 and least O, and as we pass from the small to the large bronchi and onward to the trachea, the composition of the air gradually approaches more closely to that of the atmosphere. Hence, if the air expired be collected in two portions, the first half (*i. e.*, the air from the larger air passages) contains less CO_2 (3.7 vols. per cent.) than the second half (5.4 vols. per cent.). The difference in the percentage of gases gives rise to a diffusion of the gases within the air passages; the CO_2 must *diffuse* from the air vesicles outward, and the O from the atmosphere and nostrils inward (§ 33). This movement is aided by the cardio-pneumatic movement (§ 59). In hibernating animals and in persons *apparently* but not actually *dead*, the exchange of gases within the lungs can only occur

in the above-mentioned ways. For ordinary purposes this mechanism is insufficient, and there are added the respiratory movements whereby atmospheric air is introduced into the larger air passages, from which and into which the diffusion currents of O and CO_2 pass, on account of the difference of tension of the gases.

129. EXCHANGE OF GASES IN THE AIR VESICLES.—The exchange of gases between the gases of the blood and those in the air vesicles occurs almost exclusively through the agency of chemical processes, and therefore independently of the diffusion of gases.

Method.—It is important to ascertain the tension of the O and CO_2 in the venous blood of the pulmonary capillaries. Pflüger and Wolfberg estimated the tension by "**catheterizing the lungs.**" An elastic catheter was introduced through an opening in the trachea of a dog into the bronchus leading to the lowest lobe of the left lung. An elastic sac was placed round the catheter, and when the latter was introduced into the bronchus, the sac around the catheter was distended so as to plug the bronchus. No air could escape between the catheter and the wall of the bronchus. The outer end of the catheter was closed at first, and the dog was allowed to respire quietly. After four minutes the air in the air vesicles was completely in equilibrium with the blood gases. The air of the lung was sucked out of the catheter by means of an air-pump, and afterward analyzed.

Thus we may measure indirectly the tension of the O and CO_2 in the venous blood of the pulmonary capillaries. The *direct* estimation of the gases in different kinds of blood is made by shaking up the blood with another gas. The gases so removed indicate directly the proportion of blood gases.

The following statement shows the tension and percentage of O and CO_2 in arterial and venous blood, in the atmosphere, and in the air of the alveoli :—

I.

O-Tension in arterial blood = 29.6 mm. Hg (corresponding to a mixture containing 3.9 vol. per cent. of O).

II.

CO_2-Tension in arterial blood = 21 mm. Hg (corresponding to 2.8 vol. per cent.).

III.

O-Tension in venous blood = 22 mm. Hg (corresponding to 2.9 vol. per cent.).

IV.

CO_2-Tension in venous blood = 41 mm. Hg (corresponding to 5.4 vol. per cent.).

V.

O-Tension in the air of the alveoli of the catheterized lung = 27.44 mm. Hg (corresponding to 3.6 vol. per cent.).

VI.

CO_2-Tension in the air of the alveoli of the catheterized lung = 27 mm. Hg (corresponding to 3.56 vol. per cent.).

VII.

O-Tension in the atmosphere = 158 mm. Hg (corresponding to 20.8 vol. per cent.).

VIII.

CO_2-Tension in the atmosphere = 0.38 mm. Hg (corresponding to 0.03–0.05 vol. per cent.).

When we compare the tension of the O in the air (VII = 158 mm. Hg) with the tension of the O in venous blood (III = 22 mm. Hg, or V = 27.44 mm. Hg), we might be inclined to assume that the passage of the O from the air of the air vesicles into the blood was due solely to diffusion of the gases; and similarly, we might assume that the CO_2 of the venous blood (IV or VI) diffused into the air vesicles, because the tension of the CO_2 in the air is much less (VIII). There are a number of facts, however, which prove that the exchanges of the gases in the lungs is chiefly due to **chemical** forces.

[v. Fleischl finds that fluids yield up their gases very much more easily when they receive a shock, and he regards the shock communicated to the blood by the contraction of the heart as an important factor in preparing the blood for the diffusion of CO_2 from the blood plasma into the lungs.]

[**Changes produced in the Blood by Respiration.**—The blood of the pulmonary artery is changed from venous into arterial blood (§ 39), the most obvious alterations being (1) the change in **color** from dark crimson to bright scarlet. (2) It loses CO_2. (3) It gains O. (4) The reduced Hb of the venous blood is converted into HbO_2. (5) As to a supposed difference of temperature, see § 209, 3. (6) Pawlow finds that blood which passes several times through the

lungs loses its power of coagulation. Are we to assume that the pulmonary tissues have the property of destroying the fibrin-ferment?

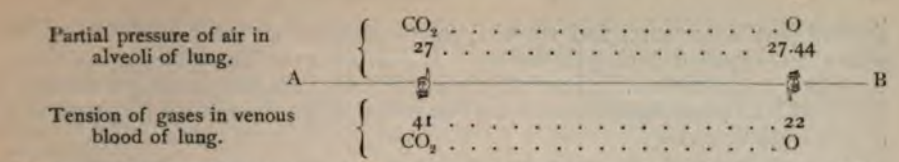
1. **Absorption of O.**—Concerning the absorption of O from the air in the alveoli into the venous blood of the lung capillaries, whereby the blood is arterialized, it is proved that this is a **chemical process.** The gas-free (reduced) hæmoglobin takes up O to form oxyhæmoglobin (§ 15, 1). That this absorption has nothing to do directly with the diffusion of gases, but is due to a chemical combination of the atomic compounds, is shown by the fact that, when pure O is respired, the blood does not take up more O than when atmospheric air is respired; further, that animals made to breathe in a limited closed space can absorb almost all the O—even to traces—into their blood before suffocation occurs. Of course, if the absorption of O were due to diffusion, in the former case more O would be absorbed, while in the latter case the absorption of O could not possibly occur to such an extent as it does. The law of diffusion comes into play in connection with the absorption of O to this extent, viz., that the O diffuses from the air cells of the lung into the blood plasma, where it reaches the blood corpuscles floating in the plasma. The hæmoglobin of the blood corpuscles forms at once a chemical compound (oxyhæmoglobin) with the O.

Even in very rarefied air, such as is met with in the upper regions of the atmosphere during a balloon ascent, the absorption of O still remains independent of the partial pressure. But a much longer *time* is required for this process at the ordinary temperature of the body, so that in rarefied air the absorption of O is greatly delayed, but it is not diminished. This is the cause of death in aeronauts who have ascended so high that the atmospheric pressure is diminished to one-third (*Setschenow*).

2. **Excretion of CO_2.**—With regard to the excretion of CO_2 from the blood, we must remember that the CO_2 in the blood exists in two conditions. Part of the CO_2 forms a loose or feeble chemical compound, while another portion is more firmly combined. The former is obtained by those means which remove gases from fluids containing them in a state of absorption, so that in removing the CO_2 from the blood it is difficult to determine whether the CO_2 so removed, obeyed the law of diffusion, or if it was expelled by chemical means.

Although it is convenient to represent the excretion of CO_2 from the blood into the air vesicles of the lung, as due to equilibrium of the tension of the CO_2 on opposite sides of the alveolar membrane, *i. e.*, to diffusion—nevertheless, **chemical processes** play an important part in this act. The absorption of O by the colored corpuscles acts, at the same time, in expelling CO_2. This is proved by the fact that the expulsion of CO_2 from the blood takes place more readily when O is simultaneously admitted. The free supply of O not only favors the removal of the CO_2, which is loosely combined, but it also favors the expulsion of that portion of the CO_2 which is more firmly combined, and which can only be expelled by the addition of acids to the blood. That the oxygenated blood corpuscles (*i. e.*, their oxyhæmoglobin) are concerned in the removal of CO_2 is proved by the fact that CO_2 is more easily removed from serum which contains oxygenated blood corpuscles than from serum charged with O.

[The following scheme may serve to illustrate the extent to which diffusion comes into play. The O must pass through the alveolar membrane, AB—including the alveolar epithelium and the wall of the capillaries—as well as the blood plasma, to reach the hæmoglobin of the blood corpuscles. Similarly, the CO_2 must leave the salts of the plasma with which it is in combination, and diffuse in the opposite direction, through the wall of the capillaries, the alveolar membrane, and epithelium, to reach the air vesicles. Let AB represent the alveolar membrane; on the one side of it is represented the partial pressure of the CO_2 and O in the air vesicles; and on the other, the partial pressure of the CO_2 and O in the venous blood entering the lung. The indexes indicate the direction of diffusion.]



Nature of the Process.—The exchange of gases between the blood and the air in the lungs has been represented by Donders as due to the process of **dissociation.**

[Bohr used a modified rheometer of Ludwig's, whereby living arterial blood was brought into direct contact with a volume of air containing a greater or less percentage of CO_2. Even when the amount of CO_2 in the air in direct contact with the blood was very small, it was found that very little CO_2 diffused from the blood into the air space. Bohr therefore concludes that the separation of CO_2 from the venous blood in the lungs, and its passage into the air vesicles, are not explicable on the hypothesis of diffusion, but we must rather regard the CO_2 as removed from the blood by the pulmonary tissue by means of a kind of secretory process, analogous to the excretion processes in glands.]

130. **DISSOCIATION OF GASES.**—Many gases form *true chemical compounds* with other bodies (*i. e.*, they combine according to their equivalents), when the contact of these bodies is effected under conditions such that the partial pressure of the gases is high. The chemical compound formed under these conditions is broken up, whenever the partial pressure is diminished, or when it reaches a certain minimum level, which varies with the nature of the bodies forming the compound. Thus, by increasing and diminishing the partial pressure alternately, a chemical compound of the gas may be formed and again broken up. This process is called **dissociation of the gases.** The minimal partial pressure is constant for each of the different substances and gases, but *temperature*, as in the case of the absorption of gases, has a great effect on the partial pressure; with increase of temperature the partial pressure, under which dissociation occurs, diminishes.

As an example of the dissociation of a gas, take the case of calcium carbonate. When it is heated in the air to 440° C., CO_2 is given off from its state of chemical combination, but is taken up again and a chemical compound formed, which is changed into chalk when it cools.

Dissociation in the Blood.—The chemical combinations containing CO_2 and those containing O within the blood stream, viz., the salts of the plasma, which are combined with CO_2, and the oxyhæmoglobin, behave in a similar manner. If these compounds of O and CO_2 are placed under conditions where the partial pressure of these gases is very low—*i. e.*, in a medium containing a very small amount of these gases, the compounds are dissociated, *i. e.*, they give off CO_2 or O. If after being dissociated they are placed under conditions where, owing to the large amount of these gases, the partial pressure of O or of CO_2 is high, these gases are taken up again, and enter into the condition of chemical combination.

The hæmoglobin of the blood in the pulmonary capillaries finds plenty of O in the alveoli; hence, it unites with the O, owing to the high partial pressure of the O in the lung, and so forms the compound oxyhæmoglobin. On its course through the capillaries of the systemic circulation, the oxyhæmoglobin of the blood comes into relation with tissues poor in O; the oxyhæmoglobin is dissociated, the O is supplied to the tissues, and the blood freed from this O returns to the right heart, and passes to the lungs, where it takes up the new O.

The blood while circulating meets with most CO_2 in the tissues; the high partial pressure of the CO_2 in the tissues causes the CO_2 to unite with certain constituents in the blood so as to form chemical compounds, which carry the CO_2 from the tissues to the lungs. In the air of the lungs, however, the partial pressure of the CO_2 is very low, dissociation of these chemical compounds occurs under

the low partial pressure, and the CO_2 passes into the air cells of the lung, from which it is expelled during expiration. It is evident that the giving up of O from the blood to the tissues, and the absorption of CO_2 from the tissues, go on side by side and take place simultaneously, while in the lungs the reverse processes occur almost simultaneously.

131. **CUTANEOUS RESPIRATION.—Methods.**—If a man or an animal be placed in the chamber of the respiratory apparatus (§ 122), and if tubes be so arranged that the respiratory gases do not enter the chamber, of course we obtain only the "*perspiration*" of the skin in the chamber. It is less satisfactory to leave the head of the person outside the chamber, while the neck is fixed air-tight in the wall of the chamber. The extent of the cutaneous respiration of a limb may be ascertained by enclosing it in an air-tight vessel (*Röhrig*) similar to that used for the arm in the plethysmograph (§ 101).

Loss by Skin.—A healthy man loses by the skin, in 24 hours, $\frac{1}{27}$ of his body weight, which is greater than the loss by the lungs, in the ratio of 3 : 2. Only 10 grammes—150 grains,—or it may be 3.9 grammes, 60 grains,—of the entire loss are due to the CO_2 given off by the skin. The remainder of the excretion from the skin is due to **water** [$1\frac{1}{2}$–2 lb daily] containing a few salts in solution. When the surrounding temperature is raised, the CO_2 is increased, in fact it may be doubled; violent muscular exercise has the same effect.

O Absorbed.—The O taken up by the skin is either equal to, or slightly less than, the CO_2 given off. As the CO_2 excreted by the skin is only $\frac{1}{220}$ of that excreted by the lungs, while the O taken in $= \frac{1}{180}$ of that taken in by the lungs, it is evident that the *respiratory activity of the skin is very slight.* Animals whose skin has been covered by an impermeable varnish die, not from suffocation, but from other causes (§ 225).

In animals with a thin, **moist epidermis** (frog) the exchange of gases is much greater, and in them the skin so far supports the lungs in their function, and may even partly replace them functionally. In mammals with thick, dry cutaneous appendages, the exchange of gases is, again, much less than in man.

132. **INTERNAL RESPIRATION.—Where CO_2 is formed.**—By the term "**internal respiration**" is understood the exchange of gases between the capillaries of the systemic circulation and the tissues of the organs of the body. As organic constituents of the tissues, during their activity, undergo gradual oxidation, and form among other products, CO_2; we may assume (1) that the chief focus for the absorption of O and the formation of CO_2 is to be sought for **within the tissues** themselves. That the O from the blood in the capillaries rapidly penetrates or diffuses into the tissues, is shown by the fact that the blood in the capillaries rapidly loses O and gains CO_2, while blood containing O, and kept warm outside the body, changes very slowly and incompletely. If portions of fresh tissues be placed in defibrinated blood containing O, then the O rapidly disappears. Frogs deprived of their blood exhibit an exchange of gases almost as great as normal. This shows that the exchange of gases must take place in the tissues themselves. If the chief oxidations took place in the blood and not in the tissues, then, during suffocation, when O is excluded, the substances which use up O, *i.e.*, those substances which act as reducing agents, ought to accumulate in the blood. But this is not the case, for the blood of asphyxiated animals contains mere traces of reducing materials (*Pflüger*). It is difficult to say how the O is absorbed by the tissues, and what becomes of it immediately it comes in contact with the living elements of the tissues. Perhaps it is temporarily stored up, or it may form certain intermediate less oxidized compounds. This may be followed by a period of rapid formation and excretion of CO_2. On this supposition, it is evident that the absorption of O and the excretion of CO_2 need not occur to the same extent, so that the amount of CO_2 given off at any period is not necessarily an index of the amount of O absorbed during the same period (§ 127).

[There are two views as to where the CO_2 is formed as the blood passes through the tissues. One view is that the seat of oxidation is in the blood itself, and the other is that it is formed in the tissues. If we knew the tension of the gases in the tissues, the problem would be easily solved, but we can only arrive at a knowledge of this subject *indirectly*, in the following ways]:—

CO_2 in Cavities.—That the CO_2 is formed in the tissues, is supported by the fact that the amount of CO_2 in the fluids of the cavities of the body is greater than the CO_2 in the blood of the capillaries. The tension of CO_2 in—

	Mm.		Mm.
Arterial blood, . .	12.28 Hg tension.	Bile, ...	50.0 Hg tension.
Peritoneal cavity, . .	58.5 " "	Hydrocele fluid, . .	46.5 " "
Acid urine, . .	68.0 " "		(*Pflüger and Strassburg*).

The large amount of CO_2 in these fluids can only arise from the CO_2 of the tissues passing into them.

Gases of Lymph.—In the lymph of the ductus thoracicus the tension of $CO_2 = 33.4$ to 37.2 mm. Hg, which is greater than in arterial blood, *but considerably less than in venous blood* (41.0 mm. Hg). [*Ludwig and Hammarsten, Tschirjew.*] This does not entitle us to conclude that in the tissues from which the lymph comes only a small quantity of CO_2 is formed, but rather that in the lymph there is less attraction for the CO_2 formed in the tissues than in the blood of the capillaries, where chemical forces are active in causing it to combine, or that in the course of the long lymph current, the CO_2 is partly given back to the tissues, or that CO_2 is formed in the blood itself. Further, the muscles, which are by far the largest producers of CO_2 contain few lymphatics, nevertheless they supply much CO_2 to the blood. The amount of free "non-fixed" CO_2 contained in the juices and tissues indicates that the CO_2 passes from the tissues into the blood; still, Preyer believes that in venous blood CO_2 undergoes chemical combination. The exchange of O and CO_2 varies much in the different tissues. The **muscles** are the most important organs, for in their active condition they excrete a large amount of CO_2, and use up much O. The O is so rapidly used up by them that no free O can be pumped out of muscular tissue (*L. Hermann*). The exchange of gases is more vigorous during the activity of the tissues. Nor are the salivary glands, kidneys, and pancreas any exception, for although, when these organs are actively secreting, the blood flows out of the dilated veins in a bright red stream, still the relative diminution of CO_2 is more than compensated by the increased volume of blood which passes through these organs.

Reductions by the Tissues.—The researches of Ehrlich have shown that in most tissues very energetic reductions take place. If coloring matters, such as alizarin blue, indophenol blue, or methyl blue, be introduced into the blood stream, the tissues are colored by them. Those tissues or organs which have a particular affinity for O (*e.g.*, liver, cortex of the kidney, and lungs), absorb O from these pigments, and render them colorless. The pancreas and sub-maxillary gland scarcely reduce them at all.

(2) In the **blood itself**, as in all tissues, O is used up and CO_2 is formed. This is proved by the following facts: That blood withdrawn from the body becomes poorer in O and richer in CO_2; that in the blood of asphyxia, free from O, and in the blood corpuscles, there are slight traces of reducing agents, which become oxidized on the addition of O. Still, this process is comparatively insignificant as against that which occurs in all the other tissues. That the walls of the vessels—more especially the muscular fibres in the walls of the small arteries—use O and produce CO_2 is unquestionable, although the exchange is so slight that the blood in its whole arterial course undergoes no visible change.

Ludwig and his pupils have proved that CO_2 is actually formed in the blood. If the easily oxidizable lactate of soda be mixed with blood, and this blood be caused to circulate in an excised but living organ, such as a lung or kidney, more O is used up and more CO_2 is formed than in unmixed blood similarly transfused.

(3) That the tissues of the living lungs use O and give off CO_2 is probable. When C. Ludwig and Müller passed arterial blood through the blood vessels of a lung deprived of air, the O was diminished and the CO_2 increased. As the total amount of CO_2 and O found in the entire blood at any one time is only 4 grammes, and as the daily excretion of $CO_2 = 900$ grammes, and the O absorbed daily $= 744$ grammes, it is clear that exchange of gases must go on with great rapidity, that the O absorbed must be used quickly, and the CO_2 must be rapidly excreted.

Still, it is a striking fact that oxidation processes of such magnitude, as *e.g.*, the union of C to form CO_2, occur at the relatively low temperature of the blood and tissues. It has been surmised that the blood acts as an ozone producer, and transforms this active form of O to the tissues. Liebig showed that the *alkaline reaction* of most of the juices and tissues favors the processes of oxidation. Numerous organic substances, which are not altered by O alone, become rapidly oxidized in the presence of free alkalies, *e.g.*, gallic acid, pyrogallic acid, and sugar; while many organic acids, which are unaffected by ozone alone, are changed into carbonates when in the form of alkaline salts (*Gorup-Besanez*); and, in the same way, when they are introduced into the body in the form of acids, they are partly or wholly excreted in the urine, but when they are administered as alkaline compounds they are changed into carbonates.

133. **RESPIRATION IN A LIMITED SPACE.**—Respiration in a **limited space** causes (1) a gradual diminution of O; (2) a simultaneous increase of CO_2; (3) a diminution in the volume of the gases. If the space be of **moderate** dimensions, the animal uses up almost all the O contained therein, and dies ultimately of spasms caused by the asphyxia. The O is absorbed, therefore—independently of the laws of absorption—by chemical means. The O in the blood is almost completely used up (§ 129). In a **larger space**, the CO_2 accumulates rapidly, before the diminution of O is such as to affect the life of the animal. As CO_2 can only be excreted from the blood when the tension of the CO_2 in the blood is greater than the tension of CO_2 in the air, as soon as the CO_2 in the surrounding air in the closed space becomes the same as in the blood, the CO_2 will be retained in the blood, and finally CO_2 may pass back into the body. This occurs in a large closed space, when the amount of O is still sufficient to support life, so that death occurs under these circumstances (in rabbits) through poisoning with CO_2 causing diminished excitability, loss of consciousness, and lowering of temperature, but no spasms (*Worm Müller*). In **pure O** animals breathe in a normal way; the quantity of O absorbed and the CO_2 excreted is quite independent of the percentage of O, so that the former occurs through chemical agency independent of pressure. In limited spaces filled with O, animals died by absorption of the CO_2 excreted. Worm Müller found that rabbits died after absorbing CO_2 equal to half the volume of their body, although the air still contained 50 per cent. O. Animals can breathe quite quietly a mixture of air containing 14.8 per cent. (20.9 per cent. normal); with 7 per cent. they breathe with difficulty; with 4.5 per cent. there is marked dyspnœa; with 3 per cent. O there is tolerably rapid asphyxia. The air expired by man normally contains 14 to 18 per cent. O. According to Hempner, mammals placed in a mixture of gases poor in O use slightly less O.

Dyspnœa occurs when the respired air is deficient in O, as well as when it is overcharged with CO_2, but the dyspnœa in the former case is prolonged and severe; in the latter, the respiratory activity soon ceases. The want of O causes a greater and more prolonged increase of the blood pressure than is caused by an excess of CO_2. Lastly, the consumption of O in the body is less affected when the O in the air is diminished than when there is an excess of CO_2. If air containing a diminished amount of O be respired, death is preceded by violent phenomena of excitement and spasms, which are absent in cases of death caused by breathing air overcharged with CO_2. In poisoning with CO_2, the excretion of CO_2 is greatly diminished, while with diminution of O it is almost unchanged.

If animals be supplied with a mixture of gases similar to the atmosphere, in which N is replaced by H, they breathe quite normally (*Lavoisier and Seguin*); the H undergoes no great change.

Cl. Bernard found that, when an animal breathed in a limited space, it became partially accustomed to the condition. On placing a bird under a bell-jar, it lived several hours; but if several hours before its death, another bird fresh from the outer air were placed under the same bell-jar, the second bird died at once of convulsions.

Frogs, when placed for several hours in air devoid of O, give off just as much CO_2 as in air containing O, and they do this without any obvious disturbance. Hence, it appears that the formation of CO_2 is independent of the absorption of O, and the CO_2 must be formed from the decomposition of other compounds. Ultimately, however, complete motor paralysis occurs, while the circulation remains undisturbed (*Aubert*).

[134. **DYSPNŒA AND ASPHYXIA.**—For the causes of dyspnœa see § 111, and those of asphyxia see § 368. If from any cause an animal be not supplied with a due amount of air, normal respiration becomes greatly altered, passing through the phases of **hyperpnœa**, or increased respiration, **dyspnœa**, or difficulty of breathing, to the final condition of suffocation or **asphyxia**. The phenomena of asphyxia may be developed by closing the trachea of an animal with a clamp, or by any means which prevents the entrance of air or blood into the lungs.

The **phenomena of asphyxia** are usually divided into several stages: 1. During the **first stage** there is hyperpnœa, the respirations being deeper, more frequent, and labored. The extraordinary muscles of respiration—both those of inspiration and expiration (§ 118)—are called into action, dyspnœa is rapidly produced, and the struggle for air becomes more and more severe. At the same time the oxygen of the blood is being used up, while the blood itself becomes more and more venous. The venous blood circulating in the medulla oblongata and spinal cord stimulates the respiratory centres, and causes the violent respirations. This stage usually lasts about a minute, and gradually gives place to—

2. The **second stage**, when the inspiratory muscles become less active, while those concerned in labored expiration contract energetically, and indeed almost every muscle in the body may contract; so that this stage of violent expiratory efforts ends in general convulsions. The convulsions are due to stimulation of the respiratory centres by the venous blood. The convulsive stage is short, and is usually reached in a little over one minute. This storm is succeeded by—

3. The **third stage**, or stage of exhaustion, the transition being usually somewhat sudden. It is brought about by the venous blood acting on and paralyzing the respiratory centres. The pupils are widely dilated, consciousness is abolished, and the activity of the reflex centres is so depressed that it is impossible to discharge a reflex act, even from the cornea. The animal lies almost motionless, with flaccid muscles, and to all appearance dead, but every now and again, at long intervals, it makes a few deep inspiratory efforts, showing that the respiratory centres are not quite, but almost paralyzed. Gradually the pauses become longer and the inspirations feebler and of a gasping character. As the venous blood circulates in the spinal cord, it causes a large number of muscles to contract, so that the animal extends its trunk and limbs. It makes one great inspiratory spasm, the mouth being widely opened and the nostrils dilated, and ceases to breathe. After this stage, which is the longest and most variable, the heart becomes paralyzed, partly from being over-distended with venous blood, and partly, perhaps, from the action of the venous blood on the cardiac tissues, so that the pulse can hardly be felt. To this pulseless condition the term "asphyxia" ought properly to be applied. In connection with the resuscitation of asphyxiated persons, it is important to note that the heart continues to beat for a few seconds after the respiratory movements have ceased.

The whole series of phenomena occupies from 3 to 5 minutes, according to the animal operated on, and depending also upon the suddenness with which the trachea was closed. If the causes of suffocation act more slowly, the phenomena are the same, only they are developed more slowly.

The Circulation.—The *post-mortem* appearances in man or in an animal are generally well marked. The right side of the heart, the pulmonary artery, the venæ cavæ, and the veins of the neck are engorged with dark venous blood. The left side is comparatively empty, because the rigor mortis of the left side of the heart, and the elastic recoil of the systemic arteries, force the blood toward the systemic veins. The **blood** itself is almost black, and is deprived of almost all its oxygen, its hæmoglobin being nearly all in the condition of reduced hæmoglobin, while ordinary venous blood contains a considerable amount of oxyhæmoglobin as well as reduced Hb. The blood of an asphyxiated animal

practically contains none of the former and much of the latter. It is important to study the changes in the circulation in relation to phenomena exhibited by an animal during suffocation.

We may measure the blood pressure in any artery of an animal while it is being asphyxiated, or we may open its chest, maintain artificial respiration, and place a manometer in a systemic artery, *e. g.*, the carotid, and another in a branch of the pulmonary artery. In the latter case, we can watch the order of events in the heart itself, when the artificial respiration is interrupted. It is well to study the events in both cases.

If the **blood pressure** be measured in a systemic artery, *e. g.*, the carotid, it is found that the blood pressure rises very rapidly, and to a great extent during the first and second stages; the pulse beats at first are quicker, but soon become slower and more vigorous. During the third stage it falls rapidly to zero. The great rise of the blood pressure, during the first and second stages, is chiefly due to the action of the venous blood on the general vasomotor centre, causing constriction of the small systemic arteries. The peripheral resistance is thus greatly increased, and it tends to cause the heart to contract more vigorously, but the slower and more vigorous beats of the heart are also partly due to the action of the venous blood on the cardio-inhibitory centre in the medulla.

If the second method be adopted, viz., to open the chest, keep up artificial respiration, and measure the blood pressure in a branch of the pulmonary artery, as well as in a systemic artery—*e. g.*, the carotid—we find that when the artificial respiration is stopped, in addition to the rise of the blood pressure indicated in the carotid manometer, the cavities of the heart and the large veins near it are engorged with venous blood. There is, however, but a slight comparative rise in the blood pressure in the pulmonary artery. This may be accounted for, either by the pulmonary artery not being influenced to the same extent as other arteries by the vasomotor centre, or by its greater distensibility (§ 88). But, as the heart itself is supplied through the coronary arteries with venous blood, its action soon becomes weakened, each beat becomes feebler, so that soon the left ventricle ceases to contract, and is unable to overcome the great peripheral resistance in the systemic arteries, although the right ventricle may still be contracting. As the blood becomes more venous, the vasomotor centre becomes paralyzed, the small systemic arteries relax, and the blood flows from them into the veins, while the blood pressure in the carotid manometer rapidly falls. The left ventricle, now relieved from the great internal pressure, may execute a few feeble beats, but they can only be feeble, as its tissues have been subjected to the action of the very impure blood. More and more blood accumulates in the right side from the causes already mentioned. The violent inspiratory efforts in the early stages aspirate blood from the veins toward the right side of the heart, but of course this factor is absent when the chest is opened.]

[**Convulsions** during asphyxia occur only in warm-blooded animals, and not in frogs. If a drug when injected into a mammal excites convulsions, but does not do so in the frog, then it is usually concluded that the convulsions are due to its action on the circulation and respiration, and not to any direct stimulating effect upon the motor centres. But if the drug excites convulsions both in the mammal and frog, then it probably acts directly on the motor centres (*Brunton*).]

[**Recovery from the condition of Asphyxia.**—If the trachea of a dog be closed suddenly and completely, the average duration of the respiratory movements is 4 minutes 5 seconds, while the heart continues to beat for about 7 minutes. Recovery may be obtained if proper means be adopted before the heart ceases to beat; but after this, never. If a dog be drowned, the result is different. After complete submersion for 1½ minutes, recovery did not take place. In **drowning**, air passes out of the chest, and water is inspired into and fills the air vesicles. It is rare for recovery to take place in a person deprived of air for more than five minutes. If the statements of sponge divers are to be trusted, a person may become accustomed to the deprival of air for a longer time than usual. In cases where recovery takes place after a much longer period of

submersion, it has been suggested that, in these cases, syncope occurs, the heart beats but feebly or not at all, so that the oxygen in the blood is not used up with the same rapidity. It is a well-known fact that newly-born and young puppies can be submerged for a long time before they are suffocated.]

Artificial Respiration in Asphyxia.—In cases of suspended animation, *artificial respiration* must be performed. The first thing to be done is to remove any foreign substance from the respiratory passages (mucus or œdematous fluids) in the newly-born or asphyxiated. In doubtful cases, open the trachea and suck out any fluid by means of an elastic catheter (*v. Hüter*). Recourse must in all cases be had to artificial respiration. There are several methods of dilating and compressing the chest so as to cause an exchange of gases. One method is to compress the chest rhythmically with the hands.

[**Marshall Hall's Method.**—"After clearing the mouth and throat, place the patient on the face, raising and supporting the chest well on a folded coat or other article of dress. Turn the body very gently on the side and a little beyond, and then briskly on the face, back again, repeating these measures cautiously, efficiently, and perseveringly, about fifteen times in the minute, or once every four or five seconds, occasionally varying the side. By placing the patient on the chest, the weight of the body forces the air out; when turned on the side, this pressure is removed, and air enters the chest. On each occasion that the body is replaced on the face, make uniform but efficient pressure with brisk movement on the back between and below the shoulder blades or bones on each side, removing the pressure immediately before turning the body on the side. During the whole of the operations let one person attend solely to the movements of the head and of the arm placed under it."]

[**Sylvester's Method.**—"Place the patient on the back on the flat surface, inclined a little upward from the feet; raise and support the head and shoulders on a small firm cushion or folded article of dress placed under the shoulder-blades. Draw forward the patient's tongue, and keep it projecting beyond the lips; an elastic band over the tongue and under the chin will answer this purpose, or a piece of string or tape may be tied round them, or by raising the lower jaw the teeth may be made to retain the tongue in that position. Remove all tight clothing from about the neck and chest, especially the braces." "*To Imitate the Movements of Breathing.*—Standing at the patient's head grasp the arms just above the elbows, and draw the arms gently and steadily upward above the head, and *keep them stretched* upward for two seconds. By this means air is drawn into the lungs. Then turn down the patient's arms, and press them gently and firmly for two seconds against the sides of the chest. By this means air is pressed out of the lungs. Repeat these measures alternately, deliberately, and perseveringly about fifteen times in a minute, until a spontaneous effort to respire is perceived, immediately upon which cease to imitate the movements of breathing, and proceed to *induce circulation and warmth.*"]

Howard advises rhythmical compression of the chest and abdomen by sitting like a rider astride of the body, while Schüller advises that the lower ribs be seized from above with both hands and raised, whereby the chest is dilated, especially when the thigh is pressed against the abdomen to compress the abdominal walls. The chest is compressed by laying the hands flat upon the hypochondria. Artificial respiration acts favorably by supplying O to, as well as removing CO_2 from, the blood; further, it aids the movement of the blood within the heart and in the large vessels of the thorax. If the action of the heart has ceased, recovery is impossible. In asphyxiated newly-born children, we must not cease too soon to perform artificial respiration. Even when the result appears hopeless, we ought to persevere. Pflüger and Zuntz observed that the reflex excitability of the fœtal heart continued for *several* hours after the death of the mother.

Resuscitation by compressing the heart.—Böhm found that in the case of cats poisoned with potash salts or chloroform, or asphyxiated, so as to arrest respiration and the action of the heart—even for a period of forty minutes—and even when the pressure within the carotid had fallen to zero, he could restore animation by *rhythmical compression of the heart*, combined with artificial respiration. The compression of the heart causes a slight movement of the blood, while it acts at the same time as a rhythmical cardiac stimulus. After recovery of the respiration, the reflex excitability and gradually also voluntary movements are restored. The animals are blind for several days, the brain acts slowly, and the urine contains sugar. These experiments show how important it is in cases of asphyxia to act at the same time upon the heart.

For **physiological purposes**, artificial respiration is often made use of, especially after poisoning with curara. Air is *forced* into the lungs by means of an elastic bag or bellows, attached to a cannula tied in the trachea. The cannula has a small opening in the side of it to allow the expired air to escape.

Pathological.—After the lungs have once been properly distended with air, it is impossible by any amount of direct compression of them to get rid of all the air. This is probably due to the pressure acting on the small bronchi, so as to squeeze them, before the air can be forced out of the air vesicles. If, however, a lung be filled with CO_2, and be suspended in water, the CO_2 is absorbed by the water, and the lungs become quite free from air and are **atelectic** (*Hermann and Keller*). The atelectasis, which sometimes occurs in the lung, may thus be explained: If a bronchus is stopped with mucus or exudation, CO_2 accumulates in the air vesicles belonging to this bronchus. If the

CO_2 is absorbed by the blood or lymph, the corresponding area of the lung will become atelectic. Sometimes there is spasm of the respiratory muscles, brought about by direct or reflex stimulation of the respiratory centre.

135. RESPIRATION OF FOREIGN GASES.—No gas without a sufficient admixture of O can support life. Even with completely innocuous and indifferent gases, if no O be mixed with them, they cause suffocation in 2 to 3 minutes.

I. **Completely indifferent Gases** are N, H, CH_4. The living blood of an animal breathing these gases yields no O to them (*Pflüger*).

II. **Poisonous Gases.—O displacing Gases.**—(*a*) Those that displace O, and form a stable compound with the hæmoglobin (1) CO (§§ 16 and 17). (2) CNH (hydrocyanic acid) displaces (?) O from hæmoglobin, forming a more stable compound, and kills exceedingly rapidly. Blood corpuscles charged with hydrocyanic acid lose the property of decomposing hydric peroxide into water and O (§ 17, 5).

(*b*) **Narcotic Gases.**—(1) CO_2.—v. Pettenkofer characterizes atmospheric air containing .1 per cent. CO_2 as "bad air;" still, air in a room containing this amount of CO_2 produces a disagreeable feeling, rather from the impurities mixed with it than from the actual amount of CO_2 itself. Air containing 1 per cent. CO_2 produces decided discomfort, and with 10 per cent. it endangers life, while larger amounts cause death, with symptoms of coma. (2) N_2O (nitrous oxide), respired, mixed with $\frac{1}{3}$ volume O, causes, after 1 to 2 minutes, a short temporary stage of excitement ("Laughing gas" of H. Davy), which is succeeded by unconsciousness, and afterward by an increased excretion of CO_2. (3) Ozonized air causes similar effects (*Binz*).

(*c*) **Reducing Gases.**—(1) H_2S (sulphuretted hydrogen) rapidly robs blood corpuscles of O, S and H_2O being formed, and death occurs rapidly before the gas can decompose the hæmoglobin to form a sulphur-methæmoglobin compound.

(2) PH_3 (phosphuretted hydrogen) is oxidized in the blood to form phosphoric acid and water, with decomposition of the hæmoglobin.

(3) AsH_3 (arseniuretted hydrogen) and SbH_3 (antimoniuretted hydrogen) act like PH_3, but the hæmoglobin passes out of the stroma and appears in the urine.

(4) C_2N_2 (cyanogen) absorbs O, and decomposes the blood.

III. **Irrespirable Gases,** *i. e.*, gases which, on entering the larynx, cause reflex spasm of the glottis. When introduced into the trachea, they cause inflammation and death. Under this category come hydrochloric, hydrofluoric, sulphurous, nitrous, and nitric acids, ammonia, chlorine, fluorine, and ozone.

136. ACCIDENTAL IMPURITIES OF THE AIR.—Among these are **dust particles,** which occur in enormous amount suspended in the air, and thereby act injuriously upon the respiratory organs. The **ciliated epithelium** of the respiratory passages eliminates a large number of them (Fig. 148). Some of them, however, reach the air vesicles of the lung, where they penetrate the epithelium, reach the interstitial lung tissue and lymphatics, and so pass with the lymph stream into the bronchial glands. Particles of *coal* or *charcoal* are found in the lungs of all elderly individuals, and blacken the alveoli. In moderate amount, these black particles do not seem to do any harm in the tissues, but when there are large accumulations they give rise to lung affections, which lead to disintegration of these organs. [In coal miners, for example, the lung tissues along the track of the lymphatics and in the bronchial glands are quite black, constituting "coal miners' lung."]

FIG. 148.

Ciliated Epithelium.

In **many trades** various particles occur in the air; miners, grinders, stone masons, file makers, weavers, spinners, tobacco manufacturers, millers, and bakers suffer from lung affections caused by the introduction of particles of various kinds inhaled during the time they are at work.

Germs.—There seems no doubt that the seeds of some contagious diseases may be inhaled. Diphtheritic bacteria (Bacillus diphtheriæ) become localized in the pharynx and in the larynx—glanders in the nose—measles in the bronchi—whooping cough in the bronchi—hay monads in the nose—the Bacillus pneumoniæ of pneumonia in the pulmonary alveoli. Tuberculosis, according to R. Koch, is due to the introduction and development of the Bacillus tuberculosis in the lungs, the bacillus being derived from the dust of tuberculous sputa. The same seems to be the case with the Bacillus of leprosy and with Bacillus malariæ, which is the cause of malaria. The latter organism thus reaches the blood; it changes the Hb within the red blood corpuscles into melanin (§ 10, 3), and causes them to break up. The Micrococcus vaccinæ of smallpox gains

access to the blood in the same way, also the Spirillum of remittent fever (Fig. 23), the Microbe of scarlet fever, etc.

Seeds of disease passing into the mouth along with air, and also with the food, are swallowed, and undergo development in the intestinal tract, as is probably the case in cholera (Comma bacillus of *R. Koch*), dysentery, typhoid, and anthrax which is due to Bacterium anthracis (Fig. 24).

137. **VENTILATION OF ROOMS.**—**Fresh air** is as necessary for the healthy as for the sick. Every healthy person ought to have a cubic space of at the very least 800 cubic feet, and every sick person at the very least 1000 cubic feet of space. [The **cubic space** allowed per individual varies greatly, but 1000 cubic feet is a fair average. If the air in this space is to be kept sweet, so that the CO_2 does not exceed .06 per cent., 3000 cubic feet of air per hour must be supplied, *i. e.*, the air in the space must be renewed three times per hour.]

[**Floor Space.**—It is equally important to secure sufficient floor space, and this is especially the case in hospitals. If possible, 100–120 square feet of floor space ought to be provided for each patient in a hospital ward, and if it is obtainable a cubic space of 1500 cubic feet (*Parkes*). In all cases the minimum floor space should not be less than $\frac{1}{12}$ of the cubic space.]

Overcrowding.—When there is overcrowding in a room, the amount of CO_2 increases. v. Pettenkofer found the normal amount of CO_2 (.04 to .05 per 1000) increased in comfortable rooms to 0.54–0.7 per 1000; in badly ventilated sick chambers = 2.4; in overcrowded auditoriums, 3.2; in pits = 4.9; in school rooms, 7.2 per 1000. Although it is not the quantity of CO_2 which makes the air of an overcrowded room injurious, but the excretions from the outer and inner surfaces of the body, which give a distinct odor to the air, quite recognizable by the sense of smell, still the amount of CO_2 is taken as an index of the presence and amount of these other deleterious substances. Whether or not the ventilation of a room or ward occupied by persons is sufficient, is ascertained by estimating the amount of CO_2. A room which does not give a disagreeable, somewhat stuffy, odor has less than 0.7 per 1000 of CO_2, while the ventilation is certainly insufficient if the CO_2 = 1 per 1000. As the air contains only 0.0005 cubic metre CO_2 in 1 cubic metre of air, and as an adult produces *hourly* 0.0226 cubic metres CO_2, calculation shows that every person requires 113 cubic metres of fresh air per hour, if the CO_2 is not to exceed 0.7 per 1000; for $0.7 : 1000 = (0.0226 + x \times 0.0005) : x$, *i. e.*, $x = 113$.

[**Vitiating Products.**—In a state of repose, an adult man gives off from 12 to 16 cubic feet of CO_2 in twenty-four hours, or on an average .6 cubic feet per hour. To this must be added a certain quantity of **organic matter**, which is extremely deleterious to health. While the CO_2 diffuses readily and is easily disposed of by opening the windows, this is not the case with the organic matter, which adheres to clothing, curtains, and furniture; hence, to get rid of it, a room, and especially a sleeping apartment, requires to be well aired for a long time, together with the free admission of sunlight. We must also remember that an adult gives off from 25 to 40 oz. of **water** by the skin and lungs. The nature of the **organic matters** is not precisely known, but some of it is particulate, consisting of epithelium, fatty matters, and organic vapors from the lungs and mouth. It blackens sulphuric acid, and decolorizes a weak solution of potassic permanganate. As a test, if we expire through distilled water, and this water be set aside for some time in a warm place, it will soon become fœtid. We must also take into consideration the **products of combustion**; thus 1 cubic foot of coal gas, when burned, destroys all the O in 8 cubic feet of air (*Parkes*).]

Methods.—In ordinary rooms, where every person is allowed the necessary cubic space (1000 cubic feet), the air is sufficiently renewed by means of the pores in the walls of the room, by the opening and shutting of doors, and by the fireplace, provided the damper is kept open. It is most important to notice that the natural ventilation be not interfered with by dampness of the walls, for this influences the pores very greatly. At the same time, damp walls are injurious to health by conducting away heat, and in them the germs of infectious diseases may develop.

[**Natural Ventilation.**—By this term is meant the ventilation brought about by the ordinary forces acting in nature; such as diffusion of gases, the action of winds, and the movements excited owing to the different densities of air at unequal temperatures.]

[**Artificial Ventilation.**—Various methods are in use for ventilating public buildings and dwelling houses. Two principles are adopted for the former, viz., **extraction** and **propulsion of air.** In the former method, the air is sucked out of the rooms by a fan or other apparatus, while in the latter, air is forced into the rooms, the air being previously heated to the necessary temperature.]

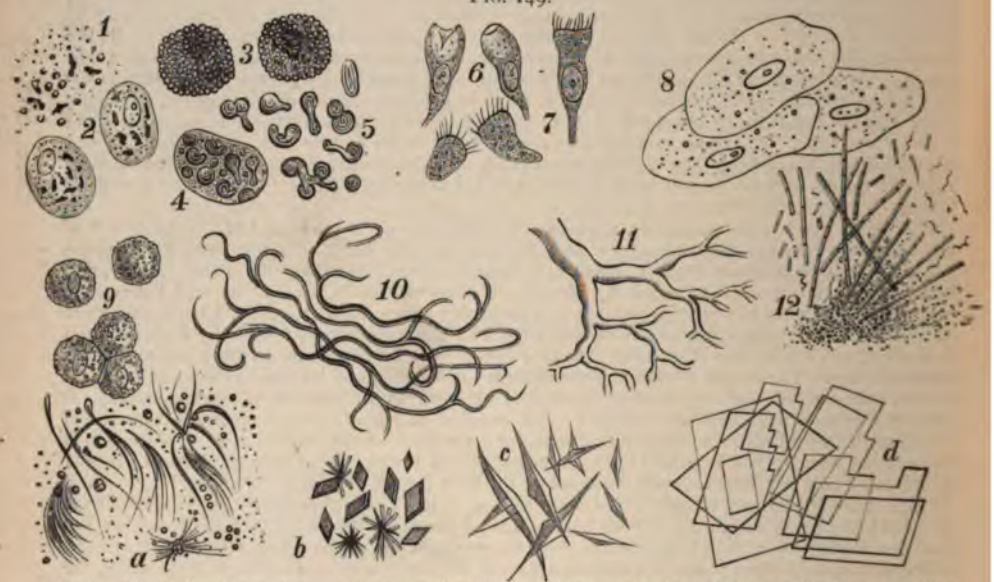
[A very convenient method of introducing air into a room is by means of **Tobin's tubes**, placed in the walls. The air enters through these tubes from the outside near the floor, and is carried up six or more feet, to an opening in the wall; the cool air thus descends slowly. For a sitting room, a convenient plan of window ventilation is **H. Bird's Method**: Raise the lower sash and place under it, so as to fill up the opening, a piece of wood 3 or 4 inches high. Air will then pass in, in an upward direction, between the upper part of the lower sash frame and the lower part of the upper one.]

MATION OF MUCUS—SPUTUM.—The respiratory mucous
·red normally with a thin layer of mucus (Fig. 130, *a*). It so
ıation of new mucus by protecting the mucous glands from the

action of cold or other irritative agents. New mucus is secreted as that already formed is removed. An increased secretion accompanies congestion of the respiratory mucous membrane [or any local irritation]. Division of the nerves on one side of the trachea (cat) causes redness of the tracheal mucous membrane and increased secretion (*Rossbach*), [but the two processes do not stand in the relation of cause and effect]. [The secretion cannot be excited by stimulating the nerves going to the mucous membrane. This merely causes anæmia of the mucous membrane, while the secretion continues].

Modifying Conditions.—If ice be placed on the belly of an animal so as to cause the animal "*to take a cold*," the respiratory mucous membrane first becomes pale, and afterward there is a copious mucous secretion, the membrane becoming deeply congested. The injection of sodium carbonate and ammonium chloride into the blood limits the secretion. The local application of alum, silver nitrate, or tannic acid, makes the mucous membrane turbid, and the epithelium is shed. The secretion is excited by apomorphin, emetin, pilocarpin, and ipecacuanha when given internally, while it is limited by atropin and morphia (*Rossbach*).

FIG. 149.



Various objects found in sputum. 1, detritus and particles of dust; 2, alveolar epithelium with pigment; 3, fatty and pigmented alveolar epithelium; 4, alveolar epithelium with myelin-forms; 5, free myelin-forms; 6, 7, ciliated epithelium, some without cilia; 8, squamous epithelium from the mouth; 9, leucocytes; 10, elastic fibres; 11, fibrin cast of a small bronchus; 12, leptothrix buccalis with cocci, bacteria, and spirochætae; *a*, fatty acid crystals and free fatty granules; *b*, hæmatoidin; *c*, Charcot's crystals; *d*, cholesterin.

[**Expectorants** favor the removal of the secretions from the air passages. This they may do either by (*a*) altering the character and qualities of the secretion itself, or (*b*) by affecting the expulsive mechanism. Some of the drugs already mentioned are examples of the first class. The second class act chiefly by influencing the respiratory centre, *e. g.*, ipecacuanha, strychnia, ammonia, senega; emetics also act energetically as expectorants, as in some cases of chronic bronchitis; warmth and moisture in the air are also powerful adjuncts.]

Sputum.—Under normal circumstances, some mucus—mixed with a little saliva—may be coughed up from the back of the throat. In catarrhal conditions of the respiratory mucous membrane, the sputum is greatly increased in amount, and is often mixed with other characteristic products. **Microscopically**, sputum contains—

1. **Epithelial Cells**, chiefly squames from the mouth and pharynx (Fig. 149), more rarely alveolar epithelium and ciliated epithelium (7) from the respiratory

passages. They are often altered owing to maceration or other changes. Thus some cells may have lost their cilia (6).

The **epithelium of the alveoli** (2) is squamous epithelium, the cells being two to four times the breadth of a colorless blood corpuscle. These cells occur chiefly in the morning sputum in individuals over 30 years of age. In younger persons their presence indicates a pathological condition of the pulmonary parenchyma.

They often undergo fatty degeneration, and they may contain pigment granules (3); or they may present the appearance of what Buhl has called "*myelin degenerated cells*," *i. e.*, cells filled with clear refractive drops of various sizes, some colorless, others with colored particles, the latter having been absorbed (4). Mucin in the form of myelin drops (5) is always present in sputum.

2. **Lymphoid cells** (9) are colorless blood corpuscles which have wandered out of the blood vessels; they are most numerous in yellow sputum, and less numerous in the clear, mucus-like excretion. The lymph cells often present alterations in their characters; they may be shriveled up, fatty, or present a granular appearance.

The **fluid substance** of the sputum contains much **mucus**, arising from the mucous glands and goblet cells, together with nuclein, and lecithin, and the constituents of saliva, according to the amount of the latter mixed with the secretion. *Albumin* occurs only during the inflammation of the respiratory passages, and its amount increases with the degree of inflammation. Urea has been found in cases of nephritis.

In cases of **catarrh**, the sputum is at first usually sticky and clear (sputa cruda), but later it becomes more firm and yellow (sputa cocta). Under **pathological conditions**, there may be found in the sputum—(*a*) red **blood corpuscles** from rupture of a blood vessel. (*b*) **Elastic fibres** (10) from disintegration of the alveoli of the lung; usually the bundles are fine, curved, and the fibres branched. [In certain cases it is well to add a solution of caustic potash, which dissolves most of the other elements, leaving the elastic fibres untouched.] Their presence always indicates destruction of the lung tissue. (*c*) Colorless plugs of **fibrin** (11), casts of the smaller or larger bronchi, occur in some cases of fibrinous exudation into the finer air passages. (*d*) **Crystals** of various kinds—crystals of *fatty acids* in bundles of fine needles (Fig. 149, *a*). They indicate great decomposition of the stagnant secretion. Leucin and tyrosin crystals are rare (§ 269). Tyrosin occurs in considerable amount when an old abscess breaks into the lungs. Colorless, sharp pointed, octagonal or rhombic plates—**Charcot's crystals** (*c*)—have been found in the expectoration in asthma, and exudative affections of the bronchi. **Hæmatoidin** (*b*) and **cholesterin** crystals (*d*) occur much more rarely.

Fungi and **other lowly organisms** are taken in during inspiration (§ 136). The threads of Leptothrix buccalis (12), detached from the teeth, are frequently found (§ 147). Mycelium and spores are found in thrush (Oïdium albicans), especially in the mouths of sucking infants. In malodorous expectoration rod-shaped bacteria are present. In pulmonary gangrene are found monads, and cercomonads; in pulmonary phthisis the tubercle bacillus; very rarely sarcina, which, however, is often found in gastric catarrh in the stomach and also in the urine (§ 270).

Physical Characters.—Sputum, with reference to its physical characters, is described as *mucous*, *muco-purulent*, or *purulent*.

Abnormal coloration of the sputum—red from blood; when the blood remains long in the lung it undergoes a regular series of changes, and tinges the sputum dark red, bluish brown, brownish yellow, deep yellow, yellowish green, or grass green. The sputum is sometimes yellow in jaundice. The sputum may be tinged by what is inspired [as in the case of the "black spit" of miners].

The odor of the sputum is more or less unpleasant. It becomes very disagreeable when it has remained long in pathological lung cavities, and it is stinking in gangrene of the lung.

139. **ACTION OF THE ATMOSPHERIC PRESSURE.**—At the normal pressure of the atmosphere (height of the barometer, 760 millimetres Hg), pressure is exerted upon the entire surface of the body = 15,000 to 20,000 kilos., according to the extent of the superficial area. This pressure acts equally on all sides upon the body, and also occurs in all *internal cavities containing air*, both those that are constantly filled with air (the respiratory passages and the spaces in the superior maxillary, frontal, and ethmoid bones), and those that are temporarily in direct communication with the outer air (the digestive tract and tympanum). As the **fluids of the body** (blood, lymph, secretions, parenchymatous juices) are practically incompressible, their volume remains unchanged under the pressure;

but they absorb gases from the air corresponding to the prevailing pressure (*i. e.*, the partial pressure of the individual gases), and according to their temperature (§ 33). The **solids** consist of elementary parts (cells and fibres), each of which presents only a microscopic surface to the pressure, so that for each cell the prevailing pressure of the air can only be calculated at a few millimetres—a pressure under which the most delicate histological tissues undergo development. As an example of the action of the pressure of the atmospheric pressure upon large masses, take that brought about by the adhesion of the smooth, sticky, moist, articular surfaces of the shoulder and hip joints; the arm and the leg are supported without the action of muscles. The thigh bone remains in its socket after section of all the muscles and its capsule. Even when the cotyloid cavity is perforated, the head of the femur does not fall out of its socket. The ordinary barometric variations affect the respiration—a rise of the barometric pressure excites, while a fall diminishes, the respirations. The absolute amount of CO_2 remains the same (§ 127, 8).

Great diminution of the atmospheric pressure, such as occurs in ballooning (highest ascent, 8600 metres), or in ascending mountains, causes a series of characteristic phenomena: (1) In consequence of the diminution of the pressure upon the parts directly in contact with the air, they become greatly congested, hence there is redness and swelling of the skin and free mucous membranes; there may be hemorrhage from the nose, lungs, gums; turgidity of the cutaneous veins; copious secretion of sweat; great secretion of mucus. (2) A feeling of weight in the limbs, a pressing outward of the tympanic membrane (until the tension is equilibrated by opening the Eustachian tube), and as a consequence noises in the ears and difficulty of hearing. (3) In consequence of the diminished tension of the O in the air (§ 129), there is difficulty of breathing, pain in the chest, whereby the respirations (and pulse) become more rapid, deeper, and irregular. When the atmospheric pressure is diminished ½–⅓, the amount of O in the blood is diminished, the CO_2 is imperfectly removed from the blood, and in consequence there is diminished oxidation within the body. When the atmospheric pressure is diminished to one-half, the amount of CO_2 in arterial blood is lessened; and the amount of N diminishes proportionally with the decrease of the atmospheric pressure. The diminished tension of the air prevents the vibrations of the vocal cords from occurring so forcibly, and hence the voice is feeble. (4) In consequence of the amount of blood in the skin, the internal organs are relatively anæmic; hence, there is diminished secretion of urine, muscular weakness, disturbances of digestion, dullness of the senses, and it may be unconsciousness, and all these phenomena are intensified by the conditions mentioned under (3). Some of these phenomena are modified by usage. The highest limit at which a man may still retain his senses is placed by Tissandier at an elevation of 8000 metres (280 mm. Hg). In dogs the blood pressure falls, and the pulse becomes small and diminished in frequency, when the atmospheric pressure falls to 200 mm. Hg.

Those who live upon high mountains suffer from a disease "**mal de montagne,**" which consists essentially in the above symptoms, although it is sometimes complicated with anæmia of the internal organs. Al. v. Humboldt found that in those who lived on the Andes the thorax was capacious. At 6000 to 8000 feet above sea level, water contains only one-third of the absorbed gases, so that fishes cannot live in it. Animals may be subjected to a further diminution of the atmospheric pressure by being placed under the receiver of an air pump. Birds die when the pressure is reduced to 120 mm. Hg; mammals at 40 mm. Hg; frogs endure repeated evacuations of the receiver, whereby they are much distended, owing to the escape of gases and water, but after the entrance of air they become greatly compressed. The cause of death in mammals is ascribed by Hoppe-Seyler to the evolution of bubbles of gas in the blood; these bubbles stop up the capillaries, and the circulation is arrested. *Local diminution of the atmospheric pressure* causes marked congestion and swelling of the part, as occurs when a cupping glass is used.

Great increase of the atmospheric pressure causes phenomena, for the most part, the reverse of the foregoing, as in pneumatic cabinets and in diving bells, where men may work even under 4½ atmospheres pressure. (1) Paleness and dryness of the external surfaces, collapse of the cutaneous veins, diminution of perspiration, and mucous secretions. (2) The tympanic membrane is pressed inward (until the air escapes through the Eustachian tube, after causing a sharp sound), acute sounds are heard, pain in the ears, and difficulty of hearing. (3) A feeling of lightness and freshness during respiration, the respiration becomes slower (by 2–4 per minute), inspiration easier and shorter, expiration lengthened, the pause distinct. The capacity of the lungs increases, owing to the freer movement of the diaphragm, in consequence of the diminution of the intestinal gases. Owing to the more rapid oxidations in the body, muscular movement is easier and more active. The O absorbed and the CO_2 excreted are increased. The venous blood is reddened. (4) Difficulty of speaking, alteration of the tone of the voice, inability to whistle. (5) Increase of the urinary secretion, more muscular energy, more rapid metabolism, increased appetite, subjective feeling of warmth, pulse beats slower, and pulse curve is lower (compare § 74). In animals subjected to

excessively high atmospheric pressure, P. Bert found that the arterial blood contained 30 vols. per cent. O (at 760 mm. Hg); when the amount rose to 35 vol. per cent., death occurred with convulsions. Compressed air has been used for therapeutical purposes, but in doing so a too rapid increase of the pressure is to be avoided. Waldenburg has constructed such an apparatus, which may be used for the respiration of air under a greater or less pressure.

Frogs, when placed in compressed O (at 14 atmospheres), exhibit the same phenomena as if they were in a vacuum, or pure N. There is paralysis of the central nervous system, sometimes preceded by convulsions. The heart ceases to beat (not the lymph hearts), while the excitability of the motor nerves is lost at the same time, and lastly the direct muscular excitability disappears. An excised frog's heart placed in O under a very high pressure (13 atmospheres), scarcely beats one-fourth of the time during which it pulsates in air. If the heart be exposed to the air again, it begins to beat, so that compressed O renders the vitality of the heart latent before abolishing it.

Phosphorus retains its luminosity under a high pressure in O, but this is not the case with the luminous organisms, *e. g.*, Lampyris, and luminous bacteria. High atmospheric pressure is also injurious to plants.

140. **COMPARATIVE AND HISTORICAL.**—**Mammals** have lungs similar to those of man. The lungs of **birds** are spongy, and united to the chest wall, while there are openings on their surface communicating with thin-walled "**air-sacs**," which are placed among the viscera. The air sacs communicate with cavities in the bones, which give the latter great lightness. The diaphragm is absent. In **reptiles** the lungs are divided into greater and smaller compartments; in snakes one lung is abortive, while the other has the elongated form of the body. The **amphibians** (frog) possess two simple lungs, each of which represents an enormous infundibulum with its alveoli. The frog pumps air into its lungs by the contraction of its throat, the nostrils being closed and the glottis opened. When young—until their metamorphosis—frogs breathe like fishes by means of gills. The perennibranchiate amphibians (Proteus) retain their gills throughout life. Among **fishes**, which breathe by gills and use the O absorbed by the water, the Dipnoi have in addition to gills a swim bladder provided with afferent and efferent vessels, which is comparable to the lung. The Cobitis respires also with its intestine. **Insects** and centipedes respire by "tracheæ," which are branched canals distributed throughout the body; they open on the surface of the body by openings (stigmata) which can be closed. Spiders respire by means of tracheæ and tracheal sacs, crabs by gills. The mollusks and cephalopods have gills; some gasteropods have gills and others lungs. Among the lower invertebrata some breathe by gills, others by means of a special "water vascular system," and others again by no special organs.

Historical.—Aristotle (384 B.C.) regarded the object of respiration to be the cooling of the body, so as to moderate the internal warmth. He observed correctly that the warmest animals breathe most actively, but in interpreting the fact he reversed the cause and effect. Galen (131–203 A.D.) thought that the "soot" was removed from the body along with the expired water. The most important experiments on the mechanics of respiration date from Galen; he observed that the lungs passively follow the movements of the chest; that the diaphragm is the most important muscle of inspiration; that the external intercostals are inspiratory; and the internal, expiratory. He divided the intercostal nerves and muscles, and observed that loss of voice occurred. On dividing the spinal cord higher and higher, he found that as he did so the muscles of the thorax lying higher up became paralyzed. Oribasius (360 A.D.) observed that in double pneumothorax both lungs collapsed. Vesalius (1540) first described artificial respiration as a means of restoring the beat of the heart. Malpighi (1661) described the structure of the lungs. J. A. Borelli († 1679) gave the first fundamental description of the mechanism of the respiratory movements. The **chemical** processes of respiration could only be known after the discovery of the individual gases therein concerned. Van Helmont († 1644) detected CO_2. [Joseph Black (1757) discovered that CO_2, or "fixed air," is given out during expiration.] In 1774 Priestley discovered O. Lavoisier detected N (1775), and ascertained the composition of atmospheric air, and he regarded the formation of CO_2 and H_2O of the breath as a result of a combustion within the lungs themselves. J. Ingen-Houss (1730–1799) discovered the respiration of plants. Vogel and others proved the existence of CO_2 in venous blood, and Hoffmann and others that of O in arterial blood. The more complete conception of the exchange of gases was, however, only possible after Magnus had extracted and analyzed the gases of arterial and venous blood (§ 36).

PHYSIOLOGY OF DIGESTION.

141. **THE MOUTH AND ITS GLANDS.**—The **mucous membrane** of the cavity of the mouth, which becomes continuous with the skin at the red margin of the lips, has a number of **sebaceous glands** in the region of the red part of the lip. The buccal mucous membrane consists of bundles of fine fibrous tissue mixed with elastic fibres, which traverse it in every direction. **Papillæ**—simple or compound—occur near the free surfaces. The **submucous tissue**, which is directly continuous with the fibrous tissue of the mucous membrane itself, is thickest where the mucous membrane is thickest, and densest where it is firmly fixed to the periosteum of the bone

FIG. 150.

FIG. 151.

Section of a mucous follicle from the tongue.

and to the gum; it is thinnest where the mucous membrane is most movable, and where there are most folds. The cavity of the mouth is lined by **stratified squamous epithelium** (Fig. 150), which is thickest, as a rule, where the longest papillæ occur.

All the glands of the mouth, including the salivary glands, may be divided into different classes, according to the nature of their secretions.

1. The **serous** or **albuminous** glands [**true salivary**], whose secretion contains a certain amount of albumin, *e. g.*, the human parotid.

2. The **mucous** glands, whose secretion, in addition to some albumin, contains the characteristic constituent mucin.

3. The **mixed** [or **muco-salivary**] glands, some of the acini secreting an albuminous fluid and others mucin, *e. g.*, the human maxillary gland.

Numerous **mucous glands** (labial, buccal, palatine, lingual, molar) have the appearance of small macroscopic bodies lying in the sub-mucosa. They are **branched tubular glands**, and the contents of their secretory cells consist partly of mucin, which is expelled from them during secretion. The excretory ducts of these glands, which are lined by cylindrical epithelium, are constricted where they enter the mouth. Not unfrequently one duct receives the secretion of a neighboring gland.

The **glands of the tongue** form two groups, which differ morphologically and physiologically. (1) The **mucous glands** (*Weber's* glands), occurring chiefly near the root of the tongue, are

branched tubular glands lined with clear, transparent, secretory cells whose nuclei are placed near the attached end of the cells. The acini have a distinct membrana propria. (2) The **serous glands** (*Ebner's*) are acinous glands occurring in the region of the circumvallate papillæ (and in animals near the papillæ foliatæ). They are lined with turbid granular epithelium with a central nucleus, and secrete saliva. (3) The glands of Blandin and Nuhn are placed near the tip of the tongue, and consist of mucous and serous acini, so that they are mixed glands (*Podwisotzky*).

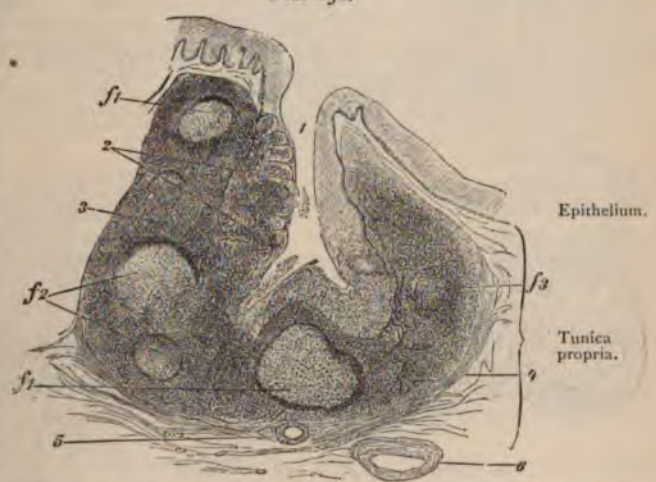
The **blood vessels** are moderately abundant, and the larger trunks lie in the sub-mucosa, while the finer twigs penetrate into the papillæ, where they form either a capillary network or simple loops.

The larger **lymphatics** lie in the sub-mucosa, while the finer branches form a fine network placed in the mucosa. The **lymph follicles** also belong to the lymphatic system (§ 197). On the dorsum of the posterior part of the tongue they form an almost continuous layer. They are round or oval (1–1.5 mm. in diameter), lying in the sub-mucosa, and consist of adenoid tissue loaded with lymph corpuscles. The outer part of the adenoid reticulum is compressed so as to form a kind of capsule for each follicle. Similar follicles occur in the intestine as solitary follicles; in the small intestine they are collected together into Peyer's patches, and in the spleen they occur as Malpighian corpuscles. On the **dorsum of the tongue** several of these follicles form a slightly oval elevation, which is surrounded by connective tissue. In the centre of this elevation there is a depression, into which a mucous gland opens, which fills the small crater with mucus (Fig. 151).

The **tonsils** have fundamentally the same structure. On their surface are a number of depressions into which the ducts of small mucous glands open. These depressions are surrounded by groups (10–20) of lymph follicles, and the whole is environed by a capsule of connective tissue (Fig. 152). Large lymph spaces, communicating with lymphatics, occur in the neighborhood of the tonsils, but as yet a direct connection between the spaces in the follicles and the lymph vessels has not been proved to exist. Similar structures occur in the **tubal and pharyngeal tonsils.** [Stöhr asserts that an enormous number of leucocytes wander out of the tonsils, solitary and Peyer's glands, and the adenoid tissue of the bronchial mucous membrane. The cells pass out between the epithelial cells, but do not pass into the interior of the latter.]

Nerves.—Numerous *medullated* nerve fibres occur in the sub-mucosa, pass into the mucosa, and terminate partly in the individual papillæ in Krause's end bulbs, which are most abundant in the lips and soft palate, and not so numerous in the cheeks and floor of the mouth. The nerves administer not only to common sensation, but they are also the organs of transmission for tactile (heat and pressure) impressions. It is highly probable, however, that some nerve fibres end in fine terminal fibrils, between the epithelial cells, as in the cornea and elsewhere.

FIG. 152.

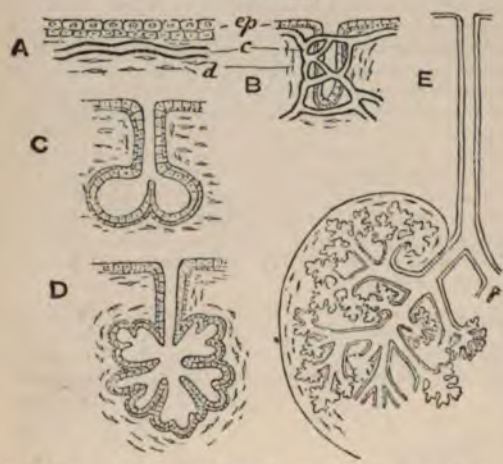


Vertical section of a human tonsil, × 20. 1, cavity; 2, epithelium infiltrated with leucocytes below and on the left, but free on the right; 3, adenoid tissue with sections *a*, *b*, *c*, of masses of it; 4, fibrous sheath; 5, section of a gland duct; *d*, blood vessel.

[**Secretory glands** may be simple (Fig. 153, B, C, D) or compound (E). In the latter case the duct is branched. In the process of development, a solid process of the epithelium sinks into the subjacent fibrous tissue, and, to form a simple gland, a cavity appears in this bud, but for a compound gland, other epithelial buds sprout from its blind end. Each bud acquires a central cavity, these elongate and increase in number, thus forming a much branched system, the terminal blind ends forming the **acini, alveoli** or true secretory part. If the alveoli are tubular in shape, the gland is called a compound tubular gland. Thus in the compound glands some parts are secretory, and others act as ducts, while in the simple glands, all the parts may be secretory. All the glands opening on the surface of the body are of epiblastic origin. The secretory cells lining the acini rest on a basement membrane, and outside this are the lymph spaces and capillary blood vessels.]

142. **THE SALIVARY GLANDS.**—The **three pairs** of salivary glands, **sub-maxillary, sublingual,** and **parotid,** are compound tubular glands. Fig. 155, A, shows a fine duct, terminating in the more or less flask-shaped alveoli or acini. [Each gland consists of a number of **lobes,** and each lobe in turn of a number of **lobules,** which, again, are composed of **acini.** All these are held together by a **framework** of connective tissue. The larger branches of the **duct** lie between the lobules, and constitute the **interlobular** ducts, giving branches to each lobule which they enter, constituting the **intralobular** ducts, which branch and finally terminate in connection with the alveoli, by means of an **intermediary** or **intercalary** part. The larger interlobar and interlobular ducts consist of a membrana propria, strengthened outside with fibrous and elastic tissue, and in some places also by non-striped muscle, while the ducts are lined by columnar epithelial cells. In the largest branches, there is a second row of smaller cells, lying between the large cells and the membrana propria. The **intralobular ducts** are lined by a single layer of large cylindrical epithelium with the nucleus about the middle of the cell, while the outer half of the cell is finely striated longitudinally, or "rodded," which is due to fibrillæ (Fig. 154); the inner half next the lumen is granular. The **intermediary part** is narrow, and is lined by a single layer of flattened cells, each with an elongated oval nucleus. There is usually a narrow "neck," where the intralobular duct becomes continuous with the intermediary part, and here the cells are polyhedral.]

FIG. 153.



Evolution of glands. A, schema of skin; *ep*, epidermis; *d*, cutis with a capillary *c*; B, simple gland with its blood vessels; C, D, more complex glands; E, compound gland, blood vessels omitted.

FIG. 154.

Rodded epithelium lining the duct of a salivary gland.

FIG. 155.

The **acini,** or **alveoli,** are the parts where the actual process of secretion takes place. They vary somewhat in shape—some are tubular, others branched, some are dilated and resemble a

Florence flask, and several of them usually open into one intermediary part of a duct. Each alveolus is bounded by a basement membrane, with a reticulate structure made up of nucleated, branched, and anastomosing cells so as to resemble a basket (D). There is a homogeneous membrane bounding the alveoli in addition to this basket shaped structure. Immediately outside this membrane is a lymph space, and outside this again the network of capillaries is distributed. [The extent to which this lymph space is filled with lymph determines the distance of the capillaries from the membrana propria. The inter-alveolar lymph spaces communicate with large lymph spaces between the lobules, which in turn communicate with perivascular lymphatics around the arteries and veins.] The lymphatics emerge from the gland at the hilum.

The **secretory cells** vary in structure, according as the salivary gland is a **mucous** [sub-maxillary and sublingual of the dog and cat], a **serous** [parotid of man and mammals, and sub-maxillary of rabbit], or **mixed** gland [human sub-maxillary and sublingual].

Mucous Acini.—The secretory cells of mucous glands, and the mucous acini of mixed glands (Fig. 156), are lined by a single layer of "**mucin cells**" (Fig. 155, B, *c*), which are large cells distended with mucin, or with a hypothetical substance, **mucigen**, which yields mucin. The mucin cells are more or less spheroidal in shape, clear, shining, highly refractive, and nearly fill the acinus. The flattened nucleus is near the wall of the acinus. Each cell has a fine process which overlaps the fixed parts of the cell next to it. Owing to the body of each cell being infiltrated with mucin, these cells do not stain with carmine, although the nucleus and its immediately investing protoplasm do. Another kind of cell occurs in the sub-maxillary gland of the dog. It forms a half-moon shaped *structure* lying in direct contact with the wall of the acinus (*Gianuzzi*). Each "**half-moon**" or "**crescent**" consists of a number of small, closely packed, angular, highly albuminous cells with small oval nuclei, which, however, are separated only with difficulty. Hence, Heidenhain has called them "**composite marginal cells**" (B, *d'*). They are granular, darker, devoid of mucin, and stain readily with pigments. [In the sub-maxillary gland of the cat, there is a complete layer of these "marginal" carmine-staining cells lying between the mucous cells and the membrana propria.]

FIG. 156.

Section of a human sub-maxillary gland. On the left is a group of serous alveoli, and on the right a group of mucous alveoli.

[**Serous Acini.**—In true serous glands (parotid of man and mammals) and in the serous acini of mixed glands, the acini are lined by a single layer of secretory columnar finely-granular cells, which in the quiescent condition completely fill the acinus, so that scarcely any lumen is left. Just before secretion, or when these cells are quiescent, Langley has shown that they are large and filled with numerous granules, which obscure the presence of the nucleus. As secretion takes place, these granules seem to be used up or discharged into the lumen; at least, the outer part of each cell gradually becomes clear and more transparent, and this condition spreads toward the inner part of the cell.]

[In the **mixed** or **muco-salivary** glands (*e.g.*, human sub-maxillary) some of the alveoli are mucous and others serous in their characters, but the latter are always far more numerous, and the one kind of acinus is directly continuous with the others (Fig. 156).]

143. HISTOLOGICAL CHANGES DURING THE ACTIVITY OF THE SALIVARY GLANDS.—[The condition of physiological activity of the gland cells is accompanied by changes in the histological characters of the secretory cells. Changes in **serous glands** have been carefully studied in the parotid of the rabbit, but the appearances vary somewhat, according as the glands are examined in the fresh condition or after hardening in various reagents, such as absolute alcohol. When the gland is at **rest**, in a preparation hardened in alcohol, and stained with carmine, the cells consist of a pale, almost uncolored substance, with a few fine granules, and a small, irregular, red-stained, shriveled nucleus

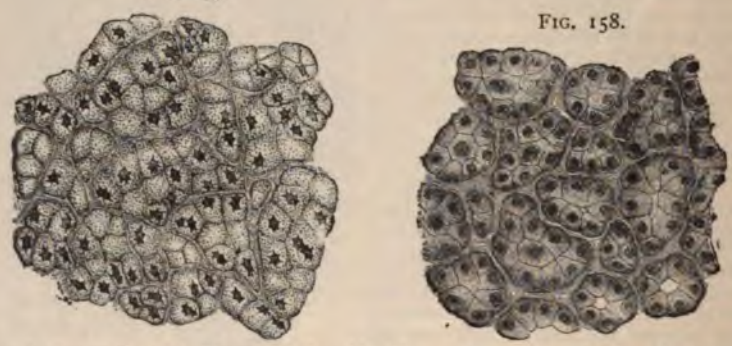
devoid of a nucleolus. The appearance of the nucleus suggests the idea of its being shriveled by the action of the hardening reagent (Fig. 157).]

[**During activity,** if the gland be caused to secrete by stimulating the sympathetic, all parts of the cells undergo a change (Figs. 157, 158). In preparations **hardened in alcohol** (1) the cells diminish somewhat in size; (2) the nuclei are no longer irregular, but round, with a sharp contour and nucleoli; (3) the substance of the cell itself is turbid owing to the diminution of the clear substance, and the increase of the granules, especially near the nuclei; (4) at the same time, the whole cell stains more deeply with carmine (*Heidenhain*).]

[On studying the changes which occur in a **living serous gland,** Langley found that the substance of the cells of the parotid is pervaded by fine granules, which are so numerous as to obscure the nucleus, while the outlines of the cells are indistinct. No lumen is visible in the acini during **activity,** the granules disappear from the outer zone of the cells, the cells themselves becoming smaller and more distinct. After prolonged secretion the granules largely disappear from the cell substance except quite near the inner margin. The cells are smaller, their outlines more distinct, their spherical nuclei apparent, and the lumen of the acini is wide and distinct. Thus, it is evident that, during rest, granules are manufactured, which disappear during the activity of the cells, the disappearance taking place from without inward. Similar changes occur in the cells of the pancreas.]

FIG. 157.

FIG. 158.



Sections of a "serous" gland. The parotid of a rabbit, Fig. 157, at rest; Fig. 158, after stimulation of the cervical sympathetic.

[More complex changes occur in the **mucous glands,** such as the sub-maxillary or orbital glands of the dog (*Lavdovsky*). The appearances vary according to the intensity and duration of the secretory activity. The mucous cells at **rest** are large, clear, and refractive, containg a flattened nucleus (Fig. 155, C), surrounded with a small amount of protoplasm, and placed near the basement membrane. The clear substance does not stain with carmine, and consists of mucigen lying in the wide spaces of an intracellular plexus of fibrils. After **prolonged secretion,** produced, it may be, by strong and continued stimulation of the chorda, the mucous cells of the sub-maxillary gland of the dog undergo a great change.] The distended, refractive, and "mucous cells," which occur in the quiescent gland, and which do not stain with carmine, do not appear after the gland has been in a state of activity. Their place is taken by small, dark, protoplasmic cells devoid of mucin (Fig. 155, C). These cells readily stain with carmine, while their nucleus is scarcely, if at all, colored by the dye. The researches of R. Heidenhain (1868) have shed much light on the secretory activity of the salivary glands.

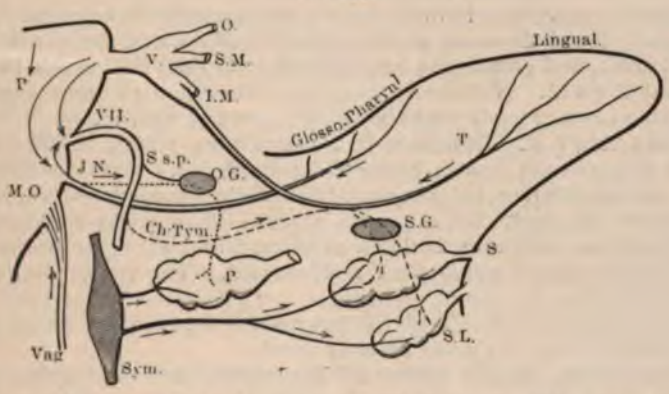
The change may be produced in two ways. Either it is due to the "mucous cells" during secretion becoming broken up, so that they yield their mucin directly to the saliva; in saliva rich in mucin, small microscopic pieces of mucin are found, and sometimes mucous cells themselves are present. Or, we must assume that the mucous cells simply eliminate the mucin from their bodies (*Ewald, Stöhr*); while, after a period of rest, new mucin is formed. According to this view, the dark granular cells of the glands, after active secretion, are simply mucous cells, which have given out their mucin. If we assume, with Heidenhain, that the mucous cells break up, then these granular non-mucous cells must be regarded as new formations produced by the proliferation and growth of the composite marginal cells, *i. e.*, the crescents, or half-moons of Gianuzzi.

[During rest, the protoplasm seems to manufacture **mucigen**, which is changed into and discharged as mucin in the secretion, when the gland is actively secreting. Thus, the cells become smaller, but the protoplasm of the cell seems to increase, new mucigen is manufactured during rest, and the cycle is repeated.]

144. THE NERVES OF THE SALIVARY GLANDS.—The nerves are for the most part medullated, and enter at the hilum of the gland, where they form a rich plexus provided with **ganglia** between the lobules. [There are no ganglia in the parotid gland (*Klein*).]

All the salivary glands are supplied by branches from two different nerves—from the sympathetic and from a cranial nerve.

FIG. 159.



Scheme of the nerves of the salivary glands. P., pons; M. O., medulla oblongata; J. N., nerve of Jacobson; O., S. M., I. M., ophthalmic, superior, and inferior maxillary divisions of fifth nerve, V.; VII., seventh nerve; S.s.p., small superficial petrosal nerve; Vag., vagus; Sym., sympathetic; O. G., otic, and S. G., sub-maxillary ganglia; P., S., and S. L., parotid, sub-maxillary, and sublingual glands: T., tongue.

1. The **sympathetic** nerve gives branches (*a*) to the sub-maxillary and the sublingual glands, derived from the plexus on the external maxillary artery; (*b*) to the parotid gland from the carotid plexus (Fig. 159).

2. The **facial** nerve gives branches to the sub-maxillary and sublingual glands from the chorda tympani, which accompanies the lingual branch of the fifth nerve (Fig. 159). The branches to the parotid arise from the tympanic branch of the **glosso-pharyngeal** nerve (dog). The tympanic plexus sends fibres to the small superficial petrosal nerve, and with it these fibres run to the anterior surface of the pyramid in the temporal bone, emerging from the skull through a fissure between the petrous and great wing of the sphenoid, and then joining the otic ganglion. This ganglion sends branches to the auriculo-temporal nerve (itself derived from the third branch of the trigeminus), which, as it passes upward to the temporal region under cover of the parotid, gives branches to this gland.

The **sub-maxillary ganglion**, which gives branches to the sub-maxillary and sublingual glands, receives fibres from the tympanico-lingual nerve (chorda

tympani) as well as sympathetic fibres from the plexus on the external maxillary artery.

Termination of the Nerve Fibres.—With regard to the ultimate distribution of these nerves we can distinguish (1) the **vasomotor nerves**, which give branches to the walls of the blood vessels, and (2) the **secretory nerves** proper.

Pflüger states, with regard to the latter, that (*a*) medullated nerve fibres penetrate the acini; the sheath of Schwann unites with the membrana propria of the acinus; the medullated fibre—still medullated—passes between the secretory cells, where it divides and becomes non-medullated, and its axial cylinder terminates in connection with the nucleus of a secretory cell. [This, however, is not proved] (Fig. 155, F). (*b*) According to Pflüger, some of the nerve fibres end in multipolar ganglion cells, which lie outside the wall of the acinus, and these cells send branches to the secretory cells of the acini. [These cells probably correspond to the branched cells of the basket-shaped structure.] (*c*) Again, he describes medullated fibres which enter the attached end of the cylindrical epithelium lining the excretory ducts of the glands (E). Pflüger thinks that those fibres entering the acini directly are cerebral, while those with ganglia in their course are derived from the sympathetic system. [(*d*) The direct termination of nerve fibres has been observed in the salivary glands of the cockroach by Kupffer.]

145. ACTION OF THE NERVOUS SYSTEM ON THE SECRETION OF SALIVA.—A. **Sub-maxillary Gland.**—Stimulation of the **facial nerve** at its origin causes a profuse secretion of a thin, **watery saliva**, which contains a very small amount of specific constituents. Simultaneously with the act of secretion, the blood vessels of the glands dilate, and the capillaries are so distended that the pulsatile movement in the arteries is propagated into the veins. Nearly four times as much blood flows out of the veins (*Cl. Bernard*), the blood being of a bright red color, and containing one-third more O than the venous blood of the non-stimulated gland. Notwithstanding this relatively high percentage of O, the secreting gland uses more O than the passive gland (§ 131, 1).

[**I. Stimulation of Chorda.**—If a cannula be placed in Wharton's duct, *e. g.*, in a dog, and the chorda tympani be divided, no secretion flows from the cannula. On stimulating the *peripheral end of the chorda tympani* with an interrupted current of electricity, the same results—copious secretion of saliva and vascular dilatation, with increased flow of blood through the gland—occur as when the origin of the seventh nerve itself is stimulated. The **watery** saliva is called **chorda saliva.**]

Two functionally different kinds of nerve fibres occur in the facial nerve—(1) true **secretory** fibres, (2) **vaso-dilator** fibres.

II. **Stimulation of the sympathetic nerve** causes a scanty amount of a very **thick**, sticky, mucous secretion, in which the specific salivary constituents, *mucin*, and the salivary corpuscles are very abundant. The specific gravity of the saliva is raised from 1007 to 1010. Simultaneously the blood vessels become contracted, so that the blood flows more slowly from the veins, and has a dark bluish color.

The sympathetic also contains *two* kinds of nerve fibres—(1) true **secretory** fibres, and (2) **vaso-constrictor** fibres.

[**Electrical Variations during Secretion.**—That changes in the electromotive properties of glands occur during secretion was shown in the frog's skin. Bayliss and Bradford find that the same is true of the sub-maxillary gland (dog). During secretion, the **excitatory change** on stimulating the **chorda** is a *positive* variation of the current of rest (the hilum of the gland becoming more positive), but it is frequently followed by a second phase of opposite sign. The latent period is always very short, about 0.37″. Atropin abolishes the chorda variation. On stimulating the **sympathetic**, the excitatory change is of an opposite sign to that of the chorda, and the hilum becomes less positive, so that there is a *negative* variation. It requires a more powerful stimulus, is less in amount, and its latent period is longer (2″–4″), while atropin lessens but does not abolish it.]

Relation to Stimulus.—On stimulating the *cerebral* nerves, at first with a weak and gradually with a stronger stimulus, there is a gradual development of the secretion in which the solid constituents—occasionally the organic—are increased (*Heidenhain*). If a strong stimulus be applied for a long time, the secretion diminishes, becomes watery, and is poor in specific constituents, especially

in the organic elements, which are more affected than the inorganic (*C. Ludwig and Becher*). After prolonged stimulation of the sympathetic, the secretion resembles the chorda saliva. It would seem, therefore, *that the chorda and sympathetic saliva are not specifically distinct, but vary only in degree.* On continuing the stimulation of the nerves up to a certain maximal limit, the rapidity of secretion becomes greater, and the percentage of *salts* also increases to a certain maximum, and this independently of the former condition of the glands. The percentage of organic constituents also depends on the strength of the nervous stimulation, but not on this alone, as it is essentially contingent upon the condition of the gland before the secretion took place, and it also depends upon the duration and intensity of the previous secretory activity. Very strong stimulation of the gland leaves an "after-effect," which predisposes it to give off organic constituents into the secretion (*Heidenhain*). A latent period of 1.2 sec. to 24 sec. may elapse between the nerve stimulation and the beginning of the secretion.

[Langley has shown that in the **cat** the sympathetic saliva of the sub-maxillary gland is *less* viscid than the chorda saliva.]

Relation to Blood Supply.—*The secretion of saliva is not simply the result of the amount of blood in the glands;* that there is a factor independent of the changes in the state of the vessels is shown by the following facts:—

(1) The secretory activity of the glands when their nerves are stimulated continues for some time after the blood vessels of the gland have been ligatured. [If the head of a rabbit be cut off, stimulation of the seventh nerve, above where the chorda leaves it, causes a flow of saliva, which cannot be accounted for on the supposition that the saliva already present in the salivary glands is forced out of them. Thus we may have **secretion without a blood stream.** The saliva is really secreted from the lymph present in the lymph spaces of the gland (*Ludwig*).]

(2) **Atropin** and **daturin** abolish the activity of the secretory fibres in the chorda tympani, but do not affect the vaso-dilator fibres (*Heidenhain*). The same results occur after the injection of acids and alkalies into the excretory duct (*Gianuzzi*).

[**Action of Atropin.**—The vascular dilatation and the increased flow of saliva, due to the activity of the secretory cells, produced by stimulation of the chorda tympani, although they occur simultaneously, do not stand in the relation of cause and effect. We may cause vascular dilatation without an increased flow of saliva, as already stated (2). If atropin be given to an animal, stimulation of the chorda produces dilatation of the blood vessels, but no secretion of saliva. Atropin paralyzes the secretory fibres, but not the vaso-dilator fibres (Fig. 160). The increased supply of blood, while not causing, yet favors the act of secretion, by placing a larger amount of pabulum at the disposal of the secretory elements, the cells.]

(3) The **pressure** in the excretory duct of the salivary gland—measured by means of a manometer tied into it—may be nearly *twice* as great as the pressure within the arteries of the glands, or even in the carotid itself (*Ludwig*). The pressure in Wharton's duct may reach 200 mm. Hg.

[**Secretory Pressure.**—The experiment described under (3) proves, in a definite manner, that the passage of the water from the blood vessels, or at least from the lymph into the acini of the gland, cannot be due to the blood pressure; that, in fact, it is *not a mere process of filtration*, such as occurs in the glomeruli of the kidney. In the case of the salivary gland, where the pressure within the gland may be double that of the arterial pressure, the water actually moves from the lymph spaces against very great resistance. We can only account for this result by ascribing it to the secretory activity of the gland cells themselves. Whether the activities of the gland cells, as suggested by Heidenhain, are governed directly by two distinct kinds of nerve fibres, a set of solid-secreting fibres, and a set of water-secreting fibres, remains to be proved.]

(4) Just as in the case of muscles and nerves, the salivary glands become **fatigued** or exhausted after prolonged action. This result may also be brought about by injecting acids or alkalies into the duct, which shows that the secretory activity of the gland is independent of the circulation (*Gianuzzi*).

All these facts lead us to conclude that **the nerves exercise a direct effect upon the secretory cells,** apart from their action on the blood vessels.

Extirpation of Salivary Glands.—When the chorda tympani is extirpated on one side in young dogs, the sub-maxillary gland on that side does not develop so much—its weight is 50 per cent. less—while the mucous cells and the "crescents" are smaller than on the sound side (*Bufalini*).

During secretion, the **temperature** of the gland rises 1.5° C. (*Ludwig*), and the blood flowing from the veins is often warmer than the arterial blood. [The **electro-motive changes** are referred to on p. 256.]

"Paralytic Secretion" of Saliva.—By this term is meant the continued secretion of a thin, watery saliva from the sub-maxillary gland, which occurs twenty-four hours after the section of the *cerebral nerves* (chorda of the seventh), *i.e.*, those branches of them that go to this gland, whether the sympathetic be divided or not (*Cl. Bernard*). It increases until the eighth day, after which it gradually diminishes, while the **gland tissue degenerates**. The injection of a small quantity of curara into the artery of the gland also causes it.

[Heidenhain showed that section of *one* chorda is followed by a continuous secretion of saliva from *both* sub-maxillary glands. The term **"paralytic"** secretion is applied to that which takes place on the side on which the nerve is cut, and Langley proposes to call the secretion on the opposite side the **antilytic**. Apnœa (§ 368) stops both the paralytic and antilytic secretion, while dyspnœa increases the flow in both cases; and as section of the sympathetic fibres to the gland (where the chorda is cut) arrests the paralytic secretion excited by dyspnœa, it is evident that both the paralytic secretion and the secretion following dyspnœa are caused by stimuli traveling down the sympathetic fibres. In the later stages of the paralytic secretion, the cause is in the gland itself, for it goes on even if all the nerves passing to the gland be divided, and is probably due to a local nerve centre. In this stage the secretion is arrested by a large dose of chloroform. The paralytic secretion in the first stage may be owing to a venous condition of the blood acting on a central secretory centre whose excitability is increased; and in the latter stages probably on local nerve centres within the gland. The fibres of the chorda in the cat are only partially degenerated thirteen days after section (*Langley*).]

[**Histological Changes.**—In the gland during paralytic secretion, the gland cells of the alveoli (serous, mucous, and demilunes) diminish in size and show the typical "resting" appearance, even to a greater extent than the normal resting gland (*Langley*).]

B. **Sub-lingual Gland.**—Very probably the same relations obtain as in the sub-maxillary gland.

C. **Parotid Gland.**—In the dog, stimulation of the sympathetic *alone* causes no secretion; it occurs when the glosso-pharyngeal branch to the parotid is simultaneously excited. This branch may be reached within the tympanum in the tympanic plexus. A *thick* secretion containing much organic matter is thereby obtained. Stimulation of the *cerebral* branch *alone* yields a clear, thin, watery secretion, containing a very small amount of organic substances, but a considerable amount of the salts of the saliva.

[**Stimulation of Jacobson's Nerve (Parotid of Dog)**—

	Total Solids.	Salts.	Organic Matter.
Without sympathetic, . .	0.56 per cent.	0.31	0.24
With sympathetic, . . .	2.42 per cent.	0.36	2.06]

[**Reflex Secretion of Saliva.**—If a cannula be placed in Wharton's duct, *e. g.*, in a dog, during fasting, no saliva will flow out, but on applying a sapid substance to the mucous membrane of the mouth or the tongue, there is a copious flow of saliva. If the sympathetic nerve be divided, secretion still takes place when the mouth is stimulated, but if the chorda tympani be cut, secretion no longer takes place. Hence, the secretion is due to a reflex act; in this case, the lingual is the afferent, and the chorda the efferent nerve carrying impulses from a centre situated in the medulla oblongata (Fig. 160).]

In the intact body, the secretion of saliva occurs through a **reflex** stimulation of the nerves concerned, whereby, under normal circumstances, the secretion is always watery (chorda or facial saliva). The **centripetal** or **afferent** nerve fibres concerned are: (1) The nerves of taste. (2) The sensory branches of the trigeminus of the entire cavity of the mouth and the glosso-pharyngeal

(which appear to be capable of being stimulated by mechanical stimuli, pressure, tension, displacement). The movements of mastication also cause a secretion of saliva. Pflüger found that one-third more saliva was secreted on the side where mastication took place; and Cl. Bernard observed that the secretion ceased in horses during the act of drinking. (3) The nerves of smell, excited by certain odors. (4) The gastric branches of the vagus. A rush of saliva into the mouth usually precedes the act of vomiting (§ 158).

FIG. 160.

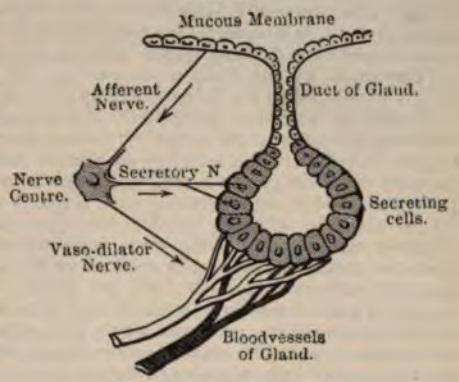


Diagram of a salivary gland.

(5) The **stimulation of distant sensory nerves**, *e. g.*, the central end of the sciatic—certainly through a complicated reflex mechanism—causes a secretion of saliva (*Owsjannikow and Tschierjew*). Stimulation of the conjunctiva, *e. g.*, by applying an irritating fluid to the eye of carnivorous animals, causes a reflex secretion of saliva (*Aschenbrandt*). Perhaps the secretion of saliva which sometimes occurs during pregnancy is caused in a similar reflex manner.

(6) The **movements of mastication** excite secretion, but although, during the act of rumination, this is the case in ruminants, in whom the process of mastication is very thorough, there is no secretion from the sub-maxillary gland, although the parotid secretes (*Colin, Ellenberger and Hofmeister*).

The **reflex centre** for the secretion of saliva lies in the medulla oblongata, at the origin of the seventh and ninth cranial nerves. The centre for the sympathetic fibres is also placed here. This region is connected by nerve fibres with the cerebrum; hence, the thought of a savory morsel, sometimes, when one is hungry, causes a rapid secretion of a thin, watery fluid—[or, as we say, "makes the mouth water"]. If the centre be stimulated directly by a mechanical stimulus (puncture), salivation occurs, while asphyxia has the same effect. The reflex secretion of saliva may be **inhibited** by stimulation of certain sensory nerves, *e. g.*, by pulling out a loop of the intestine. Stimulation of the cortex cerebri of a dog, near the sulcus cruciatus, is often followed by secretion of saliva. Disease of the brain in man sometimes causes a secretion of saliva, owing to the effects produced on the intracranial centre.

So long as there is no stimulation of the nerves, there is no secretion of saliva, as in sleep. *Immediately after* the section of all nerves, secretion stops, for a time at least.

Pathological Conditions and Poisons.—Certain affections, as inflammation of the mouth, neuralgia, ulcers of the mucous membrane, and affections of the gums, due to teething or the prolonged administration of mercury, often produce a copious secretion of saliva or **ptyalism**. Certain **poisons** cause the same effect by direct stimulation of the nerves, as Calabar bean (physostigmin), digitalin, and especially pilocarpin. Many poisons, especially the narcotics—above all, atropin—*paralyze the secretory nerves*, so that there is a cessation of the secretion and the mouth becomes dry; while the administration of muscarin in this condition causes secretion. Pilocarpin acts on the chorda tympani, causing a profuse secretion, and if atropin be given, the secretion is again arrested. Conversely, if the secretion be arrested by atropin, it may be restored by the action of pilocarpin or physostigmin. Nicotin, in small doses, excites the secretory nerves, but in large doses paralyzes them. Daturin, cicutin, and iodide of æthylstrychnin, paralyze the chorda. The saliva is diminished in amount in man, in cases of *paralysis of the facial* or sympathetic nerves, as is observed in unilateral paralysis of these nerves.

[**Sialogogues** are those drugs which increase the secretion of saliva. Some are **topical**, and take effect when applied to the mouth. They excite secretion reflexly by acting on the sensory nerves of the mouth. They include acids, and various pungent bodies, such as mustard, ginger, pyrethrum, tobacco, ether, and chloroform; but they do not all produce the same effect on the amount or quality of the saliva; others, the **general** sialogogues, cause salivation when introduced

into the blood; physostigmin, nicotin, pilocarpin, muscarin. The drugs named act after all the nerves going to the gland are divided, so that they stimulate the peripheral ends of the nerves in the glands. The two former also excite the central ends of the secretory nerves.]

[**Antisialics** are those substances which diminish the secretion of saliva, and they may take effect upon any part of the reflex arc, *i. e.*, on the mouth, the afferent nerves, the nerve centre and afferent nerves, or upon the blood stream through the glands, or on the glands themselves. Opium and morphia affect the centre, large doses of physostigmin affect the blood supply, but atropin is the most powerful of all, as it paralyzes the terminations of the secretory nerves in the glands, *e. g.*, the chorda tympani, and even the sympathetic in the cat (but not in the dog).]

[**Excretion by the Saliva.**—Some drugs are excreted by the saliva. Iodide of potassium is rapidly eliminated by the kidneys, and by the salivary glands, and so also is iodide of iron.]

Theory of Salivary Secretion.—Heindenhain has recently formulated the following theory regarding the secretion of saliva: "During the passive or quiescent condition of the gland, the organic materials of the secretion are formed from and by the activity of the protoplasm of the secretory cells. A *quiescent* cell, which has been inactive for some time, therefore contains little protoplasm, and a large amount of these secretory substances. In an actively secreting gland, there are two processes occurring together, but independent of each other, and regulated by two different classes of nerve-fibres; *secretory fibres* cause the act of secretion, while *trophic fibres* cause chemical processes within the cells, partly resulting in the formation of the soluble constituents of the secretion, and partly in the growth of the protoplasm. According to the number of both kinds of fibres present in a nerve passing to a gland, such nerve being stimulated, the secretion takes place more rapidly (cerebral nerve) or more slowly (sympathetic), while the secretion contains less or more solid constituents. The *cerebral* nerves contain many secretory fibres and few trophic fibres, while the *sympathetic* contain more trophic but few secretory fibres. The rapidity and chemical composition of the secretion vary according to the strength of the stimulus. During continued secretion, the supply of secretory materials in the gland cells is used up more rapidly than it is replaced by the activity of the protoplasm; hence, the amount of organic constituents diminishes, and the microscopic characters of the cells are altered. The microscopic characters of the cells are altered also by the increase of the protoplasm, which takes place in an active gland. The mucous cells disappear, and seem to be dissolved after prolonged secretion, and their place is taken by other cells derived from the proliferation of the marginal cells. The energy which causes the current of fluid depends upon the protoplasm of the gland cells."

146. THE SALIVA OF THE INDIVIDUAL GLANDS.—(*a*) **Parotid saliva** is obtained by placing a fine cannula in Steno's duct; it has an *alkaline* reaction, but during fasting, the first few drops may be neutral or even acid on account of free CO_2; its specific gravity is 1003 to 1004. After standing it becomes turbid, and deposits, in addition to albuminous matter, calcium carbonate, which is present in the fresh saliva in the form of bicarbonate. It contains small quantities (more abundant in the horse) of a globulin-like body, and never seems to be without CNKS, *i. e.*, sulphocyanide of potassium (or sodium),—which, however, is absent in the sheep and dog.

[The **sulphocyanide** gives a dark red color (ferric sulphocyanide) with ferric chloride, and the color is discharged by mercuric chloride, but this is not the case with meconic acid, which gives a similar color reaction.] It also reduces iodic acid when added to saliva, causing a yellow color from the liberation of iodine, which may be detected at once by starch (*Solera*).

Among the **organic** substances the most important are **ptyalin**, a small amount of *urea*, and traces of a volatile acid. **Mucin is absent**, hence the parotid saliva is not sticky, and can readily be poured from one vessel into another. It contains 1.5 to 1.6 per cent. of solids in man, of which 0.3 to 1.0 per cent. is inorganic.

Of the **inorganic** constituents—the most abundant are potassium and sodium chlorides; then potassium, sodium, and calcium carbonates, some phosphates, and a trace of an alkaline sulphate.

Salivary calculi are formed in the ducts of the salivary glands owing to the deposition of lime salts, and they contain only traces of the other salivary constituents; in the same way is formed the **tartar** of the teeth, which contains many threads of leptothrix, and the remains of low organisms which live in decomposing saliva in carious cavities between the teeth.

(*b*) **Sub-maxillary saliva** is obtained by placing a cannula in Wharton's duct; it is alkaline, and may be strongly so. After standing for a time, fine crystals of calcium carbonate are deposited, together with an amorphous albuminous body. It always contains **mucin** (which is precipitated by acetic acid);

hence, it is usually somewhat tenacious. It contains **ptyalin**, but in less amount than in parotid saliva; and, according to Oehl, only 0.0036 per cent. of potassium sulphocyanide.

Chemical Composition.—Sub-maxillary saliva (dog):—

Water, 991.45 per 1000,
Organic Matter, 2.89 " "
Inorganic Matter, 5.66 { 4.50 NaCl and $CaCl_2$.
{ 1.16 $CaCO_3$, Calcium and Magnesium phosphates.

	Mixed Saliva (Human) (*Jacubowitsch*).	Parotid (Human) (*Hoppe-Seyler*).	Sub-maxillary (Dog) (*Herter*).
[Water,	99.51	99.32	99.44
Solids,	0.49	0.68	0.56
Soluble organic bodies (ptyalin),	0.13	0.34	0.066
Epithelium, mucin,	0.16		0.17
Inorganic salts,	0.102	0.34	0.43
Potassic sulphocyanide,	0.006	0.03	. .
Potassic and sodic chlorides,	0.084	. .	. .]

Gases.—Pflüger found that 100 cubic centimetres of the saliva contained 0.6 O; 64.7 CO_2 (part could be pumped out, and part required the addition of phosphoric acid); 0.8 N.; or, in 100 vol. gas, 0.91 O; 97.88 CO_2; 1.21 N. [It therefore contains much more CO_2 than venous blood. Külz obtained from 100 c.c. of human saliva 7 c.c. of gas—O = 1 c.c., N = 2.5 c.c. and CO_2 = 3.5 c.c. Besides this there is 40–60 c.c. of fixed CO_2 in the form of carbonates.]

(*c*) **Sub-lingual saliva** is obtained by placing a very fine cannula in the ductus Rivinianus; it is *strongly alkaline* in reaction, very sticky and cohesive, contains much mucin, numerous salivary corpuscles, and some potassium sulphocyanide.

147. THE MIXED SALIVA IN THE MOUTH.—The **mixed saliva** in the mouth is a mixture of the secretions from the salivary, mucous, and other glands of the mouth.

(1) **Physical Characters.**—It is an opalescent, tasteless, odorless, slightly glairy fluid, with a specific gravity of 1004 to 1009, and an alkaline reaction. The **amount** secreted in twenty-four hours = 200 to 1500 grammes (7 to 50 oz.); according to Bidder and Schmidt, however, = 1000 to 2000 grammes. The solid constituents = 5.8 per 1000.

Composition.—The **solids** are: Epithelium and mucus, 2.2; ptyalin and albumin, 1.4; salts, 2.2; potassium sulphocyanide, 0.04 per 1000. The ash contains chiefly potash, phosphoric acid, and chlorine (*Hammerbacher*).

Decomposition products of epithelium, salivary corpuscles, or the remains of food, may render it *acid temporarily*, as after long fasting, and after much speaking; the reaction is acid in some cases of dyspepsia and in fever, owing to the stagnation and insufficient secretion.

(2) **Microscopic Constituents.**—(*a*) The **salivary corpuscles** are slightly larger than the white blood corpuscles (8 to 11 μ), and are nucleated protoplasmic globular cells without an envelope (Fig. 150, *s*). During their living condition, the particles in their interior exhibit *molecular* or **Brownian movement.** The dark granules lying in the protoplasm are thrown into a trembling movement, from the motion of the fluid in which they are suspended. This dancing motion stops when the cell dies.

[The **Brownian movements** of these suspended granules are purely physical, and are exhibited by all fine microscopic particles suspended in a limpid fluid, *e. g.*, gamboge rubbed up in water, particles of carmine, charcoal, etc.]

(*b*) **Pavement epithelial cells** from the mucous membrane of the mouth and tongue; they are very abundant in catarrh of the mouth (Fig. 150).

(*c*) **Living organisms,** which live and thrive in the cavities of teeth, nourished by the remains of food. Among these are *Leptothrix buccalis* (Fig. 149, 12) and small bacteria-like organisms. The threads of the leptothrix penetrate into the canals of the dentine, and produce dental caries. [Miller has found twenty-five varieties of microörganisms, including cocci, bacteria, vibrios, spirilla, and spirochætæ, eight of them present in the stomach and twelve in the intestines.]

(3) **Chemical Properties.**—(*a*) **Organic Constituents.**—*Serum-albumin* is precipitated by heat and by the addition of alcohol. In saliva, mixed with much water and shaken up with CO_2, a *globulin-like* body is precipitated; *mucin* occurs in small amount. Among the extractives, the most important is **ptyalin**; *fats* and *urea* occur only in traces. In twenty-four hours 130 milligrammes of potassium or sodium sulphocyanide are secreted.

(*b*) **Inorganic Constituents.**—Sodium and potassium chlorides, potassium sulphate, alkaline and earthy phosphates, ferric phosphate.

According to Schönbein, the saliva contains traces of *nitrites* (detected by adding dilute sulphuric acid and diamido-benzol to dilute saliva), which give a yellow color (*Gries*). There are also traces of ammonia (*Brücke*).

Abnormal Constituents.—In diabetes mellitus, *lactic acid*, derived from a further decomposition of grape sugar, is found. It dissolves the lime in the teeth, giving rise to diabetic dental caries. Frerichs found *leucin*, and Vulpian increase of albumin in albuminuria. Of foreign substances taken into the body, the following appear in the saliva: Mercury, potassium, iodine, and bromine.

Saliva of New-born Children.—In new-born children, the parotid alone contains ptyalin. The diastatic ferment seems to be developed in the sub-maxillary gland and pancreas, at the earliest after two months. Hence, it is not advisable to give starchy food to infants. No ptyalin has been found in the saliva of infants suffering from thrush (Oïdium albicans—*Zweifel*). The diastatic action of saliva is not absolutely necessary for the suckling, feeding as it does upon milk. The mouth during the first two months is not moist, but at a later period saliva is copiously secreted (*Korowin*); after the first six months, the salivary glands increase considerably. The eruption of the teeth—owing to the irritation of the mucous membrane—produce a copious secretion of saliva.

148. PHYSIOLOGICAL ACTION OF SALIVA.—I. **Diastatic Action.**—The most important chemical action exerted by saliva in digestion is its diastatic or amylolytic action (*Leuchs*, 1831), *i. e.*, the transformation of starch into *dextrin* and some form of **sugar.** This is due to the **ptyalin**—a **hydrolytic ferment** or **enzym**—which, even when it is present in very minute quantity, causes starch to take up water and become soluble, the ferment itself undergoing no essential change in the process. [Ptyalin belongs to the group of unorganized ferments (§ 250, 9). Like all other ferments it acts only within a certain range of temperature, being most active about 40° C. Its energy is permanently destroyed by boiling. It acts best in a slightly alkaline or neutral medium.]

[**Action on Starch.**—Starch grains consist of *granulose* or starch enclosed by coats of *cellulose*. Cellulose does not appear to be affected by saliva, so that saliva acts but slowly on raw, unboiled starch. If the starch be boiled, so as to swell up the starch grains and rupture the cellulose envelopes, the amylolytic action takes place rapidly. If starch paste or starch mucilage, made by boiling starch in water, be acted upon by saliva, especially at the temperature of the body, the first **physical** change observable is the liquefaction of the paste, the mixture becoming more fluid and transparent. The change takes place in a few minutes. When the action is continued, important **chemical** changes occur.]

According to O'Sullivan, Musculus, and v. Mering, the diastatic ferment of saliva (and of the pancreas), by acting upon starch or glycogen, forms **dextrin** and **maltose** (both soluble in water). Several closely allied varieties of dextrin, distinguishable by their color reactions, seem to be produced (*Brücke*). **Erythrodextrin** is formed first, it gives a red color with iodine; then a reducing dextrin—**achroodextrin**, which gives no color reaction with iodine. The sugar formed by the action of ptyalin upon starch is **maltose** ($C_{12}H_{22}O_{11} + H_2O$), which is distinguished from grape sugar ($C_{12}H_{24}O_{12}$) by containing one molecule less of water, which, however, it holds as a molecule of water of hydration. [Maltose also differs from grape sugar in its greater rotatory power on polarized

light, the former = + 150°, the latter + 56°, the ratio being 61 : 100; and in its smaller power of reducing cupric oxide. Thus, between the original starch and the final product, maltose, several intermediate bodies are formed. The starch gives a blue with iodine, but after it has been acted on for a time it gives a red or violet color, indicating the presence of erythrodextrin, there being a simultaneous production of sugar; but ultimately no color is obtained on adding iodine—achroodextrin, which gives no color with iodine, maltose being formed. The presence of the maltose is easily determined by testing with Fehling's solution.]

[Brown and Heron suggest that the final result of the transformation may be represented by the equation—

$$\underset{\text{Soluble starch.}}{10(C_{12}H_{20}O_{10})} + \underset{\text{Water.}}{8H_2O} = \underset{\text{Maltose.}}{8(C_{12}H_{22}O_{11})} + \underset{\text{Achroodextrin.}}{2(C_{12}H_{20}O_{10})}$$

The ferment slowly changes maltose into grape sugar or dextrose. This result may be brought about much more rapidly by boiling maltose with dilute sulphuric or hydrochloric acid.] Achroodextrin ultimately passes into maltose, and this again into dextrose; the other form of dextrin does not seem to undergo this change (Seegen's Dystropodextrin). For the further changes that maltose undergoes in the intestine, see § 183, II, 2.

[The formula of starch is usually expressed as $C_6H_{10}O_5$, but the researches already mentioned, and those of Brown and Heron, make it probable that it is more complex, which we may provisionally represent by $n(C_{12}H_{20}O_{10})$. According to Musculus and Meyer, erythrodextrin is a mixture of dextrin and soluble starch.]

Preparation of Ptyalin.—(1) Like all other hydrolytic ferments, it is carried down with any copious precipitate that is produced in the fluid which contains it, and it can be isolated from the precipitate. The saliva is acidulated with phosphoric acid, lime-water is added until the reaction becomes alkaline, when a precipitate of the basic calcium phosphate occurs, which carries the ptyalin along with it. This precipitate is collected on a filter, washed with water, which dissolves the ptyalin, and from its watery solution it is precipitated by alcohol as a white powder. It is redissolved in water and reprecipitated, and is obtained pure (*Cohnheim*).

(2) **Glycerine or v. Wittich's Method.**—The salivary glands [rat] are chopped up, placed in absolute alcohol for twenty-four hours, taken out and dried, and afterward placed in glycerine for several days, which extracts the ptyalin. It is precipitated by alcohol from the glycerine extract.

(3) William Roberts recommends the following solutions for extracting ferments from organs which contain them: (1) A 3 to 4 per cent. solution of a mixture of 2 parts of boracic acid and 1 part borax. (2) Water, with 12 to 15 per cent. of alcohol. (3) 1 part chloroform to 200 of water.

Diastatic Action of Saliva.—(*a*) The diastatic or sugar-forming action is known by (1) The **disappearance of the starch.** When a small quantity of starch is boiled with several hundred times its volume of water, starch mucilage is obtained, which strikes a blue color with iodine. If to a small quantity of this starch a sufficient amount of saliva be added, and the mixture kept for some time at the temperature of the body, the blue color disappears. (2) The **presence of sugar** is proved directly by using the tests for sugar (§ 149).

(*b*) The action takes place more slowly in the *cold* than at the temperature of the body—its action is enfeebled at 55° C., and destroyed at 75° C. (*Paschutin*). The most favorable temperature is 35° to 39° C.

(*c*) The ptyalin itself does not seem to be changed during its action, but ptyalin which has been used for one experiment is less active when used the second time (*Paschutin*).

Ptyalin differs from diastase—the ferment in germinating grains—in so far that the latter first begins to act at + 66° C. Ptyalin decomposes salicin into saligenin and grape sugar (*Frerichs and Städler*).

(*d*) Saliva acts best in an exactly **neutral medium**, but it also acts in an alkaline and even in a slightly acid fluid; strong acidity prevents its action. The ptyalin is only active in the stomach when the acidity is due to *organic acids* (lactic or butyric), and not when free hydrochloric acid is present (*van de Velde*). In both cases, however, dextrin is formed. Ptyalin is destroyed by hydrochloric acid or digestion by pepsin (*Chittenden and Griswold, Langley*). Even butyric and lactic acids formed from grape sugar in the stomach may prevent its action; but if the acidity be neutralized, the action is resumed (*Cl. Bernard*).

(*e*) The addition of common salt, ammonium chloride, or sodium sulphate (4 per cent. solution), *increases* the activity of the ptyalin, and CO_2, acetate of quinine, strychnia, morphia, curara, 0.025 per cent. sulphuric acid, have the same effect.

(*f*) Much alcohol and caustic potash destroy the ptyalin; long exposure to the air weakens its action; sodium carbonate and magnesium sulphate delay the action (*Pfeiffer*). Salicylic acid and much atropin arrest the formation of sugar.

(*g*) Ptyalin acts very feebly and very gradually upon **raw starch**, only after 2 to 3 hours (*Schiff*); while upon boiled starch it acts rapidly. [Hence the necessity for boiling thoroughly all starchy foods.]

(*h*) The various kinds of starch are changed more or less rapidly according to the amount of cellulose which they contain; raw potato starch after 2 to 3 hours, raw maize starch after 2 to 3 minutes (*Hammarsten*); wheat starch more quickly than that of rice. When the starches are powdered and boiled, they are changed with equal rapidity.

(*i*) A *mixture* of the saliva from all the glands is more active than the saliva from any single gland (*Jakubowitsch*), while mucin is inactive.

[**Effect of Tea.**—Tea has an intensely inhibitory effect on salivary digestion, which is due to the large quantity of tannin contained in the tea-leaf. Coffee and cocoa have only a slight effect on salivary digestion. The only way to mitigate the inhibitory effect of tea on salivary digestion is "not to sip the beverage with the meal, but to eat first and drink afterward" (*Roberts*).]

II. Saliva dissolves those substances which are soluble in water; while the alkaline reaction enables it to dissolve some substances which are not soluble in water alone, but require the presence of an alkali.

III. Saliva moistens dry food and aids the formation of the "bolus," while by its mucin it helps the act of swallowing, the mucin being given off unchanged in the fæces. The ultimate fate of ptyalin is unknown.

[IV. Saliva also aids articulation, while according to Liebig it carries down into the stomach small quantities of O.]

[V. It is necessary to the sense of taste to dissolve sapid substances, and bring them into relation with the end organs of the nerves of taste.]

Saliva has no action on proteids or on fats.

The presence of a peptone-forming ferment has recently been detected in saliva (*Hüfner*, *Munk*, *Kühne*). [Perfectly healthy human saliva has no poisonous properties.]

149. TESTS FOR SUGAR.—1. Trommer's test depends upon the fact that, in alkaline solutions, sugar acts as a **reducing agent**; in this case a metallic oxide is changed into a sub-oxide. To the fluid to be investigated, add ½ of its volume of a solution of caustic potash (soda), specific gravity 1.25, and a few drops of a weak solution of cupric sulphate, which causes at first a bluish precipitate, consisting of hydrated cupric oxide, but it is redissolved, giving a clear blue fluid, if sugar be present. Heat the upper stratum of the fluid, and a yellow or red ring of cuprous oxide is obtained, which indicates the presence of sugar; $2CuO - O = Cu_2O$.

The solution of hydrated cupric oxide is caused by other organic substances; but the final stage, or the production of cuprous oxide, is obtained only with certain sugars—grape, fruit and milk (but not cane) sugar. Fluids which are turbid must be previously filtered, and if they are highly colored, they must be treated with basic lead acetate; the lead acetate is afterward removed by the addition of sodium phosphate and subsequent filtration. If very small quantities of sugar are present along with compounds of ammonia, a yellow color instead of a yellow precipitate may be obtained. In doing the test, care must be taken not to add too much cupric sulphate.

[2. **Fehling's Solution** is an alkaline solution of potassio-tartrate of copper. Boil a small quantity of the deep-blue colored Fehling's solution in a test-tube, and add to the boiling test a few drops of the fluid supposed to contain the sugar. If sugar be present, the copper solution is reduced, giving a yellow or reddish precipitate. The reason for boiling the test itself is, that the solution is apt to decompose when kept for some time, when it is precipitated by heat alone. This is one of the best and most reliable tests for the presence of sugar. In **Pavy's** modification of this test, ammonia is used instead of a caustic alkali (§ 267).]

(3) **Böttger's Test.**—Alkaline bismuth oxide solution is best prepared, according to **Nylander**, as follows: 2 grms. bismuth subnitrate, 4 grms. potassic and sodic tartrate, 100 grms. caustic soda of 8 per cent. Add 1 c.c. to every 10 c.c. of the fluid to be investigated. When boiled for several

minutes, the sugar causes the reduction and deposits a black precipitate of metallic bismuth. [According to Salkowski, the urine of a person taking rhubarb gives the same reaction with this test.]

(4) **Moore and Heller's Test.**—Caustic potash or soda is added until the mixture is strongly alkaline; it is afterward boiled. If sugar be present, a yellow, brown, or brownish-black coloration is obtained. If nitric acid be added, the odor of burned sugar (caramel) and formic acid is obtained.

(5) **Mulder and Neubauer's Test.**—A solution of indigo-carmine, rendered alkaline with sodic carbonate, is added to the sugar solution until a slight bluish color is obtained. When the mixture is heated, the color passes into purple, red, and yellow. When shaken with atmospheric air, the fluid again becomes blue.

Molisch's Test.—To 5 c.cm. of the fluid add 2 drops of a 17 per cent. alcoholic solution of α-naphthol, or a solution of thymol. Add 1 to 2 c.cm. of concentrated sulphuric acid, and shake the mixture. The presence of sugar colors the α-naphthol mixture deep violet, the thymol deep red. The subsequent addition of water causes a precipitate of similar color, which is insoluble in concentrated hydrochloric acid. Albumin, casein and peptone give the same reaction (*Seegen*), but the deposit on the addition of water is soluble in concentrated hydrochloric acid.

Other tests are described in § 266.

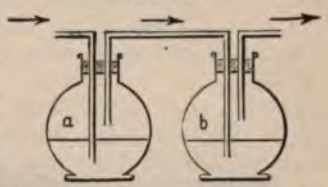
In all cases where albumin is present it must be removed—in urine by acidulating with acetic acid and boiling; in blood, by adding four times its volume of alcohol and afterward filtering, while the alcohol is expelled by heat.

150. **QUANTITATIVE ESTIMATION OF SUGAR.—I. By Fermentation.**—In the glass vessel (Fig. 161, *a*) a measured quantity (20 c.cm.) of the fluid (sugar) is placed along with some yeast, while *b* contains concentrated sulphuric acid. The whole apparatus is then weighed. When exposed to a sufficient temperature (10° to 40° C.), the sugar splits into 2 molecules of alcohol and 2 of carbon dioxide,

$$\underset{\text{Grape sugar}}{C_6H_{12}O_6} = \underset{2\text{ alcohol}}{2\,(C_2H_6O)} + \underset{2\text{ carbon dioxide}}{2\,(CO_2)},$$

and in addition there are formed traces of glycerine and succinic acid. The CO_2 escapes from *b*, and as it passes through the H_2SO_4, the CO_2 yields to the latter its water. The apparatus is weighed after two days, when the reaction is ended, and the amount of sugar is calculated from the loss of weight in the 20 c.cm. of fluid. 100 parts of water-free sugar = 48.89 parts CO_2, or 100 parts CO_2 correspond to 204.54 parts of sugar.

FIG. 161.



Apparatus for the quantitative estimation of sugar by fermentation.

II. Titration.—By means of Fehling's solution, which is made of such strength that all the copper in 10 cubic centimetres of the solution is reduced by 0.05 gramme of grape sugar (§ 267).

III. Circumpolarization.—The saccharimeter of Soleil-Ventzke may be used to determine the amount of sugar present. It may also be used for the quantitative estimation of albumin. Sugar rotates the ray of polarized light to the right and albumin to the left. The amount of rotation, or "specific rotatory power," is directly proportional to the amount of the rotating substance present in the solution, so that the amount of rotation of the ray indicates the amount of the substance present. By the term "specific rotatory power" is meant the degree of rotation which is produced by 1 grm. of the substance dissolved in 1 c.cm of water, when examined in a layer 1 decimeter thick. For yellow light the specific rotation of grape sugar is + 56°.

In Fig. 162 the light from the lamp falls upon a crystal of calc-spar. Two Nicol's prisms are placed at *v* and *s*, *v* is movable round the axis of vision, while *s* is fixed. In *m* Soleil's double plate of quartz is placed, so that one-half of it rotates the ray of polarized light as much to the right as the other rotates it to the left. In *n* the field of vision is covered by a plate of *left-rotatory* quartz. At *b c* is the *compensator*, composed of two right-rotatory prisms of quartz, which can be displaced laterally by the milled head, *g*, so that the polarized light passing through the apparatus can be made to pass through a thicker or thinner layer of quartz. When these right-rotatory prisms are placed in a certain position, the rotation of the left-rotatory quartz at *n* is exactly neutralized. In this position the scale on the compensator has its nonius exactly at *o*, and both halves of the double plate at *m* appear to have the same color to the observer, who from *v* looks through the telescope placed at *e*. Rotate the Nicol's prism at *v* until a bright rose-colored field is obtained. In this position the telescope must be so adjusted that the vertical line bounding the two halves shall be distinctly visible. The apparatus is now ready for use.

Fill a tube, 1 decimetre in length, with urine containing sugar or albumin, the urine being perfectly clear. The tube is placed between *m* and *n*. By rotating the Nicol's prisms, *v*, the rose color is again obtained. The compensator at *g* is then rotated until both halves of the field of vision

have exactly the same color. When this is obtained, read off on the scale the number of degrees the nonius is displaced to the right (sugar) or to the left (albumin) from zero. The number of degrees indicates directly the number of grammes of the rotating substance present in 100 c. c. of the fluid. If the fluid is very dark colored, it must be decolorized by filtering it through animal charcoal (*Seegen*), [or the coloring matter may be precipitated by the addition of lead acetate]. If the sugary urine contains albumin, the latter must be removed by boiling and filtration. A turbidity not removed by filtration may be got rid of by adding a drop of acetic acid or several drops of sodic carbonate or milk of lime, and afterward filtering. [One may also employ the apparatus of Mitscherlich, or the "half-shadow apparatus" of Laurent.]

FIG. 162.

Soleil-Ventzke's Polarization Apparatus.

151. MECHANISM OF THE DIGESTIVE APPARATUS.—This embraces the following acts:—

1. The introduction and mastication of the food; the movements of the tongue; insalivation; formation of the bolus of food.
2. Deglutition.
3. The movements of the stomach, small and large intestine.
4. The excretion of fecal matters.

152. INTRODUCTION OF THE FOOD.—**Fluids** are taken into the mouth in three ways: (1) By **suction**, the lips are applied air-tight to the vessel containing the fluid, while the tongue is retracted (the lower jaw being often depressed) and acts like the piston in a suction pump, thus causing the fluid to enter the mouth. Herz found that the negative pressure caused by an infant while sucking = 3 to 10 mm. Hg. (2) The fluid is **lapped** when it is brought into direct contact with the lips, and is raised by aspiration and mixed with air so as to produce a characteristic sound in the mouth. (3) Fluid may be **poured** into the mouth, and as a general rule the lips are applied closely to the vessel containing the fluid.

Solids, when they consist of small particles, are licked up with the lips, aided by the movements of the tongue. In the case of large masses, a part is bitten off with the incisor teeth, and is afterward brought under the action of the molar teeth by means of the lips, cheeks, and tongue.

153. MASTICATION.—The articulation of the jaw is provided with an interarticular cartilage—the meniscus—which prevents direct pressure being made upon the articular surface when the jaws are energetically closed, and which also divides the joint into two cavities, one lying over the other. The capsule is so lax that, in addition to the raising and depressing of the lower jaw, it permits of the lower jaw being displaced forward, whereby the meniscus moves with it, and covers the articular surface.

The **process of mastication** embraces: (*a*) The **elevation of the jaw**, accomplished by the combined action of the Temporal, Masseter, and Internal Pterygoid Muscles. If the lower jaw was previously so far depressed that its articular surface rested upon the tubercle, it now passes backward upon the articular surface.

(*b*) The **depression of the lower jaw** is caused by its own weight, aided by the action of the anterior bellies of the Digastrics, the Mylo- and Genio-hyoid and Platysma. The muscles act especially during forcible opening of the mouth. The necessary fixation of the hyoid bone is obtained through the action of the Omo- and Sterno-hyoid, and by the Sterno-thyroid and Thyro-hyoid.

When the articular surface of the lower jaw passes forward on to the tubercle, the External Pterygoids actively aid in producing this (*Bérard*).

(*c*) **Displacement of the Articular Surfaces.**—During rest, when the mouth is closed, the incisor teeth of the lower jaw are within the arch of the upper incisors. When in this position the jaw is protruded by the External Pterygoids, whereby the articular surface passes on to the tubercle (and, therefore, downward), while the lateral teeth are thereby separated from each other. The jaw is retracted by the Internal Pterygoids without any aid from the posterior fibres of the Temporals. When one articular surface is carried forward, the jaw is protruded and retracted by the External and Internal Pterygoid of the same side. At the same time, there is a transverse movement, whereby the back teeth of the protruded side are separated from each other.

During mastication, the individual movements of the lower jaw are variously combined, and especially with lateral grinding movements, while the food to be masticated is kept from passing outward by the action of the muscles of the lips (Orbicularis oris) and the Buccinators, while the tongue continually pushes the particles between the molar teeth. The energy of the muscles of mastication is regulated by the **sensibility of the teeth**, and the muscular sensibility of the muscles of mastication, as well as by the general sensibility of the mucous membrane of the mouth and lips. At the same time, the mass is mixed with saliva, the divided particles cohere, and are formed into a mass or **bolus**, of a long, oval shape, by the muscles of the tongue. The bolus then rests on the back of the tongue, ready to be swallowed.

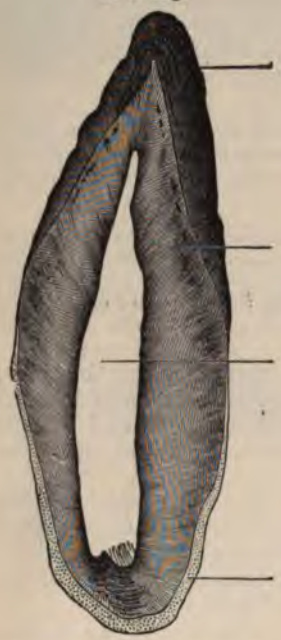
Nerves of Mastication.—The muscles of mastication receive their **motor** nerves from the third branch of the trigeminus, the mylo-hyoid and the anterior belly of the digastric being sup-

plied from the same source. The genio-, omo-, and sterno-hyoid, sterno-thyroid, and thyro-hyoid are supplied by the hypoglossal, while the facial supplies the posterior belly of the digastric, the stylo-hyoid, the platysma, the buccinator, and the muscles of the lips. The general **centre** for the muscles of mastication lies in the medulla oblongata (§ 367).

When the mouth is closed, the jaws are kept in contact by the pressure of the air, as the cavity of the mouth is rendered free from air, and the entrance of air is prevented anteriorly by the lips, and posteriorly by the soft palate. The pressure exerted by the air is from 2 to 4 mm. Hg. (*Metzger and Donders*).

[**Effect on the Circulation.**—Marey found that mastication trebled the velocity of the blood current in the carotid (horse), while François Frank observed that the circulation of the brain (in man) is increased; hence it is evident that mastication implies an increased supply of blood to the nerve centres.]

FIG. 163.



Longitudinal section of an incisor tooth.

154. STRUCTURE AND DEVELOPMENT OF THE TEETH.—A **tooth** is just a papilla of the mucous membrane of the gum, which has undergone a characteristic development. In its simplest form, as in the teeth of the lamprey, the connective-tissue basis of the papilla is covered with many layers of corneous epithelium. In human teeth, part of the papilla is transformed into a layer of calcified **dentine**, while the epithelium of the papilla produces the **enamel**, the fang of the tooth being covered by a thin accessory layer of bone, the **crusta petrosa** or **cement.**

The **dentine** or ivory which surrounds the pulp cavity and the canal of the fang (Fig. 163) is very firm, elastic, and brittle. Dentine, like the matrix of bone, when treated in a certain way, presents a fibrillar structure. It is permeated by innumerable long, tortuous, wavy tubes —the **dentinal tubules**—each of which communicates with the pulp cavity by means of a fine opening, and passes more or less horizontally outward as far as the outer layers of the dentine. The tubules are bounded by an extremely resistant, thin, cuticular membrane, which strongly resists the action of chemical reagents. These tubules are filled completely by soft fibres, the "**fibres of Tomes,**" which are merely greatly elongated and branched processes of the **odontoblasts** of the pulp.

The dentinal tubules, as well as the fibres of Tomes, anastomose throughout their entire extent by means of fine processes. As the fibres approach the enamel, which they do not penetrate, some of them bend on themselves, and form a loop (Fig. 166, *c*), while others pass into the "**interglobular spaces**" (Fig. 165) which are so abundant in the outer part of the dentine. The interglobular spaces are small spaces bounded by curved surfaces. Certain curved lines, "**Schreger's lines,**" may be detected with the naked eye in the dentine (*e. g.*, of the elephant's tusk) running parallel with the contour of the tooth. They are caused by the fact that at these parts all the chief curves in the dentinal tubules follow a similar course.

The **enamel**, the hardest substance in the body (resembling apatite), covers the crown of the teeth. It consists of hexagonal flattened prisms arranged side by side like a palisade (Fig. 166, *B* and *C*). They are 3 to 5 μ ($\frac{1}{5000}$ inch) broad, not quite uniform in thickness, curved slightly in different directions, and, owing to inequalities of thickness, they exhibit transverse markings. They are elongated, **calcified, cylindrical, epithelial cells.** Retzius described dark brown lines running parallel with the outer boundary of the enamel, due to the presence of pigment (Fig. 163). The fully-formed enamel is negatively doubly refractive and uniaxial, while the developing enamel is positively doubly refractive (*Hoppe-Seyler*).

The **cuticula** or **Nasmyth's membrane** covers the free surface of the enamel as a completely structureless membrane 1 to 2 μ thick, but in quite young teeth it exhibits an epithelial structure, and is derived from the outer epithelial layer of the enamel organ.

The **cement** or **crusta petrosa** is a thin layer of bone covering the fang (Fig. 167, *a*). The bone lacunæ communicate directly with the dental tubules of the fang. Haversian canals and lamellæ are only found where the layer of cement is thick, and the former may communicate with the pulp cavity. Very thin layers of cement may be devoid of bone corpuscles. Sharpey's fibres occur in the cement of the dog's tooth; while in the horse's tooth single bone corpuscles are developed by a capsule. In the **periodontal membrane,** which is just the periosteum of the

alveolus, coils of blood vessels similar to the renal glomeruli occur. They anastomose with each other, and are surrounded by a delicate capsule of connective tissue.

Chemistry of a Tooth.—The teeth consist of a gelatine-yielding matrix infiltrated with calcium phosphate and carbonate (like bone). (1) The **dentine** contains—organic matter, 27.70; calcium phosphate and carbonate, 72.06; magnesium phosphate, 0.75; with traces of iron, fluorine, and sulphuric acid.

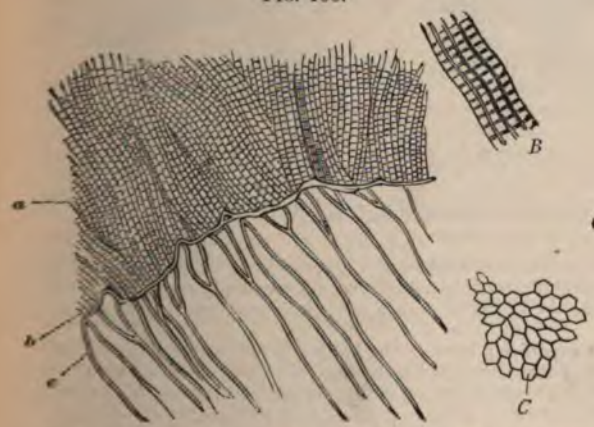
FIG. 164.

Transverse section of dentine. The light rings are the walls of the dentinal tubules; the dark centres with the light points are the fibres of Tomes lying in the tubules.

FIG. 165.

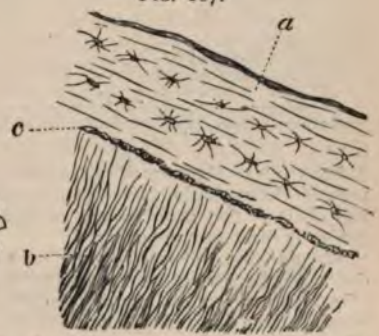
Interglobular spaces in dentine.

FIG. 166.



Section of a tooth between the dentine and enamel. *a*, enamel; *c*, dentinal tubules; *B*, enamel prisms highly magnified; *C*, transverse sections of enamel prisms.

FIG. 167.



Transverse section of the fang. *a*, cement with bone corpuscles; *b*, dentine with tubules; *c*, boundary between both.

(2) The **enamel** contains an organic proteid matrix allied to the substance of epithelium. It consists of 3.60 organic matter and 96.00 of calcium phosphate and carbonate, 1.05 magnesium phosphate, with traces of calcium fluoride and an insoluble chlorine compound.

(3) The **cement** is identical with bone.

The **pulp** in a fully-grown tooth represents the remainder of the dental papilla around which the dentine was deposited. It consists of a very vascular, indistinctly fibrillar connective tissue, laden with cells. The layers of cells, resembling epithelium, which lie in direct contact with the dentine,

are called **odontoblasts**, *i. e.*, those cells which build up the dentine. These cells send off long-branched processes into the dentinal tubules, while their nucleated bodies lie on the surface of the pulp, and form connections by processes with other cells of the pulp and with neighboring odontoblasts. Numerous non-medullated nerve fibres (sensory from the trigeminus), whose mode of termination is unknown, occur in the pulp.

The **periosteum** or **periodontal membrane** of the fang is, at the same time, the alveolar periosteum, and consists of connective tissue with elastic fibres and many nerves.

The **gums** are devoid of mucous glands, very vascular, and often provided with long vascular papillæ, which are sometimes compound.

Development of a Tooth.—It begins at the end of the second month of fœtal life. Along the whole length of the fœtal gum is a thick projecting ridge (Fig. 168, *a*) composed of many layers of epithelium. A depression, the **dental groove**, also filled with epithelium, occurs in the gum, and runs along under the ridge. The dental groove becomes deeper throughout its entire length, and on transverse section presents the appearance of a dilated flask (*b*), while at the same time it is filled with elongated epithelial cells, which form the "**enamel organ.**" A conical papilla, the "**dentine germ,**" grows up from the mucous tissue, of which the gum consists, toward the enamel organ (Fig. 169, *c*), so that the apex of the papilla comes to have the enamel organ resting upon it like a double cap. Afterward, owing to the development of connective tissue, the parts of the enamel organ lying between and uniting the individual dentine germs, disappear, and gradually the connective tissue forms a **tooth sac** enclosing the papilla and its enamel organ (*d*).

Those epithelial cells (Fig. 169, 3) of the enamel organ which lie next the top of the papilla, are cylindrical, and become calcified to form enamel prisms. The layer of cells of the double cap, which

FIG. 168. FIG. 169. FIG. 170.

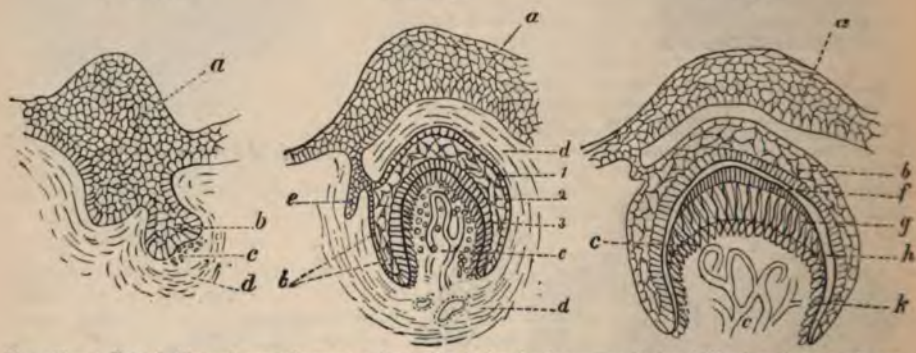


FIG. 168.—*a*, Dental ridge; *b*, enamel organ; *c*, beginning of the dentine germ; *d*, first indication of the tooth sac. FIG. 169.—*a*, Dental ridge; *b*, enamel organ with (1) outer epithelium, (2) middle stellate layer, (3) enamel prism-cell layer; *c*, dentine germ with blood vessels and the long osteoblasts on the surface; *d*, tooth sac; *e*, secondary enamel germ. FIG. 170.—*a*, Dental ridge; *b*, enamel organ; *c*, dentine germ; *f*, enamel; *g*, dentine; *h*, interval between enamel organ and the position of the tooth; *k*, layer of odontoblasts.

is directed toward the tooth sac (1), becomes flattened, fuses, undergoes a horny transformation, and becomes the **cuticula**, while the cells which lie between both layers undergo an intermediate metamorphosis, so that they come to resemble the branched stellate cells of the mucous tissue (2), and gradually disappear altogether.

The **dentine** is formed in the most superficial layer of the projecting connective tissue of the dental papilla, owing to the calcification of the continuous layer of odontoblasts which occur there (Figs. 169 and 170, *k*). During the process, fibres or branches of these cells are left unaffected, and remain as the fibres of Tomes. Exactly the same process occurs as in the formation of bone, the odontoblasts forming around themselves a calcified matrix. The **cement** is formed from the soft connective tissue of the dental alveolus.

Dentition.—During the development of the first **temporary** or **milk teeth** a special enamel organ (Fig. 169, *c*) is formed near these, but it does not undergo development until the milk teeth are shed; even the papilla is wanting at first. When the **permanent** tooth begins to develop, it opens into the alveolar wall of the milk teeth from below. The tissue of this dental sac causes erosion, or eating away of the fang and even of the body of the milk teeth, without its blood vessels undergoing atrophy. The chief agents in the absorption are the amœboid cells of the granulation tissue. [Multinuclear giant cells also erode the fangs of the teeth.]

Eruption of the Milk Teeth.—The following is the order in which the twenty milk teeth cut the gum, *i. e.*, from the seventh month to the second year: Lower central incisors, upper central incisors, upper lateral incisors, lower lateral incisors, first molar, canine, the second molars.

[The figures indicate in **months** the period of eruption of each tooth.]

Molars.	Canines.	Incisors.	Canines.	Molars.
24 12	18	9 7 7 9	18	24 12

[The **permanent teeth** succeed the milk teeth, the process beginning about the *seventh year*. Ten teeth in each jaw take the place of the milk teeth, while six teeth appear further back in each jaw. Thus the total number of permanent teeth is thirty-two. As the sacs, from which the permanent teeth are developed, are formed before birth, they merely undergo the same process of development as the temporary teeth, only at a much later period. The last of the permanent molars —the *wisdom tooth*—may not cut the jaw until the *seventeenth to the twenty-fifth year*. At the sixth year the jaw contains the largest number of teeth, as all the temporary teeth are present, and, in addition, the crowns of all the permanent teeth, except the wisdom teeth, making forty-eight in all.]

[**Eruption of Permanent Teeth.**—The age at which each tooth cuts the gum is given in **years** in the following table :—

Molars.	Bicuspid.	Canines.	Incisors.	Canines.	Bicuspid.	Molars.
17 12 to to 6 25 13	10 9	11 to 12	8 7 7 8	11 to 12	9 10	12 17 6 to to 13 25

[**Action of Drugs on the Teeth.**—All the conditions for putrefaction are present in the mouth; and when putrefaction occurs, the products (often acid) attack the dentine and hasten its decay. Hence, the necessity for thorough daily cleansing of the teeth and mouth. The teeth may be cleaned by means of a soft tooth brush and water, with or without the use of any of the numerous dentifrices, such as powdered chalk or charcoal. Astringents, such as catechu and areca-nut, are sometimes used. Mineral acids attack the teeth, and ought, when taken, to be sucked through a tube.]

155. MOVEMENTS OF THE TONGUE.—The **tongue**, being a muscular organ, and extremely mobile, plays an important part in the process of mastication: (1) It keeps the food from passing from between the molar teeth. (2) It forms into a bolus the finely divided food after it is mixed with saliva. (3) When the tongue is raised, the bolus lying on its dorsum is pushed backward into the pharynx and œsophagus.

The **course of the fibres** is threefold—*longitudinally*, from base to tip: *transversely*, the fibres for the most part proceeding outward from the vertically placed septum linguæ; *vertically*, from below upward. Some of the muscles are confined to the tongue (**intrinsic**), while others (**extrinsic**) are attached beyond it to the hyoid bone, lower jaw, the styloid process, and the palate.

Microscopically, the fibres are transversely striated, with a delicate sarcolemma, and very often they are branched where they are inserted into the mucous membrane. The muscular bundles cross each other in various directions, and in the interspaces fat cells and glands occur.

Changes in form and position :—

(1) *Shortening and broadening* by the longitudinal muscle, aided by the hyo-glossus.

(2) *Elongation and narrowing*, by the transversus linguæ.

(3) *The dorsum is rendered concave* by the transversus and the simultaneous action of the median vertical fibres.

(4) *Arching of the dorsum:* (*a*) Transversely by the lowest transverse bundles; (*b*) longitudinally, by the lowest longitudinal muscles.

(5) *Protrusion*, by the genio-glossus, while at the same time the tongue usually becomes narrower and longer (2).

(6) *Retraction*, by the hyo-glossus and stylo-glossus, and (1) usually occurring at the same time.

(7) *Depression* into the floor of the mouth, by the hyo-glossus. The floor of the mouth may be made deeper by depressing the hyoid bone.

(8) *Elevation* of the tongue toward the palate: (*a*) At the tip by the anterior part of the longitudinal fibres; (*b*) in the middle by elevating the entire hyoid bone by the mylo-hyoid (*N. trigeminus*); (*c*) at the root by the stylo-glossus and palato-glossus, as well as indirectly by the stylo-hyoid (*N. facialis*).

(9) *Lateral movements*, the tip of the tongue passing to the right or left; these are caused by the longitudinal fibres of *one* side.

Motor Nerves.—The motor nerve of the tongue is the hypoglossal. When this nerve is divided or paralyzed on one side, the tip of the tongue lying in the floor of the mouth is directed toward the sound side, because the tonus of the non-paralyzed longitudinal fibres shortens the sound side slightly. If the tongue be *protruded*, however, the tip passes toward the *paralyzed* side. This arises from the direction of the genio-glossus (from the middle downward and outward), and the tongue follows the direction of its action. The tongues of animals which have been killed exhibit fibrillar contractions of the muscles, sometimes lasting for a whole day. [Stirling has frequently found nerve ganglia in the nerves of the tongue.]

156. DEGLUTITION.—The onward movements of the contents of the digestive canal are effected by a special kind of action whereby the tube or canal contracts upon its contents, and as this contraction proceeds along the tube, the contents are thereby carried along. This is the "**peristaltic movement**," or peristalsis.

In the first and most complicated part of the act of deglutition, we distinguish in order the following individual movements:—

(1) The aperture of the mouth is closed by the orbicularis oris (*N. facialis*).

(2) The jaws are pressed against each other by the muscles of mastication (*N. trigeminus*), while at the same time the lower jaw affords a fixed point for the action of the muscles attached to it and the hyoid bone.

(3) The tip, middle, and root of the tongue, one after the other, are pressed against the hard palate, whereby the contents of the mouth are propelled toward the pharynx.

(4) When the bolus has passed the anterior palatine arch (the mucus of the tonsillar glands making it slippery again), it is prevented from returning to the mouth by the palato-glossi muscles which lie in the anterior pillars of the fauces, coming together like two side screens or curtains, meeting the raised dorsum of the tongue (Stylo-glossus).

(5) The morsel is now behind the anterior palatine arch and the root of the tongue, and has reached the pharynx, where it is subjected to the successive action of the three pharyngeal constrictor muscles which propel it onward. The action of the superior constrictor of the pharynx is always combined with a horizontal elevation (Levator veli palatini; *N. facialis*) and tension (Tensor veli palatini; *N. trigeminus, otic ganglion*) of the soft palate. The upper constrictor presses (through the pterygo-pharyngeus) the posterior and lateral walls of the pharynx tightly against the posterior margin of the horizontal, tense, soft palate, whereby the margins of the posterior palatine arches (palato-pharyngeus) are approximated. The pharyngo-nasal cavity is thus completely shut off, so that the bolus cannot be pressed backward into the nasal cavity.

In persons with congenital or acquired defects of the soft palate, or **cleft-palate**, during swallowing, food passes into the nose.

(6) Falk and Kronecker assert that, by the energetic contraction of the muscles which diminish the cavity of the mouth, especially the mylo-hyoid, the bolus is "projected" through the pharynx and œsophagus. [They even assert that the bolus reaches the cardia before even the musculature of the pharynx or œsophagus can contract, and further that the pharyngeal muscles of a dog may be divided

without making swallowing impossible.] If we make a series of efforts to swallow, one after the other, as in drinking, contraction of the pharynx and œsophagus takes place only after the *last* effort. Thus each new act of deglutition in the mouth inhibits (by stimulation of the glosso-pharyngeal nerve) the movements in the parts of the œsophageal tube situated below it.

(7) The bolus is propelled onward by the successive contraction of the upper, middle, and lower constrictors of the pharynx until it passes into the œsophagus. At the same time the entrance to the glottis is closed, else the morsel would pass into the larynx, or, as is generally said, would "pass the wrong way."

Duration.—According to Meltzer and Kronecker, the duration of deglutition in the mouth is 0.3 sec.; then the constrictors of the pharynx contract 0.9 sec.; afterward, the upper part of the œsophagus; then after 1.8 sec. the middle; and after another 3 sec. the lower constrictor. The closure of the cardia, after the entrance of the bolus into the stomach, is the final act in the total series of movements.

Sounds during Deglutition.—If the region of the stomach be auscultated during the act of swallowing, two sounds may be heard; the first one is produced when the bolus is projected into the stomach; the second occurs when the peristalsis, which takes place at the end of swallowing, squeezes the contents of the œsophagus through the cardia (*Meltzer, Zenker, Ewald*). [The latter occurs 4–5 mins. afterward. In man, when water alone is swallowed, there is no sound, but when it is mixed with air there is, and it is generally heard because air is usually swallowed with the food or drink (*Quincke*).]

The **closure of the glottis** is effected in the following manner: (*a*) The whole larynx—the lower jaw being fixed—is raised *upward and forward*, while at the same time the root of the tongue hangs over it. The hyoid bone is raised forward and upward by the genio-hyoid, anterior belly of the digastric, and mylo-hyoid; the larynx is approximated close to the hyoid bone by the thyro-hyoid. (*b*) When the larynx is raised, so that it comes to lie below the overhanging root of the tongue, the epiglottis is pressed downward over the entrance to the glottis, and the bolus passes over it. The epiglottis is also pulled down by the special muscular fibres of the reflector epiglottidis and aryepiglotticus. (*c*) The closure of the glottis by the constrictors of the larynx also prevents the entrance of substances into the larynx (§ 313, II, 2).

Injury to the Epiglottis.—Intentional injury of the epiglottis in animals, or its destruction in man, may cause fluids to "go the wrong way," *i. e.*, into the glottis, while solid food can be swallowed without disturbance. In dogs, colored fluids placed on the root of the tongue have been observed to pass directly into the pharynx without coming into contact with it, so as to tinge the upper surface of the epiglottis (*Magendie*). [The basis of the epiglottis is yellow elastic cartilage, so that it shows no tendency to ossify, and always retains its elasticity (§ 313).]

In order that the descending bolus may be prevented from carrying the pharynx with it, the stylo-pharyngeus, salpingo-pharyngeus, and baseo-pharyngeus contract upward when the constrictors act.

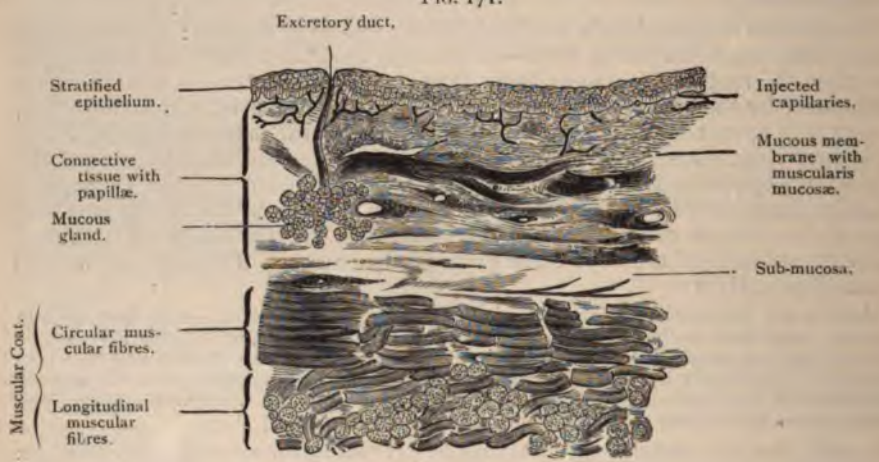
Nervous Mechanism.—Deglutition is **voluntary** only during the time the bolus is in the mouth. When the food passes through the palatine arch into the gullet the act becomes **involuntary**, and is, in fact, a well-regulated reflex action. When there is no bolus to be swallowed, voluntary movements of deglutition can be accomplished only within the mouth; the pharynx only takes up the movement, provided a bolus (food or saliva) mechanically excites the reflex act. The **afferent** nerves, which, when mechanically stimulated, excite the involuntary act of deglutition, are, the palatine branches of the trigeminus (from the spheno-palatine ganglion) and the pharyngeal branches of the vagus. The **centre** for the nerves concerned (for the striped muscles) lies in the superior olives of the medulla oblongata. Swallowing can be carried out when a person is unconscious, or after destruction of the cerebrum, cerebellum, and pons (§ 367, 6). [Even in the deep coma of alcoholism, the tube of a stomach pump is carried into the stomach reflexly, provided the surgeon passes it back into the pharynx.] The nerves of the pharynx are derived from the **pharyngeal plexus**, which receives branches from the vagus, glosso-pharyngeal and sympathetic (§ 352, 4).

Within the **œsophagus**, whose stratified epithelium is moistened with the mucus derived from the mucous glands in its walls, the downward movement is involuntary, and depends upon a complicated reflex movement discharged from the centre for deglutition. There is a peristaltic movement of the outer longitudinal and inner circular non-striped muscular fibres.

In the upper part of the œsophagus, which contains striped muscular fibres, the peristalsis takes place more quickly than in the lower part. The movements of the œsophagus never occur independently, but are always the continuation of a foregoing act of deglutition. If food be introduced into the œsophagus through a hole in its wall, there it lies; and it is only carried downward when a movement to swallow is made. The peristalsis extends along the whole length of the œsophagus, even when it is ligatured or when a part of it is removed (*Mosso*). If a dog be allowed to swallow a piece of flesh tied to a string, so that the flesh goes half-way down the œsophagus, and if the flesh be withdrawn, the peristalsis still passes downward (*C. Ludwig and Wild*).

The **motor nerve of the œsophagus** is the vagus (not the accessory fibres) [œsophageal, whose branches have numerous small ganglia in their course]. After it is divided, the food lodges in the lower part of the œsophagus. Very large and very small masses are swallowed with more difficulty than those of moderate size. Dogs can swallow an olive-shaped body weighted with a counterpoise of 450 grammes (*Mosso*). When the thorax is greatly distended, as in Müller's experiment, or greatly diminished, as in Valsalva's experiment (§ 60), deglutition is rendered more difficult.

FIG. 171.



Transverse section of part of the œsophagus.

Goltz's Experiments.—The œsophagus and stomach of the frog become more excitable, *i. e.*, the excitability of the ganglionic plexuses in their walls is increased, when the brain and spinal cord or both vagi are destroyed. These organs contract energetically after slight stimulation, while frogs, whose central nervous system is intact, swallow fluids simply by peristalsis. Females, and sometimes men also, suffering from hysteria, not unfrequently have similar spasmodic contractions of the œsophageal region (globus hystericus). After section of both vagi in the dog, Schiff observed spasmodic contraction of the œsophagus.

Effect on Circulation.—Every time one swallows, the heart's action is accelerated, the blood pressure falls, the necessity for respiration diminishes, while many movements (labor pains, erection) are inhibited. These effects are brought about reflexly (*Kronecker and Meltzer*, § 369).

[**Structure of the Œsophagus.**—The walls of the œsophagus are composed of **four coats**—mucous, sub-mucous, muscular, and fibrous (Fig. 171).

(1) The **mucous coat** is firm, and is thrown into longitudinal folds, which disappear when the tube is distended. It is lined by several layers of **stratified squamous epithelium.** The membrane itself is composed, especially at its inner part, of dense fibrous tissue, which projects, in the form of **papillæ**, into the stratified epithelium. The papillæ are present in the child, but are largest in old people. At its outer part is a continuous longitudinal layer of non-striped muscle, the **muscularis mucosæ.** The layer consists of small bundles of non-striped muscle separate from each other.

(2) The **sub-mucous coat** is thicker than the foregoing, and consists of loose connective tissue, with the acini of small mucous glands imbedded in it. The ducts pierce the muscularis mucosæ to open on the inner surface of the tube.

(3) The **muscular coat** consists of an *inner*, thicker, circular, and an *outer*, thinner, longitudinal layer of non-striped muscle, commencing on a level with the cricoid cartilage. In man the upper third of the gullet consists of striped muscular fibres. (4) Outside the muscular coat is a layer of **fibrous tissue** with elastic fibres. The structure of the muscular coat of the œsophagus varies much in different animals. In the rabbit, in the first quarter of its length, it has two layers, but below this there are three layers, *i. e.*, a circular between an outer and an inner longitudinal layer, while the non-striped fibres are confined to the lowest quarter of the tube.]

[**Nerve Plexuses.**—As in the intestine, there are two plexuses of nerves with ganglia; one in the sub-mucous coat (*Meissner's*) and the other between the two muscular coats (*Auerbach's*), which are continuous with those in the stomach and intestine. Blood vessels and numerous lymphatics lie in the mucous and sub-mucous coats.]

157. MOVEMENTS OF THE STOMACH.—Position.—When the stomach is empty, the great curvature is directed downward and the lesser upward; but when the organ is full, it rotates on an axis running horizontally through the pylorus and cardia, so that the great curvature appears to be directed to the front and the lesser backward.

Arrangement of the Muscular Fibres.—The non-striped muscular fibres of the stomach are arranged in three directions or layers, an outer **longitudinal** continuous with those of the œsophagus. This layer is best developed along the curvatures, especially the lesser. At the pylorus the fibres form a thick layer, and become continuous with the longitudinal fibres of the duodenum. The **circular** fibres form a complete layer; at the pylorus they are more numerous, and constitute the sphincter muscle or **pyloric valve**; while at the cardia (inlet), such a muscular ring is absent. The innermost **oblique** or diagonal layer is complete.

The Movements of the Stomach are of two kinds—(1) The **rotatory** or **churning** movements, whereby the parts of the wall of the stomach in contact with the contents glide to and fro with a slow rubbing movement. Such movements seem to occur periodically, every period lasting several minutes (*Beaumont*). By these movements the contents are moistened with the gastric juice, while the masses of food are partly broken down. The formation of hair balls in the stomach of dogs and oxen indicates that such rotatory movements of the contents of the stomach take place. (2) The other kind of movement consists in a periodically occurring **peristalsis**, whereby, as with a push, the first dissolved portions of the contents of the stomach are forced into the duodenum. They begin after a quarter of an hour, and recur until about five hours after a meal. This peristalsis is most pronounced toward the pyloric end, and the muscles of the pyloric sphincter relax to allow the contents to pass into the duodenum. According to Rüdinger, the longitudinal muscular fibres, when they contract, especially when the pyloric end is filled, may act so as to dilate the pylorus.

Gizzard.—The strongly muscular walls of the stomach of grain-eating birds effect a trituration of the food. The older physiologists found that glass balls and lead tubes, which could be compressed only by a weight of 40 kilos, were broken or compressed in the stomach of a turkey.

Influence of Nerves.—[The stomach is supplied by the vagi and by the sympathetic, the right vagus being distributed to the posterior surface, and the left to the anterior surface, of the organs.] **Auerbach's ganglionic plexus** of nerve fibres and nerve cells, which lies between the muscular coats of the stomach, must be regarded as its proper motor centre, and to it motor impulses are conducted by the vagi. **Section of both vagi** does not abolish, but it diminishes the movements of the stomach. The muscular fibres of the cardia may be excited to action, or their action inhibited by fibres which run in the vagus (Nn. constrictores, et dilatator cardiæ). [If the vagi be divided in the neck, there is a short temporary spasmodic contraction of the cardiac aperture. On stimulating the peripheral end of the vagus with electricity, after a latent period of a few seconds, the cardiac end contracts, more especially if the stomach be distended, but the movements are slight if the stomach be empty. In curarized dogs, the

pylorus contracts with varying intensity, and irregularly whether the vagi and splanchnics be intact or divided. Stimulation of the vagi in the neck causes contraction of the pylorus, when the latent period may be seven seconds. Stimulation of the splanchnics in the thorax arrests the spontaneous pyloric contractions, the left splanchnic being more active than the right (*Oser*).]

Local electrical stimulation of the surface of the stomach causes circular constrictions of the organ, which disappear very gradually, while the movement is often propagated to other parts of the gastric wall. When heated to 25° C., the excised empty stomach exhibits movements. Injury to the pedunculi cerebri, optic thalamus, medulla oblongata, and even to the cervical part of the spinal cord, according to Schiff, causes paralysis of the vessels of certain areas of the stomach, resulting in congestion and subsequent hemorrhage into the mucous membrane. [It is no uncommon occurrence to find hemorrhage into the gastric mucous membrane of rabbits, after they have been killed by a violent blow on the head.]

[**Action of Drugs.**—The *automatic centres are* excited by emetin, apomorphin, tartar emetic, while muscarin causes general contraction of the stomach. The activity of the automatic centres is diminished by chloral, urethan, morphin, and nicotin, while atropin causes paralysis of the nerve endings (*E. Schütz*).]

158. VOMITING.—Mechanism.—Vomiting is caused by contraction of the walls of the stomach, the pyloric sphincter being closed. It occurs most readily when the stomach is distended—(dogs usually greatly distend the stomach by swallowing air before they vomit); it readily occurs in infants, in whom the cul-de-sac at the cardia is not developed. It is quite certain that in children vomiting occurs through contraction of the walls of the stomach, without the spasmodic action of the abdominal walls. When vomiting is violent, the abdominal muscles act energetically. [The act of vomiting is generally preceded by a feeling of nausea, and usually there is a rush of saliva into the mouth, caused by a reflex stimulation of afferent fibres in the gastric branches of the vagus, the efferent nerve for the secretion of saliva being the chorda tympani. After this a deep inspiration is taken and the glottis closed, so that the diaphragm is firmly pressed downward against the abdominal contents, and it is kept contracted; the lower ribs are pulled in. The diaphragm being kept contracted and the glottis closed, a violent expiratory effort is made, so that the contraction of the abdominal muscles acts upon the abdominal contents, the stomach being forcibly compressed. The cardiac orifice is opened at the same time, and the contents of the stomach are ejected. The chief agent seems to be the abdominal compression, but the walls of the stomach also help, though only to a slight extent.]

The contraction of the walls of the stomach, which causes a general diminution of the gastric cavity, is not a true anti-peristalsis, as can be seen in the stomach when it is exposed. The *cardia is opened* by the longitudinal muscular fibres, which pull toward the lower orifice of the œsophagus, so that when the stomach is full they must act as dilators. The act of vomiting is preceded by a ructus-like dilating movement of the intra-thoracic part of the œsophagus, which is caused thus: The glottis is closed, inspiration occurs suddenly and violently, whereby the œsophagus is distended by gases proceding from the stomach. The larynx and hyoid bone, by the combined action of the genio-hyoid, sterno-hyoid, sterno-thyroid, and thyro-hyoid muscles, are forcibly pulled forward, so that the air passes from the pharynx downward into the upper section of the œsophagus. If the abdominal walls contract suddenly, and if this sudden impulse be aided by the movements of the stomach itself, the contents of the stomach are forced outward. During continued vomiting, anti-peristalsis of the duodenum may occur, whereby bile passes into the stomach, and becomes mixed with its contents.

Children, in whom the fundus is absent, vomit more easily than adults. [In them also the nervous system is more excitable.]

Influence of Nerves.—The **centre** for the movements concerned in vomiting lies in the medulla oblongata, and is in relation with the respiratory centre, as is shown by the fact that nausea may be overcome by rapid and deep respirations. In animals, vomiting may be inhibited by vigorous artificial respiration. On the other hand, the administration of certain emetics prevents the occurrence of apnœa.

In vomiting, the **afferent** impulses may be discharged from (1) the mucous

membrane of the soft palate, pharynx, root of the tongue (*glosso-pharyngeal nerve*), as in tickling the fauces with the finger; (2) the nerves of the stomach (*vagus* and *sympathetic*); (3) stimulation of the uterine nerves (pregnancy); (4) the *mesenteric* nerves (inflammation of the abdomen and hernia); (5) nerves of the urinary apparatus (passing a renal calculus); (6) nerves to the liver and gall duct (*vagus*); (7) nerves to the lungs in phthisis (*vagus*). Vomiting is also produced by *direct* stimulation of the vomiting centre. [The **efferent** impulses are carried by the phrenics (diaphragm), vagus (œsophagus and stomach), and intercostals (abdominal muscles).]

Vomiting, produced by the thought of something disagreeable, appears to be caused by the conduction of the excitement from the cerebrum to the vomiting centre. [It may also be excited through the *brain* by a disagreeable smell, shocking sight, or by other impressions on the nerves of special sense.] Vomiting is very common in diseases of the brain [tubercle, inflammation, hemorrhage]. Section of both vagi generally, but not always, prevents vomiting.

Emetics act (1) partly by mechanically or chemically stimulating the ends of the centripetal (afferent) nerves of the mucous membrane. [These are *local* emetics.] Tickling the fauces, touching the surface of the exposed stomach (dog); and many chemical emetics, *e.g.*, mustard, cupric and zinc sulphate, and other metallic salts, act in this way. (2) Other substances cause vomiting when they are introduced into the blood (without being first introduced into the stomach), and act directly upon the vomiting centre, *e.g.*, apomorphin. [These are *general* emetics.] (3) Lastly, there are some substances which act in both ways, *e.g.*, tartar emetic. Emetics may also remove mucus from the lungs, and in this case it is probable that the emetic acts upon the respiratory centre, and so favors the respirations. The *general* emetics usually create considerable depression, while the vomiting lasts longer than with local emetics. The former increase the salivary, gastric, and respiratory secretions.

[**Uses of Emetics.**—Emetics are useful not only for removing from the stomach any offending body, be it a poison or the products of imperfect or perverted gastric digestion, or bile which has passed back into the stomach, but foreign bodies impacted in the œsophagus may be got rid of on exciting vomiting by the subcutaneous injection of apomorphin. As the diaphragm contracts vigorously during vomiting, it compresses the liver, and thus bile is expelled into the duodenum, or the passage of a small calculus along the bile duct may be aided. They also are useful in removing mucus or false membranes from the respiratory passages.]

[**Anti-Emetics.**—Vomiting may be allayed by *local* anti-emetics, such as ice, and many chemical substances, such as bismuth, hydrocyanic acid, opium, and morphia, as well as by *general* remedies which act on the vomiting centre. Some of the foregoing drugs perhaps act both locally and generally.]

Vomiting is analogous to the process of **rumination** in animals that chew the cud (§ 187). Some persons can empty their stomach in this way.

159. MOVEMENTS OF THE INTESTINE.—Peristalsis.—The best example of peristaltic movements is afforded by the small intestine; the progressive narrowing of the tube proceeds from above downward, thus propelling the contents before it. Frequently after death, or when air acts freely upon the gut, the peristalsis develops at various parts of the intestine simultaneously, whereby the loops of intestine present the appearance of a heap of worms creeping among each other. The advance of new intestinal contents again increases the movement. In the large intestine, the movements are more sluggish and less extensive. The peristaltic movements may be seen and felt when the abdominal walls are very thin, and also in hernial sacs. They are more lively in vegetable feeders than in carnivora. The peristalsis is perhaps conducted directly through the muscular substance itself, as in the heart and ureter. The movements of the stomach and intestine cease during sleep (*Busch*).

[**Rate of Motion.**—In a Thiry-Velly fistula (§ 183, II) Fubini estimated the rate of motion of a smooth sphere of sealing wax. It took 55 sec. to travel 1 ctm. [½ in.]; an induction current greatly increases the motion, to 1 ctm. in 10 seconds; NaCl does not affect it, but excites secretion; laudanum paralyzes it.]

Method of Observation.—Open the abdomen of an animal under a .6 per cent. saline solution to prevent the exposure of the gut to air (*Sanders and Braam-Houckgeest*).

The **ileo-colic valve**, as a rule, prevents the contents of the large intestine from passing backward into the small intestine.

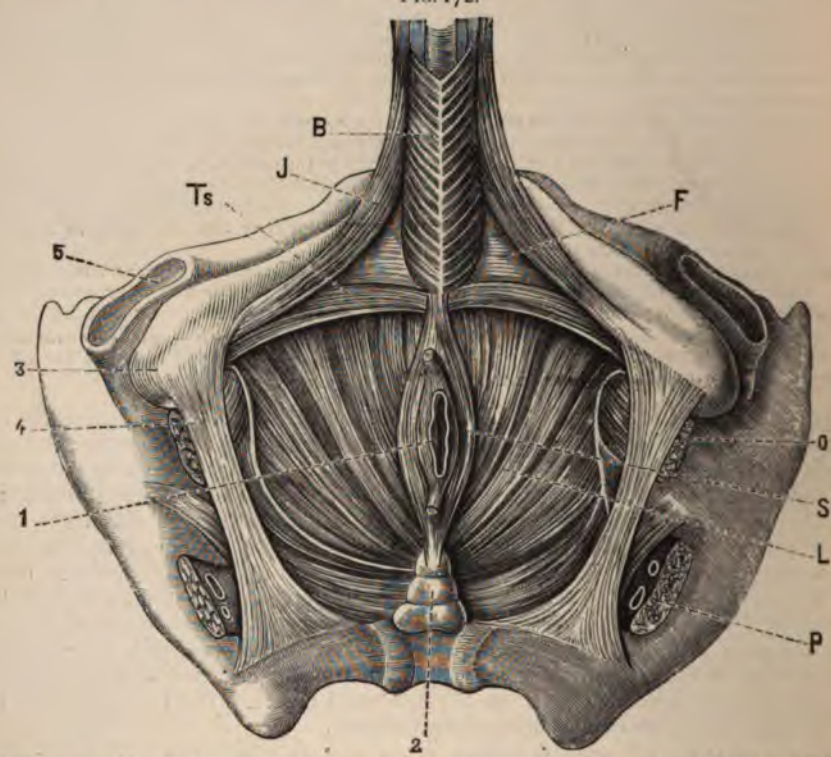
When fluid is slowly introduced into the rectum through a tube, it passes upward into the intestine, and even goes through the ileo-colic valve into the small intestine. Muscarin excites very lively peristalsis of the intestines, which may be set aside by atropin (*Schmiedeberg and Koppe*).

Pathological.—When any condition excites an acute inflammation of the intestinal mucous membrane, catarrh is rapidly produced, and very strong contractions of the inflamed parts filled with food take place. When these parts of the gut become empty, the movements are not stronger than normal. If new material passes into the inflamed part, the peristalsis recurs, becomes more lively than normal, and the result is diarrhœa (*Nothnagel*). Sometimes a greatly contracted part of the small intestine is pushed into the piece of gut directly continuous with it, giving rise to **invagination** or intussusception.

Anti-peristalsis, *i. e.*, a movement which travels in an upward direction toward the stomach, does not occur normally. This has been inferred from the fact, that in cases where the intestine is occluded, called ileus, fecal matter is vomited. Nothnagel's experiments throw doubts upon this view, as he failed to observe anti-peristalsis in cases where the intestine was occluded artificially. The fecal odor of the ejecta may result from the prolonged retention of the material within the small intestine.

160. EXCRETION OF FECAL MATTER.—The contents of the small intestine remain in it about three hours, and about twelve hours in the large intestine, where they become less watery, and they assume the characters of fæces,

FIG. 172.

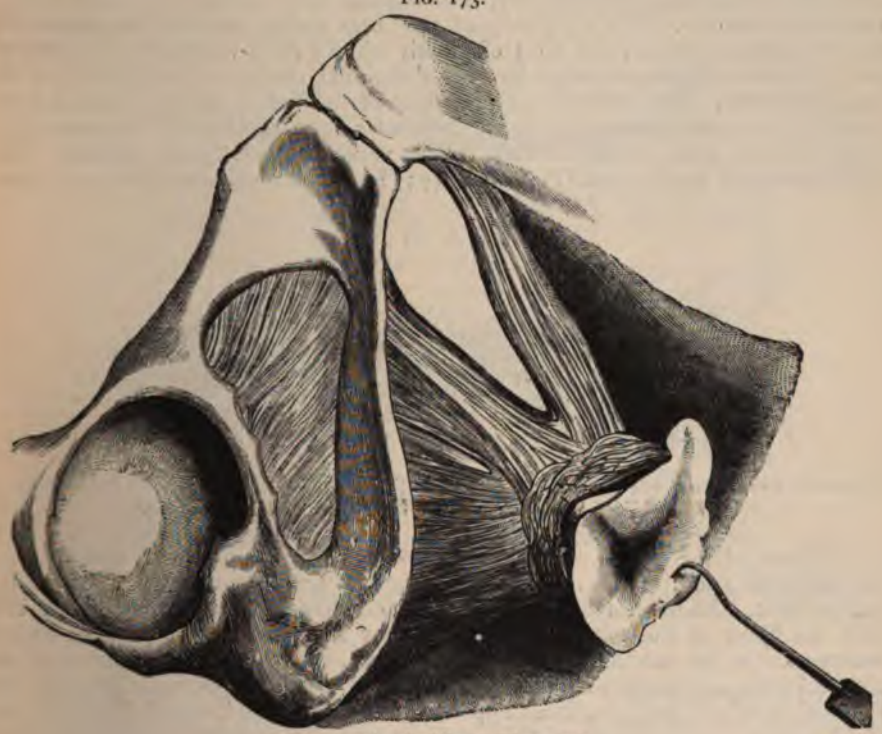


The perinæum and its muscles. 1, anus; 2, coccyx; 3, tuberosity; 4, sciatic ligament; 5, cotyloid cavity; B, bu... cavernosus muscle; Ts, superficial transverse perineal muscle; F, fascia of the deep transverse perineal mus... J, ischio-cavernosus muscle; M, obturator internus; S, external anal sphincter; L, levator ani; P, pyriform...

become "formed" in the lower part of the great intestine. The fæces are gr... ually carried along by the peristaltic movement, until they reach a point a li... above that part of the rectum which is surrounded by both sphincters, the inter... sphincter consisting of non-striped, and the external of striped muscle.

Immediately after the expulsion of the fæces the external sphincter (Fig. 172, S, and Fig. 173) usually contracts vigorously, and remains so for some time. Afterward it relaxes, when the elasticity of the parts surrounding the anal opening, particularly of the two sphincters, suffices to keep the anus closed. In the interval between two evacuations, there does not seem to be a continued tonic contraction of the sphincters. As long as the fæces lie above the rectum, they do not excite any conscious sensations, but the sensation of requiring to go to stool occurs when the fæces pass into the rectum. At the same time, the stimulation of the sensory nerves of the rectum causes a reflex excitement of the sphincters. The centre for these movements (Budge's centrum ano-spinale) lies in the lumbar region of the spinal cord (§ 362); in the rabbit between the sixth and seventh, and in the dog at the fifth lumbar vertebra (*Masius*).

FIG. 173.



Levator ani and sphincter ani externus.

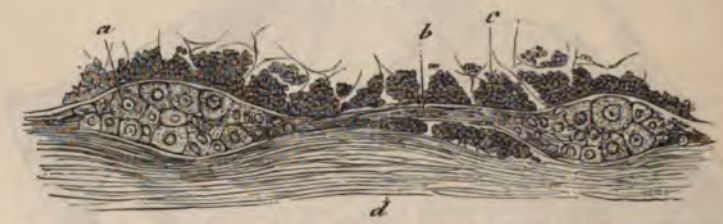
In animals whose spinal cord is divided above the centre, a slight touch in the region of the anus causes this orifice to contract, but after this lively reflex contraction, the sphincters relax again, and the anus may remain open for a time. This occurs because the voluntary impulses which proceed from the brain to cause the contraction of the external sphincter are absent. Landois observed that in dogs with the posterior roots of their lower lumbar and sacral nerves divided, the anus remained open, and not unfrequently a mass of fæces remained half ejected. As the sensibility of the rectum and anus was abolished in these animals, the sphincters could not contract reflexly, nor could there be any voluntary contraction of the sphincters, the result of sensory impulses from the rectum.

The external sphincter can be contracted *voluntarily*, like any voluntary muscle, but the closure of the anus can only be effected up to a certain degree. When the pressure from above is very great, the energetic peristalsis at last overcomes the strongest voluntary impulses. Stimulation of the peduncles of the cerebrum

and of the spinal cord below this point causes contraction of the external sphincter.

Defecation.—The evacuation of the fæces, which in man usually occurs at certain times, begins with a lively peristalsis of the large intestine, which passes downward to the rectum. In order that the mass of fæces may not excite reflexly the sphincter muscles, in consequence of mechanical stimulation of the sensory nerves of the rectum, there seems to be a centre which **inhibits** the reflex action of the sphincters, which is called into play, owing, as it appears, to voluntary impulses. Its seat is in the brain, perhaps in the optic thalami. When this inhibitory apparatus is in action, the fecal mass passes through the anus, without causing it to close reflexely. The strong peristalsis which precedes defecation can be aided, and to a certain degree excited, by rapid voluntary movements of the external sphincter and levator ani, whereby the plexus myentericus of the large intestine is stimulated mechanically, thus causing lively peristaltic movements in the large intestine. The expulsion of the fæces is also aided by the pressure of the abdominal muscles, and most efficiently when a deep respiration is taken, so as to fix the diaphragm, whereby the abdominal cavity is diminished to the greatest extent. The soft parts of the floor of the pelvis, during a strong effort at stool, are driven downward in the form of a cone, causing the mucous membrane of the anus, which contains much venous blood, to be everted. The function of the levator ani (Figs. 172, 173) is to raise voluntarily the soft parts

FIG. 174.



Auerbach's plexus shown in section (human). *a*, ganglionic cells; *b*, nerve fibres; *c*, section of the circular muscular fibres; *d*, longitudinal muscular fibres.

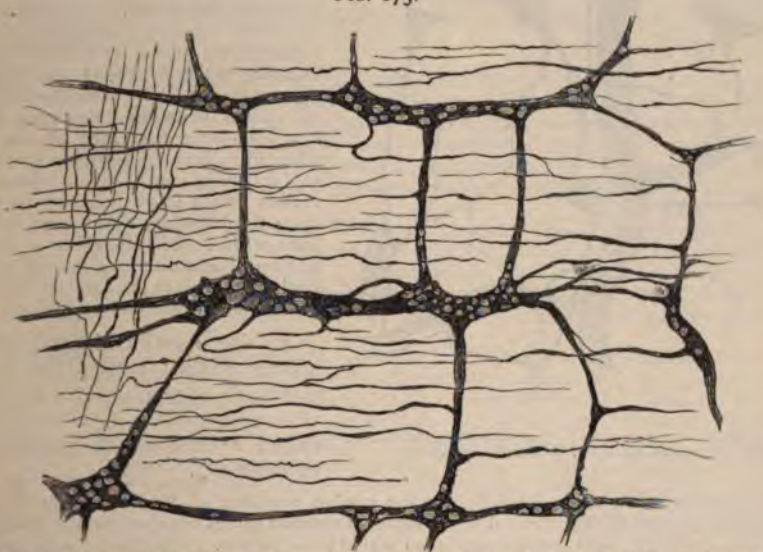
of the floor of the pelvis, and to pull the anus to a certain extent upward over the descending fecal mass. At the same time, it prevents the distention of the pelvic fascia. As the fibres of both levatores converge below, and become united with the fibres of the external sphincter, they aid the latter, during energetic contraction of the sphincter; or, as Hyrtl put it, the levatores are related to the anus, like the two cords of a tobacco pouch. During the periods between the evacuation of the gut, the fæces appear only to reach the lower end of the sigmoid flexure. As a rule, from thence downward, the rectum is normally devoid of fæces. It seems that the strong circular fibres of the muscular coat, which Nélaton has called sphincter ani tertius, when they are well developed, contract and prevent the entrance of the fæces. When the tendency to the evacuation of the rectum is very pressing, the anus may be closed more firmly from without, by energetically rotating the thigh outward, and contracting the muscles of the gluteal region.

161. CONDITIONS INFLUENCING THE INTESTINAL MOVEMENTS.—The intestinal canal contains an *automatic motor centre* within its walls—the **plexus myentericus** of **Auerbach**—which lies between the longitudinal and circular muscular fibres of the gut. It is this plexus which enables the intestine, when cut out of the body, to execute, apparently spontaneously, movements for some time.

[**Structure.—Auerbach's Plexus** consists of non-medullated nerve fibres which form a dense network, groups of ganglion cells occurring at the nodes (Fig. 175, and when seen in vertical sections between the muscular coats it is like Fig. 174). A similar plexus extends throughout the whole intestine between the longitudinal and circular muscular coats from the œsophagus to the rectum. Branches are given off to the muscular bundles. A similar, but not so rich a plexus lies in the submucous coat, **Meissner's plexus**, which gives branches to supply the muscularis mucosæ, the smooth muscular fibres of the villi, and the glands of the intestine (Fig. 176).

1. If this centre is not affected by any stimulus, the movements of the intestine cease—comparable to the condition of the medulla oblongata in apnœa. The same is true—just as in the case of the respiration—during intra-uterine life, in consequence of the fœtal blood being well supplied with O. This condition may be termed **aperistalsis.** It also occurs during sleep, perhaps on account of the greater amount of O in the blood during that state.

FIG. 175.



Plexus of Auerbach, prepared from the small intestine of a dog, by the action of gold chloride. The nerve cells are shown at the nodes, while the fibrils proceeding from the ganglia, and the anastomosing fibres, lie between the muscular bundles.

2. When blood containing the normal amount of blood gases passes through the intestinal blood vessels, the quiet peristaltic movements of health occur (**euperistalsis**) provided no other stimulus be applied to the intestine.

3. All stimuli applied to the plexus myentericus increase the peristalsis, which may become so very violent as to cause evacuation of the contents of the large gut, and may even produce spasmodic contraction of the musculature of the intestine. This condition may be termed **dysperistalsis,** corresponding to dyspnœa. The *condition of the blood* flowing through the intestinal vessels affects the peristalsis.

Condition of the Blood.—Dysperistalsis may be produced by (*a*) interrupting the circulation of the blood in the intestines, no matter whether anæmia (as after compressing the aorta—*Schiff*) or venous hyperæmia be produced. The stimulating condition is the want of O, *i. e.*, the increase of CO_2. Very slight disturbance in the intestinal blood vessels, *e. g.*, venous congestion after copious transfusion into the veins, whereby the abdominal and portal veins become congested, causes

increased peristalsis. The intestines become nodulated at one part and narrow at another, and involuntary evacuation of the fæces takes place when there is congestion, owing to the plugging of the intestinal blood vessels when blood from another species of animal is used for transfusion (§ 102). The marked peristalsis which occurs on the approach of death is undoubtedly due to the derangements of the circulation, and the consequent alteration of the amount of gases in the blood of the intestine. The same is true of the increased movements of the intestines which occur as a result of psychical excitement, *e. g.*, grief. The stimulus, in this case, passes from the cerebrum through the medulla oblongata (vasomotor centre) to the intestinal nerves, and causes anæmia of the intestine (corresponding to the pallor occurring elsewhere). When the normal condition of the circulation is restored, the peristalsis diminishes. (*b*) Direct stimulation of the intestine, conducted to the plexus myentericus, causes *dysperistalsis*; direct exposure of the intestines to the air (stronger when CO_2 or Cl is present)—introduction of various irritating substances into the intestine—increased filling of the intestine when there is any difficulty in emptying the gut (often in man)—direct stimulation of various kinds (also inflammation)—all act upon the intestine, either from without or from within. Induction shocks applied to a loop of intestine in a hernial sac cause lively peristalsis in the hernia. The intestinal movements are favored by heat.

FIG. 176.

Plexus of Meissner. *a*, ganglia; *b*, anastomosing fibres; *c*, artery; *d*, vasomotor nerve fibres accompanying *c*.

4. The continued application of strong stimuli causes the dysperistalsis to give place to rest, owing to over-stimulation, which may be called "**intestinal paresis**," or exhaustion.

This condition is absolutely different from the passive condition of the intestine in aperistalsis. Continued congestion of the intestinal blood vessels ultimately causes intestinal paralysis, *e. g.*, when transfusion of foreign blood causes coagulation within these vessels. Filling the blood vessels with "indifferent" fluids, after the peristalsis has been previously brought about by compressing the aorta, also causes cessation of the movements (*O. Nasse*). The movements cease when the intestines are cooled to 19° C. (*Horwath*), while severe inflammation of the intestine has a similar effect. Under favorable circumstances, the intestine may recover from this condition. Arterial blood admitted into the vessels of the exhausted intestine causes peristalsis, which at first is more vigorous than normal.

5. The continued application of strong stimuli causes **complete paralysis** of the intestine, such as occurs after violent peritonitis, or inflammation of the musculature or mucous coat in man. In this condition, the intestine is greatly distended, as the paralyzed musculature does not offer sufficient resistance to the intestinal gases which are expanded by the heat. This constitutes the condition of **meteorism.**

Influence of Nerves.—With regard to the nerves of the intestine, stimulation of the **vagus** increases the movements (of the small intestine), either by conducting impressions to the plexus myentericus, or by causing contraction of the stomach, which stimulates the intestine in a purely mechannical manner (*Braam-Houckgeest*). The **splanchnic** is (1) the *inhibitory* nerve of the small intestine (*Pflüger*), but only as long as the circulation in the intestinal blood-vessels is undisturbed, and the blood in the capillaries does not become venous; when the latter

condition occurs, stimulation of the splanchnic increases the peristalsis. If arterial blood be freely supplied, the inhibitory action continues for some time. Stimulation of the origin of the splanchnics, of the spinal cord in the dorsal region (under the same conditions), and even when general tetanus has been produced by the administration of strychnia, causes an inhibitory effect. It is inferred that the splanchnic contains (2) inhibitory fibres, which are easily exhausted by a venous condition of the blood, and also *motor fibres*, which remain excitable for a longer time, because after death stimulation of the splanchnics always causes peristalsis, just like stimulation of the vagus. (3) It is the *vasomotor nerve* of the intestinal blood vessels, so that it governs the largest vascular area in the body. When it is stimulated, all the vessels of the intestine which contain muscular fibres in their walls contract; when it is divided, they dilate. In the latter case, a large amount of blood accumulates within the blood vessels of the abdomen, so that there is anæmia of the other parts of the body, which may be so great as to cause death—owing to the deficient supply of blood to the medulla oblongata. (4) It is the *sensory nerve* of the intestine, and, under certain circumstances, it may give rise to very painful sensations.

As stimulation of the splanchnic contracts the blood vessels, von Basch has raised the question whether the intestine does not come to rest, owing to the want of the blood, which acts as a stimulus. But when a weak stimulus is applied to the splanchnic, the intestine ceases to move before the blood vessels contract (*van Braam-Houckgeest*); it would therefore seem that the stimulation diminishes the excitability of the plexus myentericus. According to Engelmann and v. Brakel, the peristaltic movement is chiefly propagated by direct muscular conduction, as in the heart and ureter, without the intervention of any nerve fibres.

[**Effect of Nerves on the Rectum.**—The nervi erigentes, when stimulated, cause the longitudinal muscular fibres of the rectum to contract, while the circular muscular fibres are supplied by the hyposgastric nerves. Stimulation of the latter nerves also exerts an inhibitory effect on the longitudinal muscles. Stimulation of the nervi erigentes inhibits not only the spontaneous movements of the circular fibres of the rectum, but also those movements excited by stimulation of the hypogastric nerves (*Fellner*).]

[**Artificial Circulation in the Intestine.**—Ludwig and Salvioli excised a loop of intestine from an animal, tied a cannula into an artery and another into a vein, and kept it in a warm moist atmosphere. The arterial cannula was connected with a vessel containing defibrinated blood, to which different drugs could be added. A lever rested on the intestine, and registered its movements on a recording surface. As long as arterial blood was transfused, the intestine was nearly quiescent, but when it was arrested, so that the blood became *venous*, a series of contractions occurred. *Nicotin* diminished the flow of blood and quickened the intestinal movements, while at the same time the circular muscular fibres remained contracted or tetanic. *Tincture of opium*, in the proportion of .01 to .04 in the blood, causes at first contraction of the vessels, and lessens the amount of blood circulating in the intestine; but it very rapidly increases—even to six times—the amount of blood which transfuses, while at the same time the movements of the intestine cease, the walls of the intestine being contracted. *Peptone* caused first strong and then irregular contractions.]

Effect of Drugs.—Among the reagents which act upon the intestinal movements are: (1) Such as diminish the excitability of the plexus myentericus, *i. e.*, which lessen or even abolish intestinal peristalsis, *e. g.*, belladonna. (2) Such as stimulate the inhibitory fibres of the splanchnic, and in large doses paralyze them—opium, morphia; 1 and 2 produce constipation. (3) Other agents excite the motor apparatus—nicotin (even causing spasm of the intestine), muscarin, caffein, and many laxatives, which act as purgatives. The movements produced by muscarin are abolished by atropin. These substances accelerate the evacuation of the intestine, and, owing to the rapid movement of the intestinal contents, only a small amount of water is absorbed; so that the evacuations are frequently fluid. (4) Among *purgatives*, colocynth and croton oil act as direct irritants. With regard to drugs of this sort, they seem to cause a watery transudation into the intestine, just as croton oil causes vesicles when applied to the skin. (5) Calomel is said to limit the absorptive activity of the intestinal wall, and to control the decompositions in the intestine. The stools are thin and greenish, from the admixture of biliverdin. (6) Certain saline purgatives—sodium sulphate, magnesium sulphate—cause fluid evacuations by retaining the water in the intestine; and it is said that if they be injected into the blood vessels of animals, they cause constipation. [When a crystal of a *potash salt* is applied to the peritoneal surface of the intestine of an animal, it causes merely a local constriction of the muscular fibres of the gut, while a *sodium salt* excites a contraction which passes upward toward the stomach, and never toward the rectum. In any case it may serve as a useful guide to the surgeon, in determining which is the upper end of a piece of intestine during an operation on the intestines (*Nothnagel*).]

[**Saline Cathartics.**—A salt exerts a genuine excito-secretory action on the glands of the intestines, while at the same time, in virtue of its low diffusibility, it impedes absorption. Thus, between stimulated secretion and impeded absorption there is an accumulation of fluid within the canal, which reaches the rectum and results in purgation. Purgation does not ensue when water is withheld from the diet for one or two days previous to the administration of the salt in a concentrated form. When a concentrated solution of a salt is administered to an animal whose alimentary canal is empty, but whose blood is in a natural state of dilution, the blood becomes rapidly very concentrated, and reaches the maximum of its concentration in from half an hour to an hour and a half; within four hours the blood has gradually returned to its normal state of concentration, without having reabsorbed fluid from the intestine. It apparently recoups itself from the tissue fluids. The salt—sulphate of magnesia or sulphate of soda—becomes split up in the small intestine, and the acid is more rapidly absorbed than the base A portion of the absorbed acid shortly afterward returns to the intestines, evidently through the intestinal glands. The salt does not purge when injected into the blood, and excites no intestinal secretion; nor does it purge when injected subcutaneously, unless on account of its causing local irritation of the abdominal subcutaneous tissue, which acts reflexly on the intestines, dilating their blood vessels, and perhaps stimulating their muscular movements. (*M. Hay*).

162. STRUCTURE OF THE STOMACH.—[The stomach receives the bolus, and secretes a juice which acts on certain constituents of the food, while by its muscular walls it moves the latter within its own cavity, and after a time expels the partially digested products toward the duodenum.]

FIG. 177.

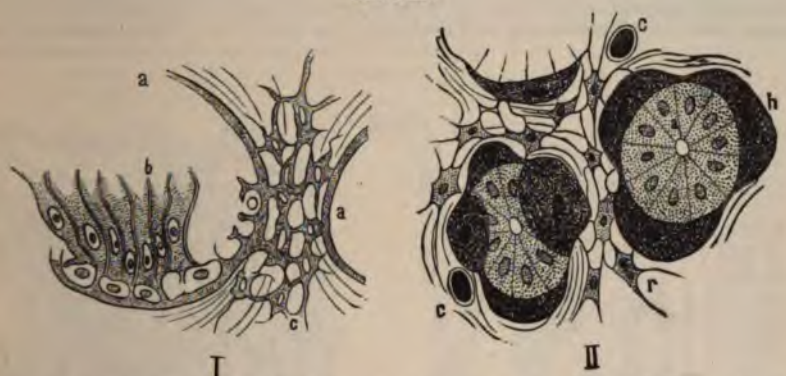
Structure.—[The walls of the stomach consist of **four coats**, which are from without inward (Fig. 177)—

(1) The **serous layer**, from the peritoneum.
(2) The **muscular layer**, composed of three layers of non-striped muscular fibres—(*a*) longitudinal, (*b*) circular, (*c*) oblique (§ 15).
(3) The **sub-mucous layer** of loose connective tissue, with the larger blood vessels, lymphatics, and nerves.
(4) The **mucous layer**.]

The well-developed **mucous membrane** of the stomach is thrown into a series of folds or **rugæ**, in a contracted condition of the organ. With the aid of a hand lens, it is seen to be beset with small irregular depressions or *pits* (Fig. 179). Throughout its entire extent it is covered by a single layer of moderately tall, narrow, **cylindrical epithelium**, which seems to consist of **mucous-secreting goblet cells** (Fig. 178). The epithelium is sharply defined at the cardia from the stratified epithelium of the œsophagus, and also at the pylorus, from the true cylindrical epithelium with the striated disk in the duodenum. [The cells contain a plexus of fibrils, and in the passive condition seem to consist of two zones, an outer clear part, next the lumen of the organ, consisting of a substance (mucigen) which yields mucus, the attached end of the cell being granular.] The oval nucleus lies about the centre of the cells. Spindle-shaped, nucleated cells, probably for replacing the others, are said by Ebstein to occur at their bases. All the cells are open at their free ends, so that the mucus is readily discharged, leaving the cells empty. Numerous **tubular glands** of *two* distinct kinds are placed vertically, like rows of test-tubes, in the mucous membrane.

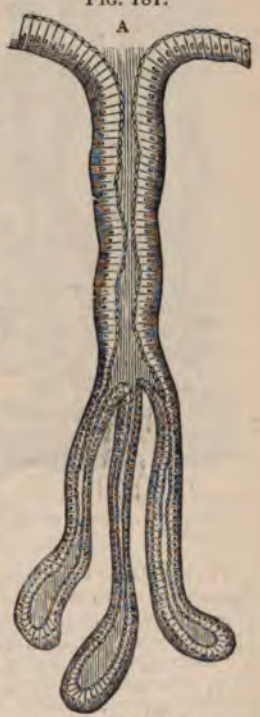
FIG. 180.



I. Transverse section of a duct of a fundus gland—*a*, membrana propria; *b*, mucous-secreting goblet cells; *c*, adenoid interstitial substance. II. Transverse section of a fundus gland—*a*, chief, *h*, parietal cells; *r*, adenoid tissue; *c*, capillaries.

The **cardiac portion** of the gastric mucous membrane consists of a number of microscopic tubular glands placed side by side, the **fundus glands** of Heidenhain, otherwise called peptic, or cardiac. Several gland tubes, which are wider below, usually open into the duct (Fig. 182). Each gland consists of a structureless membrana propria with anastomosing branched cells in relation with it. The **duct** is short, about one-fifth of the whole tube, and is lined by a layer of cells like those lining the stomach, while the **secretory part** of the tubes is lined throughout by a layer of granular, short, small, polyhedral, or columnar nucleated cells. These cells border the very narrow lumen, and are called **principal** (*Heidenhain*), **central** (Fig. 180, II, *a*), or **adelomorphous cells** (ἀδηλος, hidden). At various places, between these cells and the membrana propria, are large, oval, or angular, well-defined, granular, densely reticulated, nucleated cells, the **parietal** cells of Heidenhain, the **delomorphous** cells of Rollett, or the **oxyntic** (acid-forming) cells of Langley (Fig. 180, II, *h*). They are most numerous in the neck of the glands, and least so in the deep blind end of the tubes. These cells are stained deeply by osmic acid and aniline blue, so that they are readily distinguished from the other cells. They bulge out the membrana propria of the gland opposite where they are placed. The parietal cells in man are said to reach to the lumen of the gland tubes (*Stöhr*). Isolated cells are sometimes found under the epithelium of the surface of the stomach, and occasionally in individual pyloric glands. The fundus glands are most numerous (about five millions), and are of considerable size in the fundus.

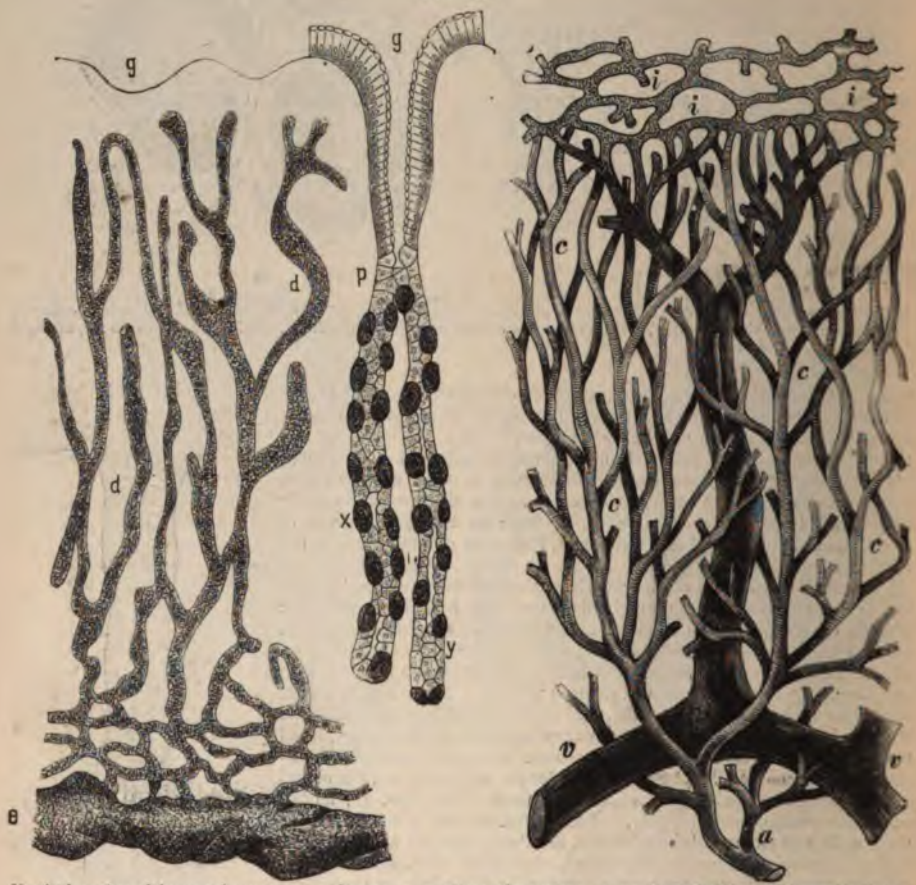
FIG. 181.



A, Isolated pyloric gland.

2. The **pyloric glands** occur only in the region of the pylorus, where the mucous membrane is more yellowish-white in color (Fig. 181, A). These glands are generally branched at their lower ends, so that several tubes open into a single duct [which, in contradistinction to the duct of the other glands, is wide and long, extending often to half the depth of the mucous membrane. The **duct** is lined by epithelium like that lining the stomach, while the **secretory part** is lined by a single layer of short, finely granular, columnar cells, whose secretion is quite different from that of the cells lining the duct. The lumen is well defined. Nussbaum has occasionally found other cells, which stain deeply with osmic acid, between the base of these. The appearance of the cells differs according to their state of physiological activity (Figs. 183, 184). When they are exhausted they are smaller and more granular, owing to the denser reticulation of their network; at any rate they are granular in preparations hardened in alcohol (Fig. 184). There are no parietal cells.]

FIG. 182.



Vertical section of the gastric mucous membrane. *g*, *g*, pits on the surface; *p*, neck of a fundus gland opening into a duct, *g*; *x*, parietal, and *y*, chief cells; *a*, *v*, *c*, artery, vein, capillaries; *d*, *d*, lymphatics, emptying into a large trunk, *e*.

The glands are supported by very delicate connective tissue mixed with adenoid tissue (Fig. 180). Below this are two layers, circular and longitudinal, of non-striped muscle, the **muscularis mucosæ** (Fig. 177, Mm.), and from it fine processes of smooth muscular fibres pass up between groups of the glands toward the free epithelial surface of the mucous membrane. Perhaps these processes are concerned in emptying the glands. [In the gastric mucous membrane of the cat there is a clear, homogeneous layer, which is stained red by picro-carmine, and placed immediately internal to the muscularis mucosæ. It is pierced by the processes passing from the muscularis mucosæ.]

Masses of **adenoid tissue** occur in the mucous membrane, especially near the pylorus, constituting **lymph follicles**, which are comparable to the solitary glands of the small intestine. **The lymphatics** are numerous, and begin close under the epithelium by dilated extremities or loops (Fig. 182, *d'*); they run vertically, and anastomose in the mucosa between the gland tubes, which they envelop in sinus-like spaces. They join large trunks in the mucosa; another plexus of large vessels exists in the sub-mucosa (*Lovén*).

[**The Nerves.**—A plexus of non-medullated nerve fibres and a few ganglion cells exist in the muscular coat [**Auerbach's**], and another [**Meissner's**] in the sub-mucosa.]

The blood vessels are very numerous. Small arterial branches, *a*, run in the sub-mucosa, and ascend between the glands to form a longitudinal capillary network, *c*,*c*, under the epithelium, and between its meshes the gland-ducts open, *g*. The veins gradually collect from this horizontal capillary network, and run toward the large veins of the sub-mucosa, *v*.

FIG. 183.

163. THE GASTRIC JUICE.—Properties.—The gastric juice is a tolerably clear, colorless fluid, with a strong **acid** reaction, sour taste, and peculiar characteristic odor; it rotates the plane of polarized light to the left. It is not rendered turbid by boiling, and resists putrefaction for a long time. Its specific gravity = 1002.5 (dog, 1005), and it contains only ½ per cent. of solid constituents. The **quantity** secreted in 24 hours was estimated by Beaumont, from observations upon Alexis St. Martin, who had a gastric fistula (1834)—at only 180 grms. daily (!); by Grunewald (1853), in a similar case, as equal to 26.4 per cent. of the body weight; while Bidder and Schmidt (from correspond-

ing observations on dogs) estimated it as equal to 6½ kilos. daily, corresponding to $\frac{1}{10}$ of the body weight. It contains:—

(1) **Pepsin**, the characteristic hydrolytic ferment or enzym, which dissolves proteids. E. Schütz obtained 0.41 to 1.17 per cent. from a fasting person by means of the œsophageal sound.

(2) **Free hydrochloric acid** (*Prout*, 1824), 0.2 to 0.3 (*Richet*, 0.8 to 2.1) per 1000; (in the dog, 0.52 per cent.). It occurs *free*, as the gastric juice always contains more free chlorine than bases, to which it can be united (*C. Schmidt*). Lactic acid is usually met with, but it arises from the fermentation of the carbohydrates of the food.

Tests.—Free hydrochloric acid is detected by the following reactions: 0.025 per cent. solution of **methyl-violet** becomes blue; or alkaline solution of **oo-tropæolin** becomes lilac; or, red Bordeaux wine, treated with amylic alcohol until its color *almost* disappears, becomes rose colored. [Günzburg recommends an alcoholic solution of **phloroglucin-vanillin.** 2 grammes of phloroglucin are mixed with 1 gramme of vanillin in 30 grammes of absolute alcohol, which gives a yellowish-red solution. Concentrated and even very weak mineral acids cause, with this solution, a bright red color with the formation of bright red crystals, while concentrated organic acids do not affect it. For gastric juice mix equal quantities of the filtered gastric juice and the above solution in a watch glass, and evaporate carefully, not allowing it to boil; a red pellicle with red crystals indicates the presence of minute traces of hydrochloric acid. **Congo red**, either in solution or as congo-red papers, becomes blue, but the reaction is interfered with by the presence of ammonia, or ammoniacal salts.]

Lactic Acid.—The freshly prepared blue solution of 10 c. c. of a 4 per cent. solution of carbolic acid, with 20 c. c. of distilled water, and 1 drop of liquor ferri perchloride, is changed to *yellow* by lactic acid (*Uffelmann*).

(3) The large amount of **mucus** covering the surface of the mucous membrane is secreted by the goblet cells of the mucous membrane (§ 162), (§ 136, II).

(4) **Mineral salts** (2 per 1000), and **a milk-curdling ferment.**

They are chiefly sodium and potassium chlorides, less calcic chloride (ammonium chloride, also in animals), and the compounds of phosphoric acid with lime, magnesium and iron.

Among foreign substances, which may be introduced into the body, the following appear in the gastric juice—HI, after the use of potassium iodide—potassium sulphocyanide, ferric lactate, and sugar; and ammonium carbonate in uræmia.

Good human saliva is not so dilute or so poor in HCl as I. Szabo has found even 3 of HCl per 1000 in man.]

164. SECRETION OF GASTRIC JUICE.—After the discovery of the two kinds of glands in the stomach and the two kinds of cells in the fundus glands, the question arose as to whether the different constituents of gastric juice were formed by different histological elements.

Changes of the Cells during Digestion.—During the course of digestion, the cells of the fundus (and pyloric glands, dog) undergo important changes (*Heidenhain*). During hunger, the

chief cells are *clear* and large, the parietal investing cells are small, the pyloric cells *clear* and of moderate size. During the first six hours of digestion, the chief cells become *enlarged* and moderately turbid or granular, the parietal cells also *enlarge*, while the pyloric cells remain unchanged. The chief cells become *diminished* and more turbid or granular until the ninth hour, the parietal cells are still swollen, and the pyloric cells enlarge. During the last hours of digestion, the chief cells again become larger and clearer, the parietal cells diminish, the pyloric cells decrease in size and become turbid (Figs. 183 and 184).

[Langley gives a different description of the appearances presented by these cells. The results may be reconciled by remembering that the gland cells were examined under different conditions. The secretory cells consist of a cell substance composed of (*a*) a framework of living protoplasm, either in the form of an intracellular fibrillar network, or in flattened bands. The meshes of this framework enclose at least two chemical substances, viz., (*b*) a hyaline substance in contact with the framework, and (*c*) spherical granules which are embedded in the hyaline substance. During active secretion, the granules decrease in number and size, the hyaline substance increases in amount, the network grows. This is the reverse of what is stated above as the observation of Heidenhain, but the granular appearance described by Heidenhain after secretion is very probably due to the action of the hardening agent, alcohol. Langley found that in the living condition, or after the use of osmic acid, in some animals at least, the chief cells are granular during rest, but during a state of activity two zones are differentiated, an outer one, which is clear, owing to the disappearance of the granules, and an inner more or less granular one. Granules reappear in the outer part after rest. During digestion, the parietal cells increase in size, but do not become granular. In all cells containing much pepsinogen, distinct granules are present, and the quantity of pepsinogen varies directly with the number and size of the granules. In the glands of some animals there is little difference between the resting and active phases. Compare *Serous Glands*, § 143, and *Pancreas*, § 168.]

The **pepsin** is formed in the chief cells (*Heidenhain*). When these are clear and large, they contain much pepsin; when they are contracted and turbid, the amount is small. The pyloric glands are also said to secrete pepsin, but only to a small extent. Pepsin accumulates during the first stage of hunger, and it is eliminated during digestion and also during prolonged hunger. Pepsin, *as such*, is not present within the cells, but only as a "mother substance," a **pepsinogen substance** (**zymogen**), or **pro-pepsin**, which occurs in the granules of the chief cells. This zymogen, or mother substance, by itself, has no effect upon proteids; but if it be treated with hydrochloric acid or sodium chloride, it is changed into pepsin. Pepsin and pepsinogen may be extracted from the gastric mucous membrane by means of water free from acids.

[**Pepsinogen and Pepsin.**—Glycerine extracts very little pepsin from the perfectly fresh gastric mucous membrane, but a large amount is afterward obtained by extracting it with dilute hydrochloric acid, or with this acid and glycerine. The relative amount of pepsinogen and pepsin in a fluid may be determined approximately by the method of Langley and Edkins. A 1 per cent. solution of sodic carbonate exerts a greater destructive action on pepsin than on pepsinogen, while a current of CO_2 destroys pepsinogen to a greater extent than pepsin. Both substances are unaffected by CO, but are destroyed at 54° to 57° C.]

The pyloric glands secrete pepsin, but no acid. Klemensiewicz excised in a living dog the pyloric portion of the stomach, and afterward stitched together the duodenum and the remaining part of the stomach. The excised pyloric part, with its vessels intact, he stitched to the abdominal wall, after sewing its lower end. The animals experimented on died, at the latest, after six days. The secretion of this part was thin, *alkaline*, and contained 2 per cent. of solids, including *pepsin*.

FIG. 185.

Diagram of Klemensiewicz's experiment (*Stirling*)

[**Pyloric Fistula.**—In Fig. 185 P represents the excised pyloric portion, C the cardiac. The parts *a*, *a*, and *a' a'* were then stitched together, and the continuity of the organ established. The lower end (*d'*) of P was closed by sutures, while the edges of P at O were stitched to the abdominal walls, thus making a pyloric fistula.]

In the **frog** the alkaline glands of the œsophagus contain only chief cells which

produce pepsin; while the stomach has glands which secrete acid (and perhaps some pepsin), and are lined by parietal cells.

Among fishes the carps have no fundus glands in the stomach (*Luchau*). [The secreting portions of glands of the cardiac sac (crop) of the herring are lined by a *single* layer of polygonal cells (*W. Stirling*).]

The **hydrochloric acid** is formed, according to Heidenhain, by the parietal cells. It occurs on the free surface of the gastric mucous membrane as well as in the ducts of the fundus glands. The deep parts of the glands are usually alkaline. Free HCl is detected in human gastric juice, within 45 minutes to 1 to 2 hours after a moderate meal, but in 10 to 15 minutes in a fasting condition after drinking water; the amount gradually increases during the process of digestion. Lactic acid, perhaps derived from the food, is found in the stomach immediately after taking food, after half an hour along with HCl, while after an hour only HCl is found (*Ewald and Boas*).

Cl. Bernard injected potassium ferrocyanide and afterward lactate of iron into the veins of a dog. After death, blue coloration occurred only in the *upper acid* layers of the mucous membrane. Nevertheless, we must assume that the hydrochloric acid is secreted in the parietal cells of the fundus of the glands, and that it is rapidly carried to the surface along with the pepsin. Brücke neutralized the surface of the gastric mucous membrane with magnesia usta, chopped up the mucous membrane with water, and left it for some time, when the fluid had again an acid reaction.

As to the **formation of a free acid**, the following statements may be noted: The parietal cells form the hydrochloric acid from the chlorides which the mucous membrane takes up from the blood. According to Voit, the formation of acid ceases, if chlorides be withheld from the food. Maly suggests that the active agent is lactic acid, which splits up sodium chloride and forms free HCl. The base set free is excreted by the urine, rendering it at the same time less acid. The formation of acid is arrested during hunger. According to H. Shultz, watery solutions of alkaline and earthy chlorides are decomposed, even at a low temperature, by CO_2, free hydrochloric acid being formed.

[The source of the HCl is undoubtedly the sodic chloride in the blood and lymph, but what other acid displaces the HCl is a matter of conjecture. In this connection, it is important to remember that Jul. Thomsen has shown that every acid can displace a part of another acid from its combination with its base, and the weaker acid may even combine with the greater part of the base. Thomsen calls this "**avidity.**" Even strong mineral acids may be displaced by weak organic ones. Thus the free CO_2 in the alkaline blood may set free a small quantity of HCl from the sodic chloride. What is still more remarkable is, that the free HCl should be transferred by the cells toward the gland duct, while the sodic carbonate diffuses toward the blood and lymph.]

Secretion.—When the stomach is **empty**, there is usually no secretion of gastric juice; this takes place only after appropriate (mechanical, thermal, or chemical) stimulation. In the normal condition, it takes place immediately on the introduction of food, but also of indigestible substances, such as pebbles. The mucous membrane becomes red, and the circulation more active, so that the venous blood becomes brighter. [That the vagi are concerned in this vascular dilatation, is proved by the fact, that if both nerves be divided during digestion, the gastric mucous membrane becomes pale (*Rutherford*).] The secretion is probably caused reflexly, and the centre perhaps lies in the wall of the stomach itself (Meissner's plexus in the submucous coat). It is asserted that the idea of food, especially during hunger, excites secretion. As yet we do not know the effect produced upon the secretion by stimulation or destruction of other nerves, *e.g.*, vagus, sympathetic. [There is no nerve passing to the stomach, whose stimulation causes a secretion of gastric juice, as the chorda tympani does in the sub-maxillary gland. If the vagi be divided sufficiently low down not to interfere with respiration, the introduction of food still causes a secretion of gastric juice; even if the sympathetic branches be divided at the same time, secretion still goes on (*Heidenhain*). This experiment points to the existence of local secretory centres in the stomach. But there is evidence to show that there is some connection, perhaps indirect, between

the central nervous system and the gastric glands. Richet observed a case of complete occlusion of the œsophagus in a woman, produced by swallowing a caustic alkali. A gastric fistula was made, through which the person could be nourished. On placing sugar or lemon juice in the person's mouth, Richet observed a secretion of gastric juice. In this case no saliva could be swallowed to excite secretion, so that it must have taken place through some nervous channels. Even the sight or smell of food caused secretion. Emotional states also are known to interfere with gastric digestion.]

Effect of Absorption.—Heidenhain isolated a part of the mucous membrane of the *fundus* so as to form a blind sac of it, and he found that mechanical stimulation caused merely a scanty *local* secretion at the spots irritated. If, however, at the same time, absorption of digested matter also occurred, secretion took place over larger surfaces. [He distinguishes a primary and merely local secretion excited by the mechanical stimulus of the ingesta, and a secondary depending on absorption, and extending to the whole of the mucous membrane.]

The statement of Schiff, that active gastric juice is secreted only after absorption of the so-called **peptogenic substances** (especially dextrin), is denied.

The acid contents of the stomach called **chyme**, which pass into the duodenum after gastric digestion is completed, are *neutralized* by the alkali of the intestinal mucous membrane and the pancreatic juice [at the same time, a precipitate is formed and deposited on the walls of the duodenum, and it carries the pepsin down with it]. Part of the pepsin is reabsorbed as such, and is found in traces in the urine and muscle juice (*Brücke*). If the gastric juice be completely discharged externally through a gastric fistula, the alkalinity of the intestine is so strong that the urine becomes alkaline (*Maly*).

The acid gastric juice of the **new-born child** is already fairly active; casein is most easily digested by it, then fibrin and the other proteids (*Zweifel*). When the amount of acid is too great in the stomach of sucklings, large, firm, indigestible masses of casein are apt to be formed, especially after the use of cow's milk (§ 230).

[**Action of Drugs on Gastric Secretion.**—Dilute alkalies, if given before food; saliva; some substances called peptogens by Schiff, such as dextrin and peptones, alcohol and ether, all excite secretion, the last being very powerful. When the secretion is excessively acid, *antacids* are given, some diminishing the acidity in the stomach, as the carbonates and bicarbonates of the alkalies, liquor potassæ, and the carbonate of magnesia; while the citrates and tartrates of the alkalies, becoming converted into carbonates in their passage through the organism, diminish the acidity of the urine.] Small doses of **alcohol**, introduced into the stomach, increase the secretion of gastric juice; large doses arrest it. Artificial digestion is affected by 10 per cent. of alcohol, is retarded by 20 per cent., and is arrested by stronger doses. Beer and wine hinder digestion, and in an undiluted form interfere with artificial digestion.

165. METHODS OF OBTAINING GASTRIC JUICE.—Historical.—Spallanzani caused starving animals to swallow small pieces of sponge enclosed in perforated lead capsules, and after a time, when the sponges had become saturated with gastric juice, he removed them from the stomach. To avoid the admixture of saliva, the sponges are best introduced through an opening in the œsophagus. Dr. Beaumont (1825), an American physician, was the first to obtain human gastric juice, from a Canadian named Alexis St. Martin, who was injured by a gunshot wound, whereby a permanent gastric fistula was established. Various substances were introduced through the external opening, which was partially covered with a fold of skin, and the time required for their solution was noted. Bassow (1842), Blondlot (1843), and Bardeleben (1849), were thereby led to make artificial gastric fistulæ.

Gastric Fistula.—The anterior abdominal wall is opened by a median incision just below the ensiform cartilage, the stomach is exposed, and its anterior wall opened and afterward stitched to the margins of the abdominal walls. A strong cannula is placed in the fistula thus formed. The tube is kept corked. If the ducts of the salivary glands be tied, a perfectly uncomplicated object for investigation is obtained.

According to Leube, dilute human gastric juice may be obtained by means of a siphon-like tube introduced into the stomach. Water is introduced first, and after a time it is withdrawn.

An important advance was made when Eberle (1834) prepared **artificial gastric juice**, by extracting the pepsin from the gastric mucous membrane with dilute hydrochloric acid. Four litres of solution of hydrochloric acid, containing 4 to 8 c.c. HCl per 1000, are sufficient to extract the

chopped-up mucous membrane of a pig's stomach. Half a litre is infused with the stomach and renewed every six hours. The collected fluid is afterward filtered. The substance to be digested is placed in this fluid, and the whole is kept at the temperature of the body, but it is necessary to add a little HCl from time to time (*Schwann*). The HCl may be replaced by ten times its volume of lactic acid and also by nitric acid; while oxalic, sulphuric, phosphoric, acetic, formic, succinic, tartaric, and citric acids are much less active; butyric and salicyclic acids are inactive.

Von Wittich's Method.—(*a*) **Glycerine** extracts pepsin in a very pure form. The mucous membrane is rubbed up with powdered glass until it forms a pulp, mixed with glycerine, and allowed to stand for eight days. The fluid is pressed through cloth, and the filtrate mixed with alcohol, thus precipitating the pepsin, which is washed with alcohol and afterward dissolved in the dilute HCl, to form an artificial digestive fluid. (*b*) Or the mucous membrane may be placed for twenty-four hours in alcohol, and afterward dried and extracted for eight days with glycerine. (*c*) Wm. Roberts has used other agents for extracting enzymes (§ 148).

Preparation of Pure Pepsin.—Brücke pours on the pounded mucous membrane of the pig's stomach a 5 per cent. solution of phosphoric acid, and afterward adds lime-water until the acid reaction is scarcely distinguishable. A copious precipitate, which carries the pepsin with it, is produced. This precipitate is collected on cloth, repeatedly washed with water, and afterward dissolved in very dilute HCl. A copious precipitation is caused in this fluid by gradually adding to it a mixture of cholesterin in four parts of alcohol and one of ether. The cholesterin pulp is collected on a filter, washed with water containing acetic acid, and afterward with pure water. The cholesterin pulp is placed in ether to dissolve the cholesterin, and the ether is then removed. The small watery deposit contains the pepsin in solution.

Pepsin so prepared is a colloid substance; it does not react like albumin with the following tests, viz.: It does not give the xanthroprotein reaction (§ 248), is not precipitated by acetic acid and potassium ferrocyanide, nor by tannic acid, mercuric chloride, silver nitrate, or iodine. In other respects it belongs to the group of albuminoids. It is rendered inactive in an acid fluid by heating it to 55° to 60° C.

166. PROCESS OF GASTRIC DIGESTION.—[In the process of gastric digestion we have to consider—

1. The secretion of gastric juice and its action on food.
2. The absorption of the products of this digestion.
3. The movements of the stomach itself.]

Chyme.—The finely divided mixture of food and gastric juice is called *chyme*. The gastric juice acts upon certain constituents of chyme.

I. Action on Proteids.—Pepsin and the dilute hydrochloric acid, at the temperature of the body, transform proteids into a *soluble* form, to which Lehmann (1850) gave the name of "**peptone**" (§ 249, III). Fibrin (or coagulated proteids) first becomes clear and swollen up.

[It is commonly stated that the first product formed during the gastric digestion of proteids is **syntonin** or **parapeptone**, then **hemi-albumose** or **propeptone**, and finally **peptone**. The products vary, however, with the proteid digested. Kühne has shown that the proteid molecule is split up, and yields two groups, which he calls **anti-peptone** and **hemi-peptone**; the former can be split up into leucin and tyrosin by trypsin, while the latter does not undergo this change. A mixture of the two he calls **ampho-peptone**. The intermediate body or propeptone, is really a mixture of several bodies. Kühne calls it hemi-albumose. These intermediate bodies from albumin are called **albumoses**, from globulins globuloses, from casein caseoses. Halliburton calls all these intermediate bodies "**proteoses.**"]

Properties.—Hemi-albumose, although a composite body, gives the following reactions: It is highly soluble in water; when heated to 50° to 60° it becomes somewhat turbid, but when boiled it becomes clear, and gets turbid again on cooling. This effect is most marked when it is treated with acetic acid and sodic chloride, or the latter alone. It is precipitated by acetic acid and potassic ferrocyanide, but the precipitate disappears on heating and reappears on cooling. It gives the biuret rosy tint reaction like peptones. It is *precipitated by nitric acid*, and the precipitate adheres to the glass, but is *soluble in the acid with the aid of heat*, yielding a yellow fluid, but is *precipitated on cooling*. It is precipitated by boiling with acetic acid and a strong solution of sodic sulphate,

metaphosphoric acid, and pyrogallic acid (*Kühne*). It is said to be present in all animal tissues except muscle and nerve (§ 293).

[**Albumoses** are the first products of the splitting up of proteids by enzymes, and from them peptones are ultimately formed. They may be made from Witte's peptone, or by the peptic digestion of fibrin. Such a mixture, on being neutralized with sodic carbonate, gives a copious precipitate of parapeptones, which can be filtered off, leaving a clear solution of albumoses. On saturating the clear fluid with NaCl, a dense white precipitate, consisting of three albumoses, called **proto-**, **dys-**, and **hetero-albumose** is obtained; a fourth, **deutero-albumose**, remains in solution, but can be precipitated by adding acetic acid. If the albumose precipitate be treated with 10 per cent. NaCl solution, proto- and hetero-albumose are dissolved, leaving dys-albumose undissolved. Dialysis of the saline solution precipitates hetero-albumose, leaving proto-albumose in solution. It is probable, however, that hetero- and dys-albumose are identical, or that the former is merely an insoluble form of the latter. The albumoses are bodies intermediate between albumins and peptones, and of the three, deutero-albumose is nearest to peptones.]

[**Properties.**—**Proto-albumose** is soluble in distilled water, is not changed by heat, but is precipitated by saturation of the solution with sodic chloride, by HNO_3, acetic acid, potassic ferrocyanide, copper sulphate, mercuric chloride. **Deutero-albumose** is very like the foregoing, but it is not precipitated by HNO_3 or on adding sodic chloride to saturation, but precipitation occurs when 20 to 30 per cent. of acetic acid is added. **Hetero-albumose** resembles a globulin in its properties; it is insoluble in distilled water, but is soluble in saline solutions (10 to 15 per cent.), and is partly precipitated from its solution by saturation with NaCl or dialysis. It is coagulated by heat. All give the rosy-pink color with the biuret reaction, and they are all precipitated by saturation with neutral ammonia sulphate, which peptones are not (*Kühne and Chittenden*).]

[**Globuloses** from the globulin of ox serum are obtained in the same way, although the ferment has much less action on globulin than on albumin. Speaking generally, they resemble the albumoses.]

By the continued action of the gastric juice, the propeptone passes into a **true soluble peptone.** The unchanged albumin behaves like an anhydride with respect to the peptone. The formation of peptone is due to the taking up of a molecule of water, under the influence of the hydrolytic ferment pepsin, and the action takes place most readily at the temperature of the body. Gelatin is changed into a *gelatin-peptone*.

According to Kühne, the proteid molecule contains two substances preformed: **anti-albumin** and **hemi-albumin.** Gastric juice at first converts them into **anti-albumose** and **hemi-albumose,** and both ultimately into anti-peptone and hemi-peptone (§ 170, II). Only the latter is split up by trypsin into leucin and tyrosin.

The greater the amount of pepsin (within certain limits), the more rapidly does the solution take place. The pepsin suffers scarcely any change, and if care be taken to renew the hydrochloric acid, so as to keep it at a uniform amount, the pepsin can dissolve new quantities of albumin. Still, it seems that some pepsin is used up in the process of digestion (*Grützner*). Proteids are introduced into the stomach either in a solid (coagulated) or fluid condition. Casein alone of the fluid forms is precipitated or coagulated, and afterward dissolved. The non-coagulated proteids are transformed into syntonin, without being previously coagulated, and are then changed into propeptone and directly peptonized, *i. e.*, actually *dissolved.*

When albumin is digested by pepsin at the temperature of the body, a not inconsiderable amount of **heat disappears,** as can be proved by calorimetric experiment (*Maly*). Hence, the temperature of the chyme in the stomach falls 0°.2 to 0°.6 C. in two to three hours (*v. Vintschgau and Dietl*).

Coagulated albumin may be regarded as the anhydride of the fluid form, and the latter again as the anhydride of peptone. The peptones, therefore, represent the highest degree of hydration of the proteids.

Hence, peptones may be formed from proteids by those reagents which usually cause hydration, viz., treatment with strong acids (from fibrin, with 0.2 HCl), caustic alkalies, putrefactive and various other ferments, and ozone.

The anhydride proteid has been prepared from the hydrated form. Henniger and Hofmeister, by boiling pure peptone with dehydrating substances (anhydrous acetic acid at 80° C.), have succeeded in decomposing it into a body resembling syntonin.

Peptones.—(1) They are completely soluble in water. (2) They diffuse very easily through membranes. (3) They filter quite easily through the pores of animal membranes. (4) They are *not precipitated* by boiling, nitric acid, acetic acid and potassium ferrocyanide, acetic acid and saturation with common salt. (5) They are *precipitated* from neutral or feebly acid solutions by mercuric chloride, tannic acid, bile acids, and phosphoro-molybdic acid. (6) With Millon's reagent they react like proteids, and give a red color, and with nitric acid give the yellow xanthoprotein reaction. (7) With caustic potash or soda and a small quantity of cupric sulphate [or Fehling's solution] they give a beautiful *rosy-red* color, the biuret reaction. (8) They rotate the plane of polarized light to the left.

[Kühne and Chittenden, making use of the fact that ammonium sulphate to saturation precipitates all proteids from solution except peptone, have reinvestigated the subject, and they find that many of the peptones of commerce contain albumoses. Pure peptone has remarkable properties. When dissolved in water, it hisses and froths like phosphoric anhydride, heat is evolved, and a brown solution is formed. It is difficult to preserve it. It is not precipitated by NaCl, or NaCl and acetic acid, but is completely precipitated by phospho-tungstic and phospho-molybdic acids, tannin, iodo-mercuric iodide, picric acid. Peptones have a cheesy taste, while albumin and albumoses are tasteless.]

The biuret reaction is obtained with propeptone, as well as with a form of albumin, which is formed during artificial digestion and is soluble in alcohol. It is called "alkophyr" by Brücke. [Darby's fluid meat gives all the above reactions, and is very useful for studying the tests for peptones.]

The rapidity of solution of fibrin is tested by placing fibrin which is swollen up by the action of 0.2 per cent. HCl in a glass funnel, and adding the digestive fluid, observing the rapidity with which the fluid, the altered fibrin, drops from the funnel, and the fibrin disappears (*Grünhagen*). Or the fibrin may be colored with carmine, swollen up in 0.1 per cent. HCl, and placed in the digestive fluid. The more rapidly the fluid is colored red, the more energetic is the digestion.

Preparation.—Pure peptones are prepared by taking fluid which contains them and neutralizing it with barium carbonate, evaporating upon a water bath, and filtering. The barium is removed from the filtrate by the careful addition of sulphuric acid, and subsequent filtration.

Ptomaines.—Brieger extracted from gastric peptones by amylic alcohol a peptone-free poison, with actions like those of curara. It belongs to the group of *ptomaines, i. e.*, alkaloids obtained from dead bodies or decomposing proteids. [Ptomaines are identical with the alkaloids in plants, and many have been isolated. The term **leucomaine** has been applied by Gautier to alkaloids formed by the decomposition of albuminous bodies during the normal metabolic processes taking place in the tissues. They are not formed by the activity of microörganisms. Some seem to be formed in muscle, and are closely allied to creatin and xanthin.]

Peptones are undoubtedly those modifications of albumin or proteids which, after their absorption from the intestinal canal into the blood, are destined to make good the proteids used up in the human organism. By giving peptones (instead of albumin) as food, life cannot only be maintained, but there may even be an increase of the body weight (*Plósz and Maly, Adamkiewicz*). Very probably, before being absorbed into the blood stream, peptones are re-transformed into serum albumin (§ 192).

Conditions affecting Gastric Digestion.—The presence of already-formed peptones interferes with the action of the gastric juice, in so far as the greater concentration of the fluid interferes with and limits the mobility of the fluid particles. Boiling, concentrated acids, alum, and tannic acid, *alkalinity* of the gastric juice (*e. g.*, by the admixture of much saliva), abolish the action; also sulphurous and arsenious acids and potassic iodide. The salts of the heavy metals, which cause pre-

cipitates with pepsin, peptone, and mucin, interfere with gastric digestion, and so do concentrated solutions of alkaline salts, common salt, magnesium and sodium sulphates. A small quantity of NaCl increases the secretion (*Grützner*) and favors the action of pepsin. Alkalies rapidly destroy pepsin, but less rapidly pro-pepsin (*Langley*). Alcohol precipitates the pepsin, but by the subsequent addition of water it is redissolved, so that digestion goes on as before. Any means that prevent the proteid bodies from swelling up, as by binding them firmly, impede digestion. Slightly over half a pint of cold water does not seem to disturb healthy digestion, but it does so in cases of disease of the stomach. Copious draughts of water, and violent muscular exercise, disturb digestion; while warm clothing, especially over the pit of the stomach, aids it. Menstruation retards gastric digestion. [Oddi finds that the presence of large quantities of ox bile, or even of its own bile in the stomach of a dog, does not affect the activity of the gastric juice, does not precipitate peptones, and does not excite vomiting.]

[**Artificial Digestion.**—The action of gastric juice on proteids may be observed outside the body, and we can prove, as is shown in the following table, after Rutherford, that pepsin and an acid—*e. g.*, hydrochloric, along with water—are essential to the formation of gastric peptones:—

Beaker A.	Beaker B.	Beaker C.
Water. Pepsin, 0.3 per cent. Fibrin.	Water. HCl, 0.2 per cent. Fibrin.	Water. Pepsin, 0.3 per cent. HCl, 0.2 " Fibrin.
Keep all in water bath at 38° C.		
Unchanged.	Fibrin swells up, becomes clear, and is changed into acid albumin or syntonin.	Fibrin ultimately changed into peptone.]

[In all animals, gastric digestion is essentially an **acid** digestion, and between the native proteid, fibrin, albumin, or any other form of proteid, and the end product peptone, there are numerous intermediate substances, many of whose properties and characters have still to be investigated.]

[**Exclusion of the Stomach.**—Ogata finds that if the stomach be divided at the pyloric end so as to exclude the stomach from the digestive apparatus, a dog can be nourished for a long time by introducing food through the pylorus into the duodenum. A dog has lived several years after excision of its stomach (*Czerny*). Raw flesh so introduced is digested more rapidly in the small intestine than in the stomach. The stomach not only digests, but it acts on the connective tissue of flesh so as to prepare the latter for intestinal digestion.]

II. Action on other Constituents of Food.—Milk coagulates when it enters the stomach, owing to the precipitation of the casein, and in doing so it entangles some of the milk globules. During the process of coagulation, heat is given off. The free hydrochloric acid of the gastric juice is itself sufficient to precipitate it; the acid removes from the alkali-albuminate or casein the alkali which keeps it in solution. Hammarsten separated a special ferment from the gastric juice—quite distinct from pepsin—the **milk-curdling ferment** which, quite independently of the acid, precipitates the casein either in neutral or alkaline solutions. It is this ferment or **rennet** which is used to coagulale casein in the making of cheese. [Rennet is an infusion of the fourth stomach of the calf in brine (§ 231). The ferment which coagulates milk is quite distinct from pepsin. If magnesic carbonate be added to an infusion of calf's stomach, a precipitate is obtained. The clear fluid has strongly coagulating properties, while the precipitate is strongly peptic.]

The action of the milk-curdling ferment is, perhaps, like the action of all ferments, a hydration of casein; it is greater in the presence of 0.2 HCl.

One part of the rennet ferment can precipitate 800,000 parts of casein. When casein coagulates, two new proteids seem to be formed—the coagulated proteid which constitutes cheese, and a body resembling peptone dissolved in the whey. The addition of calcium chloride accelerates, while

water retards the coagulation (§ 231) (*Hammarsten*). [A ferment similar to rennet is contained in the seeds of *Withania coagulans* (*S. Lea*).]

Casein is first precipitated in the stomach, then a body like syntonin is formed, and finally peptone. During the process, a substance containing phosphorus and resembling nuclein appears (*Lubavin*).

There is a "**lactic acid ferment**" also present, which changes milk sugar into lactic acid (*Hammarsten*). Part of the milk sugar is changed in the stomach and intestine into grape sugar.

Action on Carbohydrates.—Gastric juice does not act as a solvent of starch, inulin, or gums. Cane sugar is slowly changed into grape sugar. According to Uffelmann, the gastric mucus, and according to Leube, the gastric acid, are the chief agents in this process. **On albuminoids.**—During the digestion of true cartilage, there is formed a chondrin peptone, and a body which gives the sugar reaction with Trommer's test. Perfectly pure elastin yields an elastin peptone, similar to albumin peptone, and hemi-elastin similar to hemi-albumose. A very minute quantity of **fat** is broken up into glycerine and fatty acids. [On neutral olive oil being injected into the stomach of a dog, after several hours—the pylorus being plugged with an elastic bag—it partly splits up and yields oleic acid (*Cash and Ogata*).]

[We still require further observations on the gastric digestion of fats. Richet observed in his case of fistula, that fatty matters remained a long time in the stomach, and Ludwig found the same result in the dog. In some dyspeptics, rancid eructations often take place toward the end of gastric digestion.]

III. Action on the Various Tissues.—(1) The **gelatine-yielding substances** (collagen) of all the connective tissues (connective tissue, white fibro-cartilage, and the matrix of bone), as well as glutin, is dissolved and peptonized by the gastric juice. [**Gelatin**, when acted on by gastric juice, no longer solidifies in the cold, but a *gelatin-peptone* is formed, which is soluble and diffusible, although it differs from true peptone. In the dog, connective tissues are especially acted on in the stomach, while the other parts of organs used as food are prepared for digestion in the small intestine, where the cellular and nuclear elements are digested by the pancreatic juice (*Bikfalvi*).] (2) The **structureless membranes** (membranæ propriæ) of glands, sarcolemma, Schwann's sheath of nerve fibres, capsule of the lens, the elastic laminæ of the cornea, the membranes of fat cells are dissolved, but the true elastic (fenestrated) membranes and fibres are not affected. (3) **Striped muscle**, after solution of the sarcolemma, breaks up transversely into disks, and, like non-striped muscle, is dissolved, and forms a true soluble peptone, but parts of the muscle always pass into the intestine. (4) The albuminous constituents of the soft cellular elements of glands, stratified epithelium, endothelium, and lymph cells, form peptones, but the nuclein of the nuclei does not seem to be dissolved. (5) The **horny parts** of the epidermis, nails, hair, as well as chitin, silk, conchiolin, and spongin of the lower animals are indigestible, and so are amyloid substance and wax. (6) The **red blood corpuscles** are dissolved, the hæmoglobin decomposed into hæmatin and a globulin-like substance; the latter is peptonized, while the former remains unchanged, and is partly absorbed and transformed into bile pigment. **Fibrin** is easily dissolved to form hemi- and anti-peptone. (7) **Mucin**, which is also secreted by the goblet cells of the stomach, passes through the intestines unchanged. (8) **Vegetable fats** are not affected by the gastric juice; these cells yield their protoplasmic contents to form peptones, while the **cellulose** of the cell wall, in the case of man at least, remains undigested (§ 184).

Why the Stomach does not digest itself.—That the stomach can digest *living* things is shown by the following facts: Bernard introduced the leg of a living frog through a gastric fistula into the stomach of a dog. Pavy did the same with the ear of a rabbit, and in both the objects introduced were digested. [Frenzel has modified this experiment, and shown that the legs of a living frog are digested by artificial gastric juice, the tissues being first killed and then digested. His experiments go to show that the alkalinity of the blood is not the protective medium.] The margins of a gastric ulcer and of gastric fistulæ in man are attacked by the gastric juice. John Hunter (1772) discussed the question why the stomach does not digest itself. Not unfrequently after death the posterior wall of the stomach is found digested [more especially if the person die after a full meal and the body be kept in a warm place, whereby the contents of the stomach may escape into the peritoneum. Cl. Bernard showed, that if a rabbit be killed and placed in an oven at the temperature of the body, the walls of the stomach are attacked by its own gastric juice. Fishes also are frequently found with their stomach partially digested after death]. It would seem, therefore, that so long as the circulation continues, the tissues are protected from the action of the acid by the *alkaline* blood; this action cannot take place if the reaction be alkaline (*Pavy*). [This, however, does not explain why the pancreatic juice does not digest the pancreas.] Ligature of the arteries of the stomach causes digestive softening of the gastric mucous membrane. The thick layer of the mucus may also aid in protecting the stomach from the action of its own gastric juice (*Cl. Bernard*).

167. GASES IN THE STOMACH.—The stomach always contains a certain quantity of gas, derived partly from the gases swallowed with the saliva, partly from gases which pass backward from the duodenum.

The air in the stomach is constantly undergoing changes, whereby its O is absorbed by the blood, and for 1 vol. of O absorbed 2 vols. of CO_2 are returned to the stomach from the blood. Hence, the amount of O in the stomach is very small, the CO_2 very considerable (*Planer*).

Gases in the Stomach.—Vol. per cent. (*Planer*).

	Human Subject after Vegetable Diet.		Dog.	
	I.	II.	I. After Animal Diet.	II. After Legumes.
CO_2,	20.79	33.83	25.2	32.9
H,	6.71	27.58	. .	. .
N	72.50	38.22	68.7	66.3
O,		0.37	6.1	0.8

By the acid of the stomach a part of the CO_2 is set free from the saliva, which contains much CO_2 (§ 146). The N acts as an indifferent substance.

Abnormal development of gases in persons suffering from gastric catarrh, occurs when the gastric contents are *neutral* in reaction; during the butyric acid fermentation H and CO_2 are formed; the acetic acid and lactic acid fermentations do not cause the formation of gases. Marsh gas (CH_4) has been found, but it comes from the intestine, as it can only be formed when no O is present (§ 184).

168. STRUCTURE OF THE PANCREAS.—The pancreas is a **compound tubular** gland, and in its general arrangement into lobes, lobules, and system of ducts and acini, it corresponds exactly to the true salivary glands. The epithelium lining the ducts is not at all, or only faintly, striated. The **acini** are tubular or flasked-shaped, and often convoluted. They consist of a membrana propria, resembling that of the salivary glands, lined by a single layer of somewhat cylindrical cells, with a more or less conical apex, directed toward the very narrow lumen of the acini. [As in the salivary glands, there is a narrow **intermediary part** of the ducts opening into the acini, and lined by flattened epithelium.] The **cells** lining the acini consist of **two zones** (Fig. 186):—

FIG. 186.

Section of the fresh pancreas.

FIG. 187.

Changes of the pancreatic cells in various stages of activity. 1, During hunger; 2, in the first stage of digestion; 3, in the second stage; 4, during paralytic secretion.

(1) The smaller outer or **parietal layer** is transparent, homogeneous, sometimes faintly striated, and readily stained with carmine and logwood; and (2) the **inner layer** (Bernard's granular layer) is granular, and stains but slightly with carmine (Fig. 186). It undoubtedly contributes to the secretion by giving off material, the granules being dissolved, while the zone itself becomes smaller. The spherical nucleus lies between the two zones. [The lumen of the acini is very small, and spindle-shaped or branched cells (**centro-acinar cells**) lie in it, and send their processes between the secretory cells, thus acting as *supporting cells* for the elements of the wall of the acini. During

secretion, there is a continuous change in the appearance of the cell substance; the granules of the inner zone dissolve to form part of the secretion; new granules are formed in the homogeneous substance of the outer zone, and pass toward the inner zone (*Heidenhain, Kühne and Lea*).

Changes in the Cells during Digestion.—During the *first* stage (6 to 10 hours) the granular inner zone diminishes in size, the granules disappear, while the striated outer zone increases in size (Fig. 187, 2). In the *second* stage (10 to 20 hours) the inner zone is greatly enlarged and granular, while the outer zone is small (Fig. 187, 3). During hunger the outer zone again enlarges (Fig. 187, 1). In a gland where paralytic secretion takes place, the gland is much diminished in size, the cells are shriveled (Fig, 187, 4) and greatly changed. According to Ogata, some cells actually disappear during secretion.

The axially-placed excretory **duct** consists of an inner thick and an outer loose wall of connective and elastic tissues, lined by a single layer of columnar epithelium. Small mucous glands lie in the largest trunks. Non-medullated **nerves**, with *ganglia* in their course, pass to the acini, but their mode of termination is unknown. The **blood vessels** form a rich capillary plexus round some acini, while round others there are very few. Kühne and Lea found peculiar small cells in groups between the alveoli, and supplied with convoluted capillaries like glomeruli. Their significance is entirely unknown. [They are probably lymphatic in their nature.] The **lymphatics** resemble those of the salivary glands. When a colored injection is forced into the ducts under a high pressure, fine intercellular passages between the secreting cells are formed (*Saviotti's canals*), but they are *artificial* products.]

[**Number of Ducts.**—In making experiments upon the pancreatic secretion, it is important to remember that the number of pancreatic ducts varies in different animals. In man there is one duct opening along with the common bile duct at Vater's ampulla, at the junction of the middle and lower third of the duodenum. The rabbit has two ducts, the larger opening separately about 14 inches (30 to 35 cm.) below the entrance of the bile duct. The dog and cat have each two ducts opening separately.]

Chemistry.—The *fresh* pancreas contains water, proteids, ferments, fats, and salts. In a gland which has been exposed for some time, much leucin, isoleucin, butalin, tyrosin, often xanthin and guanin, are found: lactic and fatty acids seem to be formed from chemical decompositions taking place.

169. **THE PANCREATIC JUICE.—Method.**—Regner de Graaf (1664) tied a cannula in the pancreatic duct of a dog, and collected the juice in a small bag. Other experimenters made a **temporary fistula.** To make a **permanent fistula,** the abdomen is opened (dog), the pancreatic duct pulled forward, and stitched to the abdominall wall, with which it unites. Heidenhain cuts out the part of the duodenum where the duct opens into it, from its continuity with the intestine, and fixes it outside the abdominal wound.

The **secretion** obtained from a **permanent fistula** is a copious, slightly active, watery secretion, containing much sodium carbonate; while the *thick* fluid obtained from the fistula before inflammation sets in, or that from a **temporary fistula,** acts far more energetically. This thick secretion, which is small in amount, is the *normal* secretion. The copious watery secretion is perhaps caused by the increased transudation from the dilated blood vessels (possibly in consequence of the paralysis of the vasomotor nerves). It is, therefore, in a certain sense, a "paralytic secretion" (§ 145). The **quantity** varies much, according as the fluid is thick or thin. During digestion, a large dog secretes 1 to 1.5 gramme of a thick secretion (*Cl. Bernard*). Bidder and Schmidt obtained in twenty-four hours 35 to 117 grammes of a watery secretion per kilo. of a dog. When the gland is not secreting, and is **at rest,** it is soft, and of a pale yellowish-red color, but **during secretion** it is red and turgid with blood, owing to the dilatation of the blood vessels.

The **normal secretion** is transparent, colorless, odorless, saltish to the taste, and has a strong **alkaline** reaction, owing to the presence of sodium carbonate, so that when an acid is added, CO_2 is given off. It contains albumin and alkali-albuminate; it is sticky, somewhat viscid, flows with difficulty, and is coagulated by heat into a white mass. In the cold, there separates a jelly-like albuminous coagulum. Nitric, hydrochloric, and sulphuric acids cause a precipitate; while the precipitate caused by alcohol is redissolved in water. Cl. Bernard found in the pancreatic juice of a dog 8.2 per cent. of organic substances, and 0.8 per cent. of ash. The juice (dog) analyzed by Carl Schmidt contained in 1000 parts:—

Solids, 90.38 in 1000 parts.	Organic,	81.84	*Sodic chloride*,	7.36
	Inorganic,	8.54	" phosphate,	0.45
	(like those of blood serum).		" sulphate,	0.10
			Soda,	0.32
			Lime,	0.22
			Magnesia,	0.05
			Potassic sulphate,	0.02
			Ferric oxide,	0.02

The more rapid and more profuse the secretion, the poorer it is in organic substances, while the inorganic remain almost the same; nevertheless, the total quantity of solids is greater than when the quantity secreted is small (*Bernstein*). Traces of leucin and soaps are present in the fresh juice. [It usually contains few or no structural elements. Any structural elements present in the fresh juice, as well as its proteids, are digested by the peptone-forming ferment of the juice, especially if the latter be kept for some time. If the fresh juice is allowed to stand for some time, and then mixed with chlorine water, a red color is obtained.]

Concretions are rarely formed in the pancreatic ducts; they usually consist of calcic carbonate. Dextrose has been found in the juice in diabetes, and urea in jaundice. Schiff's statement that the pancreas secretes only after the absorption of dextrin, has not been confirmed. The secretory activity of the pancreas is not dependent on the presence of the spleen.

170. ACTION OF THE PANCREATIC JUICE.—The presence of at least **four enzymes**, or hydrolytic ferments, makes the pancreatic juice one of the most important digestive fluids in the body.

I. **Diastatic action** is due to the diastatic ferment, **amylopsin**, a substance which seems to be identical with the saliva ferment; but it acts much more energetically than the ptyalin on saliva, on *raw* starch as well as upon boiled starch; at the temperature of the body the change is effected almost at once, while it takes place more slowly at a low temperature. Glycogen is changed into dextrin and grape sugar; and achroodextrin into sugar. Even cellulose is said to be dissolved, and gum changed into sugar by it, but inulin remains unchanged.

According to v. Mering and Musculus, the starch (as in the case of the saliva, § 148) is changed into **maltose**, and a reducing dextrin; so also is glycogen. Amylopsin changes achroodextrin into maltose; at 40° C. maltose is slowly changed into dextrose, but cane sugar is not changed into invert sugar. The ferment is precipitated by alcohol, while it is extracted by glycerine without undergoing any essential change. All conditions which destroy the diastatic action of saliva (§ 148) similarly affect its action, but the admixture with acid gastric juice (its acid being neutralized) or bile does not seem to have any injurious influence. This ferment is absent from the pancreas of new-born children (*Korowin*).

Preparation.—The ferment is isolated by the same methods as obtain for ptyalin (§ 148); but the tryptic ferment is precipitated at the same time. The addition of neutral salts (4 per cent. solution), *e. g.*, potassium nitrate, common salt, ammonium chloride, increases the diastatic action.

II. **Tryptic action**, or the action on proteids, depends upon the presence of a hydrolytic ferment which is now termed **trypsin** (*Kühne*). Trypsin acts upon proteids at the temperature of the body, when the reaction is *alkaline*, and changes them first into a globulin-like substance, then into propeptone or albumose, and lastly into a *true peptone*, sometimes called tryptone. The albumoses are not so abundant or so easily separated as in gastric digestion (see also p. 293). The proteids do not swell up before they are changed into peptone [but they are eroded or eaten away by the action of the juice]. When the proteid has been previously swollen up by the action of an acid, or when the reaction of the medium is acid, the transformation is interfered with.

Substances yielding gelatin, nuclein, and Hb, resist trypsin; glutin and swollen-up gelatin-yielding substances are changed into gelatin-peptone, but the latter undergoes no further change. Hb-O_2 is split up into albumin and hæmochromogen. In other respects, trypsin acts on tissues containing albumins just like pepsin (§ 166, III).

Trypsin is never absent from the pancreas of **new-born children** (*Zweifel*), and it may be extracted by water, which, however, also dissolves the albumin. Kühne has carefully separated the albumin and obtained the ferment in a pure state. It is soluble in water, insoluble in alcohol. Pepsin and hydrochloric acid together act upon trypsin and destroy it; hence it is not advisable to administer trypsin by the mouth, as it would be destroyed in the stomach. When dried it may be heated to 160° without injury.

Trypsin is formed within the pancreas by a "**mother substance,**" or **zymogen,** taking up oxygen. The zymogen is found in small amount, 6 to 10 hours after a meal, in the inner zone of the secretory cells, but after 16 hours it is very abundant in the inner zone of the cells. It is soluble in water and glycerine. Trypsin is formed in the watery solution from the zymogen, and the same result occurs when the pancreas is chopped up and treated with strong alcohol (*Kühne*). The addition of sodium chloride, carbonate, and glycocholate, favors the activity of the tryptic ferment (*Heidenhain*). [The following facts show that zymogen (ζύμη, ferment), or, as it has been called, **trypsinogen,** is the precursor of trypsin, that it exists in the gland cells, and requires to be acted upon before trypsin is formed. If a glycerine extract be made of a pancreas taken from an animal just killed, and if another extract be made from a similar pancreas which has been kept for 24 hours, it will be found that an alkaline solution of the former has practically no effect on fibrin, while the latter is powerfully proteolytic. If a fresh and still warm pancreas be rubbed up with an equal volume of a 1 per cent. solution of acetic acid, and then extracted with glycerine, a powerfully proteolytic extract is at once obtained. Trypsin is formed from zymogen by the action of acetic acid. There is reason to believe that trypsin is formed from zymogen by oxidation, and that the former loses its proteolytic power after removal of its oxygen. The amount of zymogen present in the gland cells seems to depend upon the number and size of the granules present in the inner granular zone of the secretory cells.]

Further Effects.—When trypsin is allowed to act upon the hemipeptone formed by its own action, the latter is partly changed into the amido-acid, **leucin,** or **amido-caproic acid** ($C_6H_{13}NO_2$), and **tyrosin** ($C_9H_{11}NO_3$), which belongs to the aromatic series (§ 252, IV, 3). Hypoxanthin, xanthin, and aspartic or amido-succinic acid ($C_4H_7NO_4$), are also formed during the digestion of fibrin and gluten, and so are glutamic ($C_5H_9NO_4$) and amido-valerianic acid ($C_5H_{11}NO_2$). *Gelatin* is first changed into a gelatin-peptone, and afterward is decomposed into *glycin* and ammonia.

Putrefactive Phenomena.—If the action of the pancreatic juice be still further prolonged, especially if the reaction be alkaline, a body with a strong, stinking, disagreeable fecal odor, **indol** (C_8H_7N), **skatol** (C_9H_9N), and **phenol** (C_6H_6O), and a substance which becomes red on the addition of chlorine water (*Bernard*), [or it gives with bromine water first a pale red and then a violet tint (*Kühne*),] volatile fatty acids are formed, while, at the same time, H, CO_2, H_2S, CH_4, and N are given off. The formation of indol and the other substances just mentioned depends upon **putrefaction** (§ 184, III). Their formation is prevented by the addition of salicylic acid, or thymol, which kills the organisms upon which putrefaction depends (*Kühne*).

[**Artificial Digestion.**—From fibrin placed in pancreatic juice, or in a 1 per cent. solution of sodium carbonate containing the ferment trypsin, peptones are rapidly formed at 40° C. When we **compare gastric with pancreatic digestion,** we find that the fibrin in pancreatic digestion is eroded, or eaten away, and never swells up. The process takes place in an alkaline medium, and never in an acid one. In fact, a 1 per cent. solution of sodic carbonate seems to play the same part in assisting trypsin that a .2 per cent. solution of HCl does for pepsin in gastric digestion. In gastric digestion acid albumin or *syntonin* is formed in addition to the true peptones. In pancreatic digestion a body resembling *alkali albumin,* which passes into a globulin-like body, and ultimately into a peptone, is formed. Of the peptones so produced, one is called **anti-peptone,** and it is not further changed, but part of the proteid is changed into **hemi-peptone.** This body, when acted upon, yields leucin and tyrosin. When putrefaction takes place, the bodies above mentioned are also formed. We might represent the action of trypsin thus: Proteid + trypsin + 1 per cent. sodium

carbonate, kept at 38° C. = formation of a globulin-like body, and then anti-peptone and hemi-peptone are formed.

ANTI-PEPTONE	HEMI-PEPTONE *yields*		
yields	Normal Digestive Products.	Putrefactive Products.	
undergoes no further change.	Leucin, Tyrosin, Hypoxanthin, Aspartic Acid.	Indol, Skatol, Phenol.	Volatile Fatty Acids, H, CO_2, H_2S, CH_4, N.

It seems that trypsin in pure water can act slowly upon fibrin to produce peptone. Pepsin cannot do this without the aid of an acid.]

[**Kühne's Pancreas Powder.**—This is prepared by the prolonged extraction of fresh pancreas of ox with alcohol and then with ether. If the dry powder be extracted for several hours with a 1 per cent. solution of salicylic acid, and filtered, a fluid with powerful proteolytic, but no diastatic, properties is obtained. Several hours afterward much tyrosin may separate out, which, of course, must be removed by filtration. The clear fluid, when mixed with fibrin and a 1 per cent. solution of sodic carbonate, rapidly digests fibrin. If it be desired to obtain a true pancreatic digestion, with none of the products of putrefaction, the mixture must be strongly "thymolized" with a 25 per cent. alcoholic solution of thymol (*Kühne*).]

[Setschenow finds that egg albumin, boiled in a vacuum at 35°–40° C., is more rapidly digested than fibrin by a specially prepared trypsin.] When proteids are boiled for a long time with dilute H_2SO_4, we obtain peptone, then *leucin* and *tyrosin*; gelatin yields *glycin*. Hypoxanthin and xanthin are obtained in the same way by similarly boiling fibrin, and the former may even be obtained by boiling fibrin with water (*Chittenden*).

It is very remarkable that the juice of the green fruit of the papaya tree, or Carica papaya, possesses digestive properties (*Roy*, *Wittmack*), and that the action is due to peptonizing ferment, closely related to trypsin, and called caricin or **papain**. [It forms a true peptone, an intermediate body, and leucin and tyrosin. It also contains a milk-coagulating ferment (*Martin*).] The milky juice of the fig tree has a similar action. Sprouting malt, vetch, hop, hemp during sprouting, and the receptacle of the artichoke contain a peptonizing ferment. Leucin, tyrosin, glutamic and aspartic acids, and xanthin are formed in the seeds of some plants; hence we may assume that the processes of decomposition in some seeds are closely allied to the fermentative actions that occur in the intestine.

III. **The action on neutral fats** is twofold: (1) It acts upon fats so as to form a **fine permanent emulsion.** (2) It causes neutral fats to take up a molecule of water and **split into glycerine** and their corresponding **fatty acids**:—

$$\underset{\text{Tristearin.}}{(C_{57}H_{110}O_6)} + 3\,\underset{\text{Water.}}{(H_2O)} = \underset{\text{Glycerine.}}{(C_3H_8O_3)} + 3\,\underset{\text{Stearic Acid.}}{(C_{18}H_{36}O_2)}.$$

The latter result is due to the action of an easily decomposable **fat-splitting ferment** (*Cl. Bernard*), also called **steapsin.** Lecithin is decomposed by it into glycero-phosphoric acid, neurin and fatty acids. The fatty acids thus liberated are partly *saponified* by the alkali of the pancreatic and intestinal juices, and partly emulsionized by the alkaline intestinal juice. Both the soaps and emulsions are capable of being absorbed (§ 191).

Emulsification.—The most important change effected on fats in the small intestine is the production of an emulsion, or their subdivision into exceedingly minute particles (§ 191). This is necessary in order that the fats may be taken up by the lacteals. If the fat to be emulsified contain a free fatty acid, *i. e.*, if it be slightly rancid, and if the fluid with which it is mixed be *alkaline*, emulsification takes place extremely rapidly (*Brücke*). A drop of cod-liver oil, which in its unpurified condition always contains fatty acids, on being placed in a drop of 0.3 per cent. solution of soda, instantly gives rise to an emulsion (*Gad*). The excessively minute oil globules that compose the

emulsion are first covered with a layer of soap, which soon dissolves, and in the process small globules are detached from the original oil globules. The fresh surface is again covered by a soap film, and the process is repeated over and over again until an excessively fine emulsion is obtained. If the fat contain much fatty acid, and the solution of soda be more concentrated, "*myelin forms*" are obtained similar to those which are formed when fresh nerve fibres are teased in water. Animal oils emulsionize more readily than vegetable oils; castor oil does not emulsionize (*Gad*). [It is extremely difficult to obtain a perfectly neutral oil, as most oils contain a trace of a fatty acid. In fact, if on adding a weak solution of sodic carbonate to oil or fatty matters, fluid at the temperature of the body, an emulsion is obtained, one may be sure that the oil contained a fatty acid, so that Bernard's view about an "emulsive ferment" being necessary is not endorsed. The fatty acid set free by the fat-splitting ferment enables the alkaline pancreatic juice at once to produce an emulsion.]

Fat-Splitting Ferment.—This is a very unstable body, and must be prepared from the perfectly fresh gland by rubbing it up with powdered glass, glycerine, and a 1 per cent. solution of sodic carbonate, and allowing it to stand for a day or two (*Grützner*). [This ferment is said to cause an emulsion of oil and mucilage tinged blue with litmus at 40° C. to become red (*Gamgee*). In performing this experiment notice that the mucilage is perfectly neutral, as gum arabic is frequently acid.]

[**Pancreatic Extracts.**—The action of the pancreas may be tested by making a watery extract of a perfectly fresh gland. Such an extract always acts upon starch and generally upon fats, but this extract and also the glycerine extract vary in their action upon proteids at different times. If the extract—watery or glycerine—be made from the pancreas of a fasting animal, the tryptic action is slight or absent, but is active if it be prepared from a gland 4 to 10 hours after a meal. The pancreatic preparations of Benger of Manchester, Savory and Moore, or Burroughs and Welcome, all possess active diastatic and proteolytic properties.]

[**Pancreas Salt.**—Prosser-James proposes to employ common salt mixed with pepsin, which he calls peptic salt; and he advocates the use of another preparation composed of the pancreatic ferments and common salt, pancreatic salt.]

The pancreas of **new-born children** contains trypsin and the fat-decomposing ferment, but not the diastatic one (*Zweifel*). A slight diastatic action is obtained after two months, but the full effect is not obtained until after the first year (*Korowin*).

IV. The pancreas contains a **milk-curdling ferment,** which may be extracted by means of a concentrated solution of common salt.

171. THE SECRETION OF THE PANCREATIC JUICE.—Rest and Activity.—As in other glands, we distinguish a quiescent state, during which the gland is soft and pale, and a state of secretory activity, during which the organ swells up and appears pale red. The latter condition only occurs after a meal, and is caused probably reflexly, owing to stimulation of the nerves of the stomach and duodenum. Kühne and Lea found that all the lobules of the gland were not active at the same time. The pancreas of the herbivora secretes uninterruptedly [but in the dog secretion is not constant].

Time of Secretion.—According to Bernstein and Heidenhain, the secretion begins to flow when food is introduced into the stomach, and reaches its maximum 2 to 3 hours thereafter. The amount falls toward the 5th or 7th hour, and rises again (owing to the entrance of the chyme into the duodenum), toward the 9th and 11th hour, gradually falling toward the 17th to 24th hour, until it ceases completely. When more food is taken, the same process is repeated. As a general rule, a rapidly-formed secretion contains less solids than one formed slowly.

Condition of Blood Vessels.—During secretion, the blood vessels behave like the blood vessels of the salivary glands after stimulation of the chorda—they dilate, and the venous blood is bright red—thus, it is probable that a similar nervous mechanism exists [but as yet no such mechanism has been discovered]. The secretion is excreted at a pressure of more than 17 mm. Hg. (rabbit).

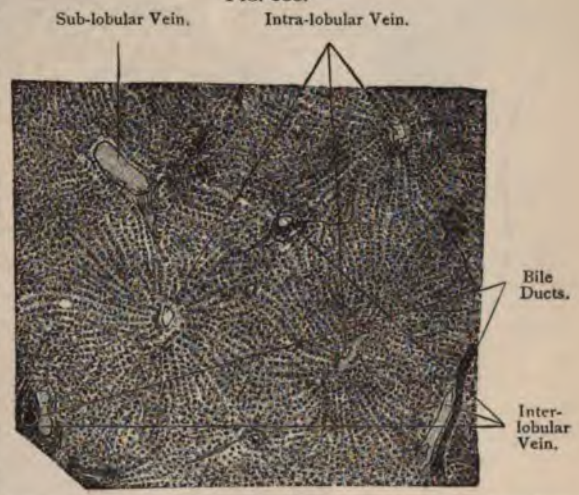
Effect of Nerves.—The nerves arise from the hepatic, splenic, and superior mesenteric plexuses, together with branches from the vagus and sympathetic. The secretion is **excited** by stimulation of the medulla oblongata, as well as by direct stimulation of the gland itself by induction shocks. [It is not arrested by section of the cervical spinal cord.] The secretion is **suppressed** by atropin

[in the dog, but not the rabbit], by producing vomiting, by stimulation of the central end of the vagus, as well as by stimulation of other sensory nerves, *e. g.*, the crural and sciatic. Extirpation of the nerves accompanying the blood vessels prevents the above-named stimuli from acting. Under these circumstances, a thin "**paralytic secretion**," with feeble digestive powers, is formed, but its amount is not influenced by the taking of food. [Secretion is excited by the injection of ether into the stomach.]

Extirpation of the gland may be performed, or the duct ligatured in animals, without causing any very great change in their nutrition; the absorption of fat from the intestine does not cease. After the duct is ligatured it may be again restored. Ligature of the duct may cause the formation of cysts in the duct and atrophy of the gland substance. Pigeons soon die after this operation.

[172. **PREPARATION OF PEPTONIZED FOOD.**—Peptonized food may be given to patients whose digestion is feeble (*Roberts*). Food may be peptonized either by peptic or tryptic digestion, but the former is not so suitable as the latter, because in peptic digestion the grateful odor and taste of the food are destroyed, while bitter by-products are formed, so that pancreatic digestion yields a more palatable and agreeable product. As trypsin is destroyed by gastric digestion, obviously it is useless to give extract of the pancreas to a patient along with his food.]

FIG. 188.



Section of human liver, × 20, showing the liver lobules and the radiate arrangement of their cells from the central or intra-lobular vein.

[**Peptonized Milk.**—"A pint of milk is diluted with a quarter of a pint of water and heated to 60° C. Two or three teaspoonfuls of Benger's liquor pancreaticus, together with 10 or 20 grains of bicarbonate of soda, are then mixed therewith." Keep the mixture at 38° C. for about two hours, and then boil it for two or three minutes, which arrests the ferment action.]

[**Peptonized Gruel**, prepared from oatmeal, or any farinaceous food, is more agreeable than peptonized milk, as the bitter flavor does not appear to be developed in the pancreatic digestion of *vegetable* proteids.]

[**Peptonized Milk Gruel** yielded Roberts the most satisfactory results, as a complete and highly nutritious food for weak digestions. Make a thick gruel from any farinaceous food, *e. g.*, oatmeal, and while still hot add to it an equal volume of cold milk, when the mixture will have a temperature of 52° C. (125° F.). To each pint of this mixture add two or three teaspoonfuls of liquor pancreaticus and 20 grains of bicarbonate of soda. It is kept warm for two hours under a "cosey." It is then boiled for a few minutes and strained. The bitterness of the digested milk is almost completely covered by the sugar produced during the process.]

[Peptonized soups and beef tea have also been made and used with success, and have been administered both by the mouth and rectum.]

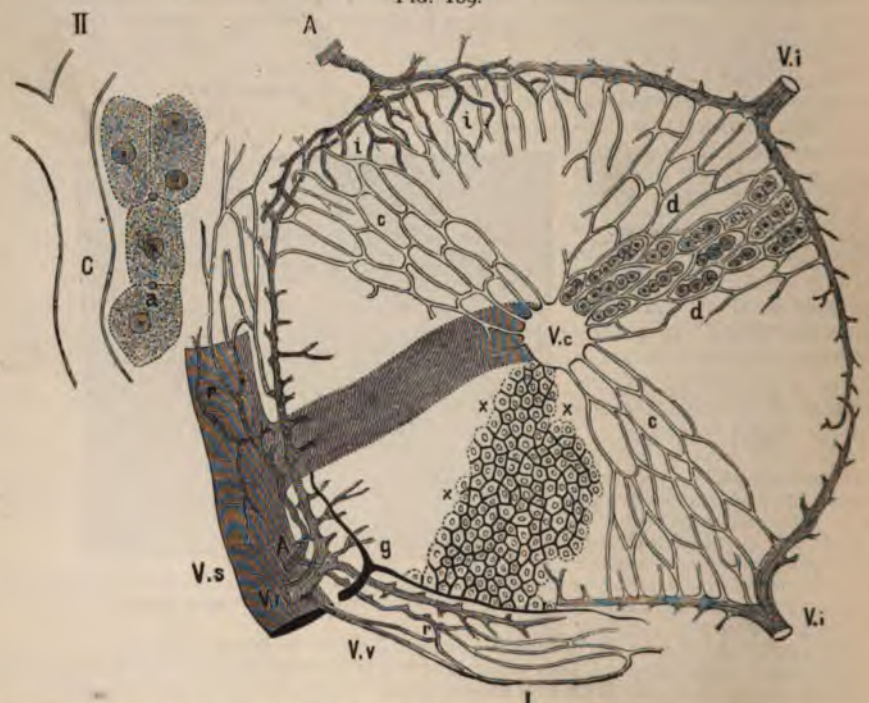
[Peptonizing powders containing the proper proportions of ferment and sodic bicarbonate are prepared by Benger, and Burroughs and Welcome.]

173. **STRUCTURE OF THE LIVER.**—The **liver**, the largest gland in the body, consists of innumerable small **lobules** or **acini**, 1 to 2 millimetres ($\frac{1}{24}$ to $\frac{1}{12}$ inch) in diameter. These lobules are visible to the naked eye. All the lobules have the same structure.

1. **The Capsule.**—The liver is covered by a thin, fibrous, firmly adherent capsule, which has on its free surface a layer of endothelium derived from the peritoneum. The capsule sends fine septa into the organ between the lobules, but it is also continued into the interior at the transverse fissure, where it surrounds the portal vein, hepatic artery, and bile-duct, and accompanies these structures as the **capsule of Glisson,** or inter-lobular connective tissue. The spaces in which these three structures lie are known as **portal canals.** In some animals (pig, camel, polar bear) the lobules are separated from each other by the somewhat lamellated connective tissue of Glisson's capsule, but in man this is but slightly developed, so that adjoining lobules are more or less fused. Very delicate connective tissue, but small in amount, is also found within the lobules. Leucocytes are sometimes found in the tissue of Glisson's capsule.

2. **Blood Vessels.**—(*a*) Branches of the **Venous System.**—The **portal vein,** after its entrance into the liver at the portal fissure, gives off numerous branches lying **between the lobules,** and ultimately forming small trunks which reach the periphery of the lobules, where they form a rich plexus. These are the **inter-lobular veins** (Figs. 188, 189, *V, i*). From these veins numerous **capillaries**

FIG. 189.



I, Scheme of a liver lobule—*V.i, V.i,* inter-lobular veins (portal); *V.c,* central or intra-lobular vein (hepatic); *c, c,* capillaries between both; *V.s,* sub-lobular vein; *V.v,* vena vascularis; *A, A,* hepatic artery, giving branches, *r, r,* to Glisson's capsule and the larger vessels, and ultimately forming the venæ vasculares at *i, i,* opening into the intra-lobular capillaries; *g,* bile ducts; *x, x,* intra-lobular biliary channels between the liver cells; *d, d,* position of the liver cells between the meshes of the blood capillaries. II, Isolated liver cells—*c,* a blood capillary; *a,* fine bile-capillary channel.

(*c, c*) are given off to the entire periphery of the lobule. The capillaries converge toward the centre of the lobule. As they proceed inward, they form elongated meshes, and between the capillaries lie rows or columns of liver cells (*d, d*). The capillaries are relatively wide, and are so disposed as to lie between the *edges* of the columns of cells, and never between the surfaces of two neighboring cells. The capillaries converge toward the centre of each lobule, where they join to form one large vein, the **intra-lobular, hepatic,** or **central vein** (*V.c*), which traverses each lobule, reaches its surface at one point, passes out, and joins similar veins from other lobules to form the **sub-lobular veins** (*V.s*). These in turn unite to form wide veins, the origins of the **hepatic vein,** which opens into the vena cava inferior.

(*b*) The branches of the **hepatic artery** accompany the branches of the portal vein and bile duct in the portal canals between the lobules, and in their course give off capillaries to supply the walls of the

portal vein and larger bile ducts. The branches of the hepatic artery anastomose frequently where they lie between the lobules. On reaching the periphery of the lobules, a certain number of capillaries are given off, which penetrate the lobule and terminate in the capillaries of the portal vein (*i*, *i*). These capillaries, however, which supply the walls of the portal vein and large bile ducts (*r*, *r*), terminate in veins which end in the portal vein (*V. v*). Several branches—*capsular*—pass to the surface of the liver, where they form a wide-meshed plexus under the peritoneum. The blood is returned by veins, which open into branches of the portal vein.

[**Hepatic Zones.**—Pathologists draw a sharp distinction between different zones within a hepatic lobule. Thus the central area, capillaries and cells, form the **hepatic vein zone,** which is specially liable to cyanotic changes; the area next the periphery of the lobule is the **portal vein zone,** whose

FIG. 190.

Human liver cells containing oil globules, *b*; *d*, has two nuclei.

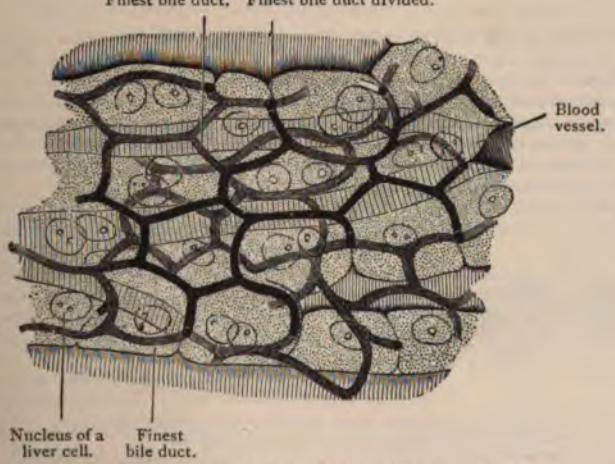
FIG. 191.

Liver cells after withholding food for 36 hours.

cells under certain circumstances are particularly apt to undergo fatty degeneration; while there is an area lying midway between the two foregoing—the **hepatic artery zone**—which is specially liable to amyloid or waxy degeneration.]

3. **The hepatic cells** (Fig. 189, II, *a*) are irregular polygonal cells of about $\frac{1}{1000}$ of an inch (34 to 45 μ) in diameter (Fig. 190). The arrangement of the capillaries within a lobule determines the arrangement of the liver cells. The liver cells form anastomosing columns which radiate from the centre to the periphery of each lobule (Fig. 191). [The liver cells are usually stated to be devoid of an envelope, although Haycraft states that they possess one. They usually contain a single nucleus,

FIG. 192.



Blood capillaries; finest bile ducts in their relative position in a rabbit's liver.

with one or more nucleoli, but sometimes two nuclei occur. The protoplasm and nucleus of each cell contain a plexus of fibrils just like other epithelial cells. In some animals, globules of oil and pigment granules are found in the cell protoplasm (Fig. 190). Each cell is in relation with the wide-meshed blood capillaries (*d*, *d*), and also with the much narrower meshwork of bile ducts (I, *x*).

Changes in Liver Cells.—The appearance of the cells varies with the period of digestion. During **hunger,** the liver cells are finely granular and very cloudy (Fig. 191) [and contain little glycogen, but many pigment granules, and the nucleus is more frequently absent. Often free nucleoli and pale nuclei are found (*Ellenberger and Baum*). During **activity,** *i. e.*, after a full meal, especially of starchy food, the cells are larger and more distinct, stain more deeply with eosin, and contain fewer granules]. The protoplasm contains coarse, glancing masses of glyocen (Fig. 194, 2), and near the surface of the cell it is condensed, and a fine network stretches toward the centre of the cell, and in it is suspended the nucleus. All the hepatic cells are not in the same phase of activity at the same time. Afanassiew finds that if the formation of bile in the liver be increased (*e. g.*, by section of the hepatic nerves, or feeding with proteids), the cells are moderately enlarged in size, and contain numerous granules, which are proteid in their nature; such cells resist the action of caustic potash. When there is a great formation of glycogen (as after feeding with potatoes and sugar), all the cells are very large and sharply defined, and contain many granules of glycogen, the cells being so large as to compress the capillaries. These cells dissolve quickly in caustic potash.

Action of Drugs.—Some substances excite the cells to activity, and cause them to present the appearance of cells in activity, *e.g.*, pilocarpin, muscarin, aloes, less so salicylate and benzoate of soda and rhubarb, while atropin and lead acetate inhibit the signs of activity. These results were obtained in the horse by Ellenberger and Baum. [Stolnikow, by using the quadruple-staining method of Gaule, finds that the hepatic cells of the frog undergo remarkable changes in **poisoning by phosphorus.** It is well known that this drug produces fatty degeneration of the liver cells, but a deeper study shows that the changes are both histological and chemical. Besides producing remarkable changes in the protoplasm of the cell, the protoplasm of the nucleus, in the form of small

FIG. 193.

Liver cells of frog. *a*, early, and *b*, late stage in poisoning by phosphorus; *c*, liver cell of frog getting water only; *d*, getting sugar, and *e*, peptone (*Stirling, after Stolnikow.*)

masses called plasmosoma, passes out into the cell body, perhaps to renew the latter. The cells are increased in size, both after poisoning with phosphorus and after excision of the fat bodies in the frog (Fig. 193). The fat present in the liver in phosphorus poisoning is not present as droplets of oil, but probably in a loose combination, *e.g.*, lecithin, and as a matter of fact the amount of liver lecithin is extraordinarily increased. There is also an increase of the nuclein; while glycogen is absent. The season of the year also affects them. There is a period of growth from July to November, and one of decay from December to May (*A. Leonard*). **Antipyrin** also produces profound changes, especially in the nuclei.]

4. **The Bile Ducts.**—The finest bile capillaries, channels, or canaliculi arise from the centre of the lobule, and indeed throughout the whole lobule they form a regular anastomosing network of very fine tubes or channels. Each cell is surrounded by a polygonal—usually hexagonal—mesh (Fig. 194, 3). The bile capillaries always lie in the middle of the surface between two adjoining cells (II, *a*), where they form actual **intercellular passages** (Fig. 192). [According to some observers, they are merely excessively narrow channels (1 to 2 μ wide) in the cement substance between the cells, while according to others they have a distinct delicate wall. The bile-capillary network is much closer than the blood-capillary network. [Thus, there are *three* networks within each lobule—

(1) A network of blood capillaries;
(2) " hepatic cells;
(3) " bile capillaries; (Fig. 192).]

FIG. 194.

1, Liver cell during fasting; 2, containing masses of glycogen; 3, a liver cell surrounded with bile channels, from which fine twigs proceed into the cell substance to end in vacuoles.

Excessively minute **intra-cellular passages** are said to pass from the bile capillaries into the interior of the liver cells, where they communicate with certain small cavities or **vacuoles** (*Arp, Kupffer*) (Fig. 194, 3). As the blood capillaries run along the edge of the liver cells, and the bile capillaries between the opposed surfaces of adjacent cells, the two systems of canals within the

lobule are kept separate. Some bile capillaries run along the edges of the liver cells in the human liver, especially during embryonic life. Toward the peripheral part of the lobule, the bile capillaries are larger, while adjoining channels anastomose, and leave the lobule, where they become **inter-lobular ducts** (*g*), which join with other similar ducts to form larger inter-lobular bile ducts. These accompany the hepatic artery and portal vein, and leave the liver at the transverse fissure. The *finer* inter-lobular ducts frequently anastomose in Glisson's capsule, possess a structureless basement membrane, and are lined by a single layer of low polyhedral epithelial cells. The *larger* inter-lobular ducts have a distinct wall, consisting of connective and elastic tissue, mixed with circularly disposed smooth muscular fibres (Fig. 195). Capillaries are supplied to the wall, which is lined by a single layer of columnar epithelium. A sub-mucosa occurs only in the largest bile ducts, and in the gall bladder. Smooth muscular fibres, arranged in single bundles, occur in the largest ducts, and as longitudinal and circular layers in the gall bladder, whose mucous membrane is provided with numerous folds and depressions. The epithelium lining the gall bladder is cylindrical, with a distinct, clear disk, and between these cells are goblet cells. Small branched tubular **mucous glands** occur in the larger bile ducts and in the gall bladder.

FIG. 195.

Inter-lobular bile duct (human).

Vasa aberrantia are isolated bile ducts which occur on the surface of the liver, but have no relation to any system of liver lobules. They occur at the sharp margin of the liver, in the region of the inferior vena cava, of the gall bladder, and of the parts near the portal fissure. It seems that the liver lobules to which they originally belonged have atrophied and disappeared (*Zuckerkandl and Toldt*).

5. **The lymphatics** begin as *pericapillary* tubes around the capillaries within the lobules, emerge from the lobule, and run *within* the wall of the branches of the hepatic and portal veins, and afterward surround the venous trunks, thus forming the *inter-lobular* lymphatics. These unite to form larger trunks, which leave the liver partly at the portal fissure, partly along with the hepatic veins, and partly at different points on the surface of the organ. There is a narrow, superficial meshwork of lymphatics under the peritoneum—*sub-peritoneal*—which communicate with the thoracic lymphatics, through the triangular ligament and suspensorium, while on the under surface they communicate with the lymphatics of the inter-lobular connective tissue.

6. **The nerves** consist partly of medullated and partly of non-medullated fibres from branches of the sympathetic and left vagus to the hepatic plexus. They accompany the branches of the hepatic artery, and *ganglia* occur on their branches within the liver. Some of the nerve fibres are vasomotor in function, and, according to Pflüger, other nerve fibres terminate directly in connection with liver cells. [MacCallum describes an inter-lobular plexus of non-medullated fibres in man and menobranchus, from which a perivascular and inter-cellular plexus proceeds. From the latter fibrils pass to terminate within the cells near the nucleus.]

Pathological.—The connective tissue between the lobules may undergo great increase in amount, especially in alcohol and gin drinkers, and thus the substance of the lobules may be greatly compressed, owing to the cicatricial contraction of the newly-formed connective tissue (cirrhosis of the liver). In such inter-lobular connective tissue, newly-formed bile ducts are found.

Ligature of the ductus choledochus [causes enlargement of the spleen (rabbit), and a diminution in the number of the blood corpuscles], and, after a time, interstitial inflammation of the liver. In rabbits and guinea pigs the liver parenchyma disappears, and its place is taken by newly-formed connective tissue and bile ducts (*Charcot and Gombault*). In all these cases of interstitial inflammation, there is proliferation of the epithelium of the bile ducts.

[**Regeneration of the Liver.**—Tizzoni finds that there may be partial regeneration and new formation of liver lobules in the dog, the process being the same as that which occurs in the embryonic development of the organ, *i. e.*, the growth of solid cylinders of liver cells, formed by the preëxisting liver cells, which penetrate into the connective tissue uniting the edges of the wound. These cells ultimately differentiate into hepatic cells and bile ducts. Other observers attribute the new formation to outgrowths of the epithelial cells of the bile cells.]

174. CHEMICAL COMPOSITION OF THE LIVER CELLS.—(1) Proteids.—The fresh, soft, parenchyma of the liver is *alkaline* in reaction; after death, coagulation occurs, the cell contents appear turbid, the tissue becomes friable, ıally an acid reaction is developed. This process closely resembles what ·. and is due to the coagulation of a myosin-like body, which is but after death undergoes spontaneous coagulation (*Plósz*). :r proteids; one coagulating at 45° C., another at 70° C.,

and one which is slightly soluble in dilute acids and alkalies. The nuclei contain nuclein. The connective tissue yields gelatin.

(2) **Glycogen or Animal Starch**—1.2 to 2.6 per cent.—is a true carbohydrate most closely related to inulin, soluble in water, but diffuses with difficulty, and has the formula $6(C_6H_{10}O_5) + H_2O$. It is stored up in the liver cells in amorphous granules around the nuclei (Fig. 194, 2), but is not uniformly distributed in all parts of the liver. Like inulin, it gives a deep red color with solution of iodine in iodide of potassium. It is changed into dextrin and sugar by diastatic ferments, and when boiled with dilute mineral acids, it yields grape sugar (§ 148, I; § 170, I; § 252, III).

Preparation of Glycogen.—[Feed a rabbit on carrots or boiled rice, and kill it three or four hours thereafter. Remove the liver immediately after death, cut it into fine pieces, and place these in *boiling* water, and boil it for some time in order to obtain a watery extract of the liver. The boiling water destroys the ferment supposed to be present in the liver, which would transform the glycogen into grape sugar. To the cold filtrate are added alternately dilute hydrochloric acid and potassio-mercuric iodide, which precipitates the proteids. Filter, when a clear **opalescent fluid**, containing the glycogen in solution, is obtained. The glycogen is precipitated from the filtrate, as a white amorphous powder, on adding an excess of 70 to 80 per cent. alcohol. The precipitate is washed with 60 per cent. and afterward with 95 per cent. alcohol, then with ether, and lastly, with absolute alcohol; it is dried over sulphuric acid and weighed (*Brücke*). Külz modifies the method somewhat. After boiling the liver for half an hour, it is rubbed up with liquor potasse (100 grms. liver, 4 grms. KHO). Evaporate in the water bath until all is dissolved, which occurs in about 3 hours. After cooling, neutralize with HCl and precipitate the proteids as above. F. Eves asserts that the *post-mortem* conversion of sugar in the liver is not attributable to a ferment action, and the rapid appearance of sugar in the liver after death is due to the specific metabolic activity of the dying cells.]

Sources.—The "**mother substance**" of the glycogen of the liver has been variously stated to be the carbohydrates of the food (*Pavy*); fats (olive oil, *Salomon*); glycerine, taurin, and glycin (the latter splitting into glycogen and urea), the proteids (*Cl. Bernard*); and gelatin (*Salomon*). If it is derived from the albumins, it must be formed from a non-nitrogenous derivative thereof.

Rohmann found that the use of ammonia carbonate and asparagin or glycin, along with a carbohydrate diet, in rabbits considerably increased the formation of glycogen. The excessive formation of acid observed by Stadelmann in diabetes unites with the ammonia and diminishes considerably the formation of glycogen.

Effects of Food.—Rabbits, whose livers have been rendered free from glycogen by starvation, yield new glycogen from their livers when they are fed with cane sugar, grape sugar, maltose, or starch. Forced muscular movements soon make the liver of dogs free from glycogen, exposure to cold diminishes its amount. Dextrin and grape sugar occur in the dead liver, but, in addition, some glycogen is found for a considerable time after death in the liver and in the muscles.

If glycogen is injected into the blood, achroodextrin appears in the urine, and also hæmoglobin, as glycogen dissolves red blood corpuscles. Ligature of the bile duct causes decrease of the glycogen in the liver.

Other Situations.—Glycogen is not confined to the liver cells; it occurs during fœtal life in all the tissues of the body of the embryo [including the embryonic skeleton], in young animals (*Kühne*), the placenta (*Bernard*). [It occurs in large amount in the liver during intra-uterine life.] In the adult it occurs in the testicle, in the muscles (*MacDonnel, O. Nasse*), in numerous pathological products, in inflamed lungs (*Kühne*), and also in the corresponding tissues of the lower animals. It also occurs in the chorionic villi, in colorless blood corpuscles, in fresh pus cells which still exhibit amœboid movements, and in fact in all developing animal cells, with amœboid movement; it is a never failing constituent in cartilage, and in the muscles and liver of invertebrata, such as the oyster. There is none in the fresh brain of the dog or rabbit, but it is found in the brain in diabetic coma (*Abeles*).]

Modifying Conditions.—If large quantities of starch, milk-, fruit-, or cane-sugar, or glycerine, but not mannite, or glycol, or inosite, be added to the proteids of the food, the amount of glycogen in the liver is very greatly increased (to 12 per cent. in the fowl), while a purely albuminous or purely fatty diet diminishes it enormously. During hunger it almost disappears. The injection of dissolved carbohydrates into a mesenteric vein of a starving rabbit causes the liv viously free from glycogen to contain glycogen.

[**Effect of Drugs.**—Arsenic, phosphorus and antimony destroy the glycogenic function of the liver, no glycogen being present in the liver in animals poisoned with these drugs, so that puncture of the floor of the fourth ventricle no longer causes glycosuria in them. In animals poisoned by strychnia or curara, it is greatly diminished, both in the liver and in the muscles. Sugar is always present in the urine in the latter case but not in the former.]

During life, under normal conditions, the glycogen in the liver is either not transformed into grape sugar (*Pavy*), or, what is more probable, only a very small amount of it is so changed. The normal amount of sugar in blood is 0.5 to 1 per 1000, although the blood of the hepatic vein contains somewhat more. A considerable amount is transformed into sugar only when there is a decided derangement of the hepatic circulation, and in these circumstances the blood of the hepatic vein contains more sugar. The glycogen undergoes this change very rapidly after death, so that a liver which has been dead for some time always contains more sugar and less glycogen.

The diastatic ferment in the liver is small in amount, and can be obtained from the extract of the liver cells by the same means as are applicable for obtaining other similar ferments, such as ptyalin; but it does not seem to be formed within the liver cells, but only passes very rapidly from the blood into them. The ferment seems to be rapidly formed when the blood stream undergoes considerable derangement. A similar ferment is formed when red blood corpuscles are dissolved (*Tiegel*), and, as red blood corpuscles are continually destroyed within the liver, there is one source from which the ferment may be formed, whereby minute quantities of sugar would be continually formed in the liver.

According to Seegen, the **blood of the hepatic vein** contains twice as much sugar (0.23 per cent.) as that in the portal vein (0.119 per cent.); observations on dogs showed that the blood flowing through the liver gives up over 400 grms. sugar in 24 hours. Hence, in carnivora, the greatest part of the C of the animal food must pass into sugar, so that the formation of sugar in the liver, and its decomposition in the blood, or in the organs traversed by the blood, must be a very important function of the metabolism. Seegen is also of opinion that the liver glycogen takes no part in the formation of sugar in the liver.

[Blood when perfused through a freshly excised liver (or through the kidneys, lungs, or muscles), gains lactic acid (*G. Aglio and Wissokowitsch*).]

(3) **Fats**, in the form of highly refractive granules, occur in the liver cells, as well as free in the bile ducts; sometimes, when the food contains much fat (more abundant in drunkards and the phthisical), olein, palmatin, stearin, volatile fatty acids, and sarcolactic acid are found.

There are also found traces of cholesterin, minute quantities of urea, uric acid, and the little-known body jecorin. [**Jecorin**, discovered by Drechsel, contains S and P, and reduces alkaline solutions of copper like grape sugar. It is also found in the spleen, muscles, and blood (*Baldi*). The liver of birds contains a relatively large amount of uric acid, even 6 to 14 times as much as the blood (*v. Schræder*).] [Leucin (? guanin), sarkin, xanthin, cystin, and tyrosin occur pathologically in certain diseases where marked chemical decompositions occur.]

[**Fatty Degeneration and Infiltration.**—Fatty granules are of common occurrence within the cells of the liver, constituting fatty infiltration, and when not too numerous do not seem to interfere greatly with the functions of the liver cells. Fatty particles occur if too much fatty food be taken, and they are commonly found in the livers of stall-fed animals; the well-known *pâté-de-foi gras* is largely composed of the livers of geese, which have been fed on large amounts of farinaceous food, and which have been subjected to other unfavorable hygienic conditions. Fatty granules are recognized by their highly refractive appearance, by their solubility in ether, and by being blackened by osmic acid.]

(4) The **inorganic substances** in the human liver are—potassium, sodium, calcium, magnesium, iron, manganese, chlorine, and phosphoric, sulphuric, carbonic, and silicic acids; while copper, zinc, lead, mercury, and arsenic may be accidentally deposited in the hepatic tissue.

Tizzoni's Reaction.—If a section of a liver (especially of a young animal) hardened in alcohol be treated with a solution of potassic ferrocyanide, and then with dilute hydrochloric acid, as a general preparation becomes blue, even to the naked eye; but failing that, one can usually see with ranules of Prussian blue in the protoplasm of the cells, indicating the presence of free

175. DIABETES MELLITUS AND GLYCOSURIA.—[**Glycosuria** is characterized by the presence of **grape sugar** in the urine. According to Brücke a *trace* of sugar exists normally in urine, and when this amount is increased we have glycosuria. When the normal amount of grape sugar in the blood is increased, grape sugar appears in the urine. In **diabetes mellitus**, grape sugar also appears in the urine, but this is really a serious disease, involving the alteration of many tissues, and distinguished by profound disturbance of the whole metabolic activity, which leads to numerous pathological changes and often to death. The appearance of grape sugar in urine does not necessarily mean that a person is suffering from this disease.]

The formation of large quantities of grape sugar by the liver, and its passage into the blood, and from the blood into the urine, constitute glycosuria. Extirpation of the liver in frogs, or destruction of the hepatic cells, as by fatty degeneration from poisoning with phosphorus or arsenic, does not cause this condition. It occurs for several hours after the injury of a certain part—the centre for the hepatic vasomotor nerves—of the *floor of the lower part of the fourth ventricle* (*Cl. Bernard's* "piqûre"); also after section of the vasomotor channels in the spinal cord, from above down as far as the exit of the nerves for the liver, viz., to the lumbar region, and in the frog to the fourth vertebra (*Schiff*). When the vasomotor nerves, which proceed from this centre to the liver, are cut or paralyzed in any part of their course, melliturıa or glycosuria is produced. All the nerve channels do not run through the spinal cord alone. A number of vasomotor nerves leave the spinal cord higher up, pass into the sympathetic, and thus reach the liver; so that destruction of the superior (*Pavy*), as well as of the inferior cervical sympathetic ganglion, and the first thoracic ganglion (*Eckhara*) of the abdominal sympathetic, and often of the splanchnic itself produces it. The paralysis of the blood vessels causes the liver to contain much blood, and the intra-hepatic blood stream is slowed. The disturbance of the circulation causes a great accumulation of sugar in the liver, as the blood ferment has time to act upon the glycogen and transform it into sugar. By stimulation of the sympathetic at the lowest cervical and first thoracic ganglion, the hepatic vessels at the periphery of the liver lobules become contracted and pale (*Cyon*). It is remarkable that glycosuria when present may be set aside by section of the splanchnic nerves. This is explained by supposing that the enormous dilatation and congestion, or the hyperæmia of the abdominal blood vessels thereby produced, renders the liver anæmic.

Continued stimulation of peripheral nerves may act *reflexly* upon the centre for the vasomotor nerves of the liver. Diabetes has been observed to occur after stimulation of the central end of the vagus (*Cl. Bernard*), and also after stimulation of the central end of the depressor nerve (*Filehne*). Even section and subsequent stimulation of the central end of the sciatic nerve causes diabetes. This may explain the occurrence of diabetes in people who suffer from sciatica. [It may occur also after perverted nervous activity, as psychical excitement, neuralgias (sciatica, trigeminal or occipital), concussion of the brain, as well as after certain injuries to the skull and vertebral column and some cerebral diseases.]

According to Schiff, the stagnation of blood in other vascular regions of the body may cause the ferment to accumulate in the blood to such an extent that diabetes occurs. The glycosuria that occurs after compression of the aorta or portal vein may perhaps be ascribed to this cause, but perhaps the pressure caused by these procedures may paralyze certain nerves. According to Eckhard, injury to the vermiform process of the cerebellum of the rabbit causes diabetes. In man, affections of the above-named nervous regions cause diabetes.

[In most individuals the use of a large quantity of sugar in the food is not followed by the appearance of sugar in the urine; but in some exceptional cases it is often present, *e. g.*, in persons suffering from gastric catarrh, especially if they are gouty.]

A number of **poisons** which paralyze the hepatic vasomotor nerves produce diabetes; curara (when artificial respiration is not maintained), CO, amyl nitrite, ortho-nitro-propionic acid, and methyl-delphinin; less certainly morphia, chloral hydrate, HCN, and some other drugs; [phlorizin (*v. Mering*)]; and some infectious diseases. But congestion of the liver produced in other ways appears to cause diabetes, *e. g.*, after mechanical stimulation of the liver. To this class belongs the injection of

dilute saline solutions into the blood (*Bock, Hoffmann*), whereby either the change in form or the solution of the colored blood corpuscles causes the congestion. The circumstance that repeated blood letting makes the blood richer in sugar, may perhaps be explained by the slowing of the circulation.

[Most of the means which produce glycosuria in other animals fail to do so in birds; even the piqûre rarely produces it. This Thiel and Minkowski attribute to the intensely active oxidation processes in birds. Phlorizin causes glycosuria, even after extirpation of the liver, which shows that in these cases there are other causes at work that obtain in the forms of glycosuria.] Phlorizin makes animals which are free from carbohydrates diabetic. In this case the sugar must be derived from proteids (*v. Mering*).

Theoretical.—In order to explain the more immediate cause of these phenomena several hypotheses have been advanced:—

(*a*) The liver glycogen may be transformed unhindered into sugar, as the blood in its passage through the liver deposits or gives up the ferment to the liver cells. So that the normal function of the vasomotor system of the liver, and its centre in the floor of the fourth ventricle, may be regarded as, in a certain sense, an "inhibitory system" for the formation of sugar.

(*b*) If we assume that, normally there is continually a small quantity of sugar passing from the liver into the hepatic vein, we might explain the diabetes as due to the disappearance of these decompositions—diminished burning up of the sugar in the blood, which are constantly removing the sugar from the blood. In fact, diabetic persons have been found to consume less O and to have an increased formation of urea.

[**Injection of Grape Sugar into the Blood.**—When grape sugar is injected into the jugular vein of a dog, only 33 per cent. at most is given off in the urine; within 2 to 5 hours the urine is free from sugar. Even within a few minutes after the injection, only a certain proportion (½–¼) of the sugar is found in the blood; part of the sugar has been detected in the muscles, liver, and kidneys, but the fate of the remainder is not known. Immediately after the injection, the amount of hæmoglobin and also of serum-albumin is diminished (50 per cent.), which is due to increase of the quantity of water within the vessels; but within two hours the normal state is restored (*Brasol*). In a curarized dog the injection of grape sugar into a vein increase the blood pressure, but this effect is not observed after the injection of morphia and chloral.]

Persons suffering from diabetes require a large amount of food; they suffer greatly from thirst, and drink much fluid. They exhibit signs of marked emaciation, when the loss of the body is greater than the supply. [In advanced diabetes the glycogenic function of the liver is almost abolished, as was proved by removing with a trocar a small part of the liver from man, when almost no glycogen was found (*Ehrlich*). The absorbed sugar in the portal vein passes directly into the general circulation without being submitted to the action of the liver (*v. Frerichs*).] In severe cases, toward death, not unfrequently a peculiar comatose condition—**diabetic coma**—occurs, when the breath often has the odor of **aceton**, which is also found in the urine. But neither aceton nor its precursor, aceto-acetic acid, nor æthyl-diacetic acid, nor the unknown substance, in diabetic urine, which gives the red color with ferric chloride (*v. Jaksch*), is the cause of the coma (*Frerichs and Brieger*).

176. THE FUNCTIONS OF THE LIVER.—[To understand the functions of the liver, we must remember its **unique relation** to the vascular and digestive systems, whereby many of the products of gastric and intestinal digestion have to traverse it before they reach the blood, and some of them as they traverse the liver are altered. We have still much to learn regarding the liver. It has several distinct functions—some obvious, others not. (1) The liver secretes **bile**, which is formed by the hepatic cells, and leaves the organ by the bile ducts, to pass into the duodenum. (2) The liver cells also form **glycogen**, which does not pass into the ducts, but in some altered and diffusible form passes into the blood stream, and leaves the liver by the hepatic veins. Hence, the study of the liver materially influences our conception of a secreting organ. In this case, we have the products of its secretory activity leaving it by two different channels—the one by the ducts, and the other by the blood stream. The liver, therefore, is a great storehouse of carbohydrates, and it serves them out to the economy as they are required. All this points to the liver as being an organ intimately related to the **general metabolism** of the body. (3) In a certain period of development it is concerned in the formation of blood corpuscles (§ 7). (4) It has some relation to the breaking up of **blood corpuscles** and the formation of **urea** and other metabolic products (§ 20, § 177, 3). (5) Brunton attributes some importance to the liver in connection with the arrest of certain substances absorbed from the alimentary canal, whereby they are either destroyed, stored up in the liver, or, it may be, prevented from entering the general circula-

tion in too large amount. It is possible that ptomaines may be arrested in this way (§ 166).]

[The liver has no special action on certain mineral substances which traverse it in the blood, *e. g.*, potassic chloride, but it retains the vegetable alkaloids, provided they are not present in too large an amount in the blood. The ptomaines are similarly retained in the liver. The liver possesses this property only as long as it contains glycogen (*H. Rogers*).]

177. **CONSTITUENTS OF THE BILE.**—**Bile** is a yellowish-brown or dark green-colored transparent fluid, with sweetish, strongly bitter taste, feeble musk-like odor, and neutral reaction. The specific gravity of human bile from the gall bladder = 1026 to 1032, while that from a fistula = 1010 to 1011. It contains—

(1) **Mucus,** which gives bile its sticky character, and not unfrequently makes it alkaline; it is the product of the mucous glands and the goblet cells of the mucous membrane of the larger bile ducts. When bile is exposed to the air, the mucus causes it to putrefy rapidly. It is precipitated by acetic acid or alcohol.

[The bile formed in the ultimate bile ducts does not seem to contain mucin or mucus, but bile from the gall bladder always does. It is formed by the mucous glands in the larger bile ducts (§ 173).]

(2) **The Bile Acids.**—Glycocholic and taurocholic acids, so-called conjugate acids, are united with soda (in traces with potash) to form glycocholate and taurocholate of soda, which have a bitter taste, and rotate the plane of polarized light to the right. In human bile (as well as in that of birds, many mammals, and amphibians) taurocholic acid is most abundant; in other animals (pig, ox) glycocholic acid is most abundant but is absent in sucklings.

(*a*) **Glycocholic acid,** $C_{26}H_{43}NO_6$; when boiled with caustic potash, or baryta water, or with dilute mineral acids, it takes up H_2O and splits into—

Glycin (= Glycocoll = Gelatin Sugar = Amido-acetic acid) = $C_2H_5NO_2$.
+ Cholalic acid (also called Cholic acid), ... = $C_{24}H_{40}O_5$.
= Glycocholic acid + Water, ... = $C_{26}H_{43}NO_6 + H_2O$.

(*b*) **Taurocholic acid,** $C_{26}H_{45}NSO_7$, when similarly treated, takes up water and splits into—

Taurin (= Amido-æthyl-sulphuric acid) = $C_2H_7NSO_3$.
+ Cholalic acid, ... = $C_{24}H_{40}O_5$.
= Taurocholic acid + Water . . . . . = $C_{26}H_{45}NSO_7 + H_2O$ (*Strecker*.)

[Solutions of taurocholic acid are antiseptic, and if sufficiently strong interfere with the development of bacteria, and prevent the alcoholic and lactic fermentations, as well as the tryptic and diastatic action of the pancreas (*Emich*).]

Preparation of the Bile Acids.—Evaporate bile to ¼ of its volume, rub it up into a paste with excess of animal charcoal and dry at 100° C. Extract the black mass with absolute alcohol, and filter. After a part of the alcohol has been removed by distillation, the bile salts are precipitated in a resinous form, and on the addition of excess of ether, there is formed immediately a crystalline mass of glancing needles (**Platner's "crystallized bile"**). The alkaline salts of the bile acids are freely soluble in water or alcohol, and insoluble in ether. *Neutral* lead acetate precipitates the glycocholic acid—as lead glycocholate—from the solution of both salts; the precipitate is collected on a filter, dissolved in hot alcohol, and the lead is precipitated as lead sulphide by H_2S; after removal of the lead sulphide, the addition of water precipitates the isolated glycocholic acid. If, after precipitating the lead glycocholate, the filtrate be treated with *basic* lead acetate, a precipitate of lead taurocholate is formed, from which the acid may be obtained in the same way as described above (*Strecker*).

With regard to the **decomposition products** of the bile acids, **glycin,** as such, does not occur in the body, but only in the bile in combination with cholic acid, in urine in combination with benzoic acid, as hippuric acid, and lastly, in gelatin in complex combination.

Cholalic acid rotates the ray of polarized light to the right, and its chemical composition is unknown. It is insoluble in water, soluble in alcohol, but soluble with difficulty in ether, from which it separates in prisms. Its crystalline alkaline salts are readily soluble in water. It is colored blue by iodine, and occurs free only in the intestine.

Cholalic acid is replaced in the bile of many animals by a nearly related acid, *e. g.*, in pig's bile by hyo-cholalic acid (*Strecker*); in the bile of the goose, cheno-cholalic acid is present (*Marsson, Otto*).

When cholalic acid is boiled with concentrated HCl, or heated dry at 200° C., it becomes an anhydride, thus:—

Cholalic acid, . . . $= C_{24}H_{40}O_5$, produces
Choloidinic acid, . $= C_{24}H_{38}O_4 + H_2O$, and this again yields
Dyslysin, ... $= C_{24}H_{36}O_3 = H_2O$.

Choloidinic acid is, however, not improbably a mixture of cholalic acid and dyslysin; dyslysin, when fused with caustic potash, is changed into cholalate of potash. By oxidation cholalic acid yields a tribasic acid, as yet uninvestigated, and a fair amount of oxalic acid, but no fatty acids (*Cleve*).

Pettenkoffer's Test.—The bile acids, cholic acid, and their anhydrides, when dissolved in water, yield on the addition of $\frac{2}{3}$ concentrated sulphuric acid (added in drops so as not to heat the fluid above 70° C.), and several drops of a 10 per cent. solution of cane sugar, a *reddish-purple*, transparent fluid, which shows two absorption bands at E and F (*Schenk*). [A very good method is to mix a few drops of the cane-sugar solution with the bile, and to shake the mixture until a copious froth is obtained. Pour the sulphuric acid down the side of the test tube, and then the characteristic color is seen in the froth. Any albumin present must be removed before applying the test.]

According to Drechsel, it is better to add phosphoric acid, instead of sulphuric acid, until the fluid is syrupy, then add the cane sugar, and afterward place the whole in boiling water. When investigating the amount of bile acids in a liquid, the albumin must be removed beforehand, as it gives a reaction similar to the bile acids, but in that case the red fluid has only *one* absorption band. If only small quantities of bile acids are present, the fluid must in the first place be concentrated by evaporation.

[**Hay's Test.**—The bile acids or their soluble salts *lower the surface tension of fluids* in which they are dissolved. Throw a small quantity of sulphur (sublimed or precipitated) on the surface of the fluid containing bile acids, and if the bile acids be present, the sulphur will at once begin to sink, and will be wholly precipitated within a few minutes. (*Privately communicated.*)]

The **bile acids are formed** in the liver. After its extirpation, there is no accumulation of biliary matters in the blood.

How the formation of the nitrogenous bile acids is effected, is quite unknown. They must be obtained from the decomposition of albuminous materials, and it is important to note that the amount of bile acids is increased by albuminous food. Taurin contains part of the sulphur of albumin; bile salts contain 4 to 4.6 per cent., which may perhaps be derived from dissolved red blood corpuscles.

(3) **The Bile Pigments.**—The freshly secreted bile of man and many animals has a yellowish-brown color, due to the presence of **bilirubin**. When it remains for a considerable time in the gall bladder, or when alkaline bile is exposed to the air, the bilirubin absorbs O and becomes changed into a green pigment, **biliverdin.** This substance is present naturally, and is the chief pigment in the bile of herbivora and cold-blooded animals.

(*a*) **Bilirubin** ($C_{32}H_{36}N_4O_6$) is perhaps united with an alkali; crystallizes in transparent fox-red clinorhombic prisms. It is insoluble in water, *soluble in chloroform*, by which substance it may be separated from biliverdin, which is insoluble in chloroform. It unites as a monobasic acid with alkalies, and as such is soluble. It is identical with Virchow's hæmatoidin (§ 20).

Preparation.—It is most easily prepared from the red (bilirubin chalk) gall stones of man or the ox. The stones are pounded, and their chalk dissolved by hydrochloric acid; the pigment is then extracted with chloroform. That bilirubin is derived from hæmoglobin is very probable, considering its identity with hæmatoidin. Very probably red blood corpuscles are dissolved in the liver, and their hæmoglobin changed into bilirubin.

(*b*) **Biliverdin,** $C_{32}H_{36}N_4O_8$, is an oxidized derivative of the former, from which it can be obtained by various oxidation processes. It is readily *soluble in alcohol*, very slightly so in ether, and not at all soluble in chloroform. It occurs in the placenta of the bitch. As yet it has not been re-transformed by reducing agents into bilirubin.

Tests for Bile Pigments.—Bilirubin and biliverdin may occur in other fluids, *e. g.*, the urine, and are detected by the **Gmelin-Heintz' reaction.** When *nitric acid containing some nitrous acid* is added to a liquid containing these pigments, a play of colors is obtained, beginning with *green* (biliverdin), blue, violet, red, ending with yellow. [This reaction is best done by placing a drop of the liquid on a *white* porcelain plate, and adding a drop of the *impure* nitric acid.]

(*c*) If, when the blue color is reached, the oxidation process is arrested, **bilicyanin** (*Heynsius, Campbell*), in acid solution blue (in alkaline violet), is obtained, which shows two ill-defined absorption bands near D (*Jaffé*).

(*d*) **Bilifuscin** occurs in small amount in decomposing bile and in gall stones = bilirubin + H$_2$O.

(*e*) **Biliprasin** (*Städler*) also occurs = Bilirubin + H_2O + O.

(*f*) The yellow pigment, which ultimately results from the prolonged action of the oxidizing reagent, is the **choletelin** ($C_{16}H_{18}N_2O_6$) of Maly; it is amorphous, and soluble in water, alcohol, acids, and alkalies.

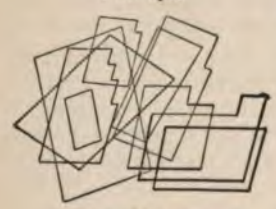
[**Spectrum of Bile.**—The bile of carnivorous animals is generally free from absorption bands, except when acids are added to it, in which case the band of bilirubin is revealed. Bilirubin and biliverdin yield characteristic spectra only when they are treated with nitric acid. The bile of some animals yields bands, but when this is the case they are due to the presence of a derivative of hæmatin, and MacMunn calls this body **cholohæmatin**, which gives a three- or four-banded spectrum (ox, sheep).]

(*g*) Bilirubin absorbs H + H_2O (by putrefaction, or by the treatment of alkaline watery solutions with the powerfully reducing sodium amalgam), and becomes converted into Maly's **hydrobilirubin** ($C_{32}H_{40}N_4O_7$), which is slightly soluble in water, and more easily soluble in solutions of salts, or alkalies, alcohol, ether, chloroform, and shows an absorption band at *b*, F. This substance, which, according to Hammarsten, occurs in normal bile, is a constant coloring matter of fæces and was called **stercobilin** by Vaulair and Masius, but is identical with hydrobilirubin (*Maly*). It is, however, probably identical with the urinary pigment *urobilin* of Jaffé (*Stokvis*, § 20).

[The bile of **invertebrates** contains none of the bile pigments present in vertebrates, although hæmochromogen is found in the cray-fish and pulmonate mollusks. In some organs, and in bile, a pigment-like vegetable chlorophyll—**entero-chlorophyll**—is found; but whether it is derived from without, or formed within the organism, is not certain (*MacMunn*).]

(4) **Cholesterin**, $C_{26}H_{44}O(H_2O)$, is a monatomic alcohol which rotates the ray of polarized light to the left; it occurs also in blood, yelk, nervous matter [and gall stones]. It forms transparent rhombic plates, which usually have a small oblong piece cut out of the corner (Fig. 196). It is insoluble in water, soluble in hot alcohol, ether, or chloroform. It is kept in solution in the bile by the bile salts.

FIG. 196.



Crystals of Cholesterin.

Preparation.—It is most easily prepared from so-called white gall stones, which not unfrequently consist entirely of cholesterin, by extracting them with hot alcohol after they are pulverized. Crystals are excreted after evaporation of the alcohol. **Tests.**—They give a red color with sulphuric acid (5 vols. to 1 vol. H_2O), while they give a blue—as cellulose does—with sulphuric acid and iodine. When dissolved in chloroform, one drop of concentrated sulphuric acid causes a deep red color (*H. Schiff*).

(5) Among the other organic constituents: **Lecithin** (§ 23), or its decomposition product, neurin (cholin), and glycero-phosphoric acid (into which lecithin may be artificially transformed by boiling with baryta); **palmatin, stearin, olein,** as well as their soda **soaps; diastatic ferment;** traces of **urea;** (in ox bile, acetic acid and propionic acid, united with glycerine and metals, *Dogiel*).

(6) **Inorganic constituents** of bile (0.6 to 1 per cent.):—

They are—sodic and potassic chloride, calcic and magnesic phosphate, and much iron, which in fresh bile gives the ordinary reactions for iron, so that iron must occur in one of its oxidized compounds in bile; manganese and silica. **Gases.**—Freshly-secreted bile contains in the dog more than 50 vols., and in the rabbit 109 vols. per cent. CO_2, partly united to alkalies, partly absorbed, the latter, however, being almost completely absorbed within the gall bladder.

The **mean composition** of **human bile** is:—

Water, ...	82 to 90 per cent.	Lecithin, ...	0.5 per cent.
Bile salts, ...	6 to 11 "	Mucin and pigments, .	1 to 3 "
Fat and soaps, ...	2 "	Ash, ...	0.61 "
Cholesterin, ...	0.4 "		

Further, unchanged fat probably always passes into the bile, but it is again absorbed therefrom (*Virchow*). The amount of S in dry dog's bile = 2.8 to 3.1 per cent., the N = 7 to 10 per cent. (*Spiro*); the sulphur of the bile is not oxidized into sulphuric acid, but it appears as a sulphur compound in the urine (*Kunkel, v. Voit*).

178. SECRETION OF BILE.—(1) **The secretion of bile** is not a mere filtration of substances already existing in the blood of the liver, but it is a chemical production of the characteristic biliary constituents, accompanied by oxidation, within the hepatic cells, to which the blood of the gland only supplies the raw material. The liver cells themselves undergo histological changes during the process of digestion. It is secreted continually; but part is stored up in the gall bladder, and is poured out copiously during digestion. The higher temperature of the blood of the hepatic vein, as well as the large amount of CO_2 in the bile, indicates that oxidations occur within the liver. The water of the bile is not merely filtered through the blood capillaries, as the pressure within the bile ducts may exceed that in the portal vein.

(2) **The quantity of bile** was estimated by v. Wittich, from a biliary fistula, at 533 cubic centimetres in twenty-four hours (some bile passed into the intestine); by Westphalen, at 453 to 566 grms. [by Murchison, at 40 oz.]; by Joh. Ranke, on a biliary-pulmonary fistula, at 652 cubic centimetres. The last observation gives 14 grms. (with 0.44 grms. solids) per kilo. of man in twenty-four hours.

Analogous values for animals are—1 kilo. dog, 32 grms. (1.2 solids); 1 kilo. rabbit, 137 grms. (2.5 solids); 1 kilo. guinea pig, 176 grms. (2.5 solids).

(3) **The excretion** of bile into the intestine shows two maxima *during one period of digestion;* the first from 3 to 5 hours, and the second from 13 to 15 hours, after food. The cause is due to simultaneous reflex excitement of the hepatic blood vessels, which become greatly dilated.

(4) **The influence of food** is very marked. The largest amount is secreted after a flesh diet, with some fat added; less after vegetable food; a very small amount with a pure fat diet; it stops during hunger. Draughts of water increase the amount, with a corresponding relative diminution of the solid constituents. [The biliary solids are increased by food, reaching their maximum about one hour after feeding.]

(5) **The influence of blood supply** is variable:—

(*a*) Secretion is greatly favored by a copious and rapid blood supply. The blood pressure is not the prime factor, as ligature of the cava above the diaphragm, whereby the greatest blood pressure occurs in the liver, *arrests* the secretion.

(*b*) Simultaneous ligature of the hepatic artery (diameter, 5½ mm.) and the portal vein (diameter, 16 mm.) abolishes the secretion (*Röhrig*). These two vessels supply the raw material for the secretion of bile.

(*c*) If the hepatic artery be ligatured, the portal vein alone supports the secretion. Ligature of the artery or one of its branches ultimately causes necrosis of the parts supplied by that branch, and eventually of the entire liver, as this artery is the nutrient vessel of the liver.

(*d*) If the branch of the portal vein to one lobe be ligatured, there is only a slight secretion in that lobe, so that the bile must be formed from the arterial blood. Complete ligature of the portal vein rapidly causes death (§ 87). Neither ligature of the hepatic artery by itself, nor *gradual* obliteration of the portal vein by itself, causes cessation of the secretion, but it is diminished. That *sudden* ligature of the portal vein causes cessation is due to the fact that, in addition to diminution of the secretion, the enormous stagnation of blood in the rootlets of the portal vein in the abdominal organs makes the liver very anæmic, and thus prevents it from secreting.

(*e*) If the blood of the hepatic artery is allowed to pass into the portal vein (which has been ligatured on the peripheral side), secretion continues (*Schiff*).

(*f*) Profuse loss of blood arrests the secretion of bile before the muscular and nervous apparatus are paralyzed. A more copious supply of blood to other organs—*e. g.*, to the muscles of the trunk—

during vigorous exercise, diminishes the secretion, while the transfusion of large quantities of blood increases it, but if too high a pressure is caused in the portal vein, by introducing blood from the carotid of another animal, it is diminished.

(*g*) **Influence of Nerves.**—All conditions which cause contraction of the abdominal blood vessels, *e. g.*, stimulation of the ansa Vieussenii, of the inferior cervical ganglion, of the hepatic nerves, of the splanchnics, of the spinal cord (either directly by strychnia, or reflexly through stimulation of sensory nerves), affect the secretion; and so do all conditions which cause stagnation or congestion of the blood in the hepatic vessels (section of the splanchnic nerves, diabetic puncture, § 175), section of the cervical spinal cord. Paralysis (ligature) of the hepatic nerves causes *at first* an increase of the biliary secretion.

(*h*) **Portal and Hepatic Veins.**—With regard to the raw material supplied to the liver by its blood vessels, it is important to note the difference in the composition of the blood of the hepatic and portal veins. The blood of the hepatic vein contains *more* sugar (?), lecithin, cholesterin (*Drosdoff*), and blood corpuscles, but *less* albumin, fibrin, hæmoglobin, fat, water, and salts.

[(*i*) Uffelmann observed that the flow of bile from a person with a biliary fistula was arrested during fever.]

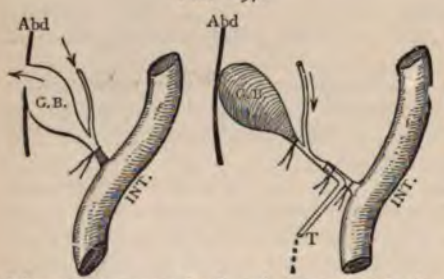
(6) The formation of bile is largely dependent upon the **decomposition of red blood corpuscles**, as they supply the material necessary for the formation of some of its constituents.

Hence, all conditions which cause solution of the colored blood corpuscles are accompanied by an increased formation of bile (§ 180).

(7) Of course a normal condition of the hepatic cells is required for a normal secretion of bile.

Biliary Fistulæ.—The mechanism of the biliary secretion is studied in animals by means of biliary fistulæ. Schwann opened the belly by a vertical incision a little to the right of the ensiform process, cut into the fundus of the gall bladder, and sewed its margins to the edges of the wound in the abdomen, and afterward introduced a cannula into the wound (Fig. 197). To secure that all the bile is discharged externally, tie the common bile duct in two places and divide it between the two ligatures. After a fistula is freshly made the secretion falls. This depends upon the removal of the bile from the body. If bile be supplied, the secretion is increased. Regeneration of the divided bile duct may occur in dogs. V. Wittich observed a biliary fistula in man. [A temporary biliary fistula may also be made. The abdomen is opened in the same way as described above. A long bent glass cannula is introduced and tied into the common bile duct, and the cystic duct is ligatured or clamped (Fig. 197). The tube is brought out through the wound in the abdomen.

FIG. 197.



Schwann's permanent fistula, and a temporary fistula. *Abd*, abdominal wall; G. B., gall bladder; INT., intestine; T., tube in temporary fistula (*Stirling*).

[**Influence of the Liver on Metabolism.**—If the liver be excluded from the circulation, important changes must necessarily occur in the metabolism. In **birds** (the goose) there is an anastomosis between the portal system of the liver and that of the kidneys, so that, when the portal circulation is interrupted in these animals, there is never any great congestion in the abdominal organs. The goose dies generally eight to ten hours after the operation. The *uric acid* in the urine rapidly falls to a minimum ($\frac{1}{10}$ to $\frac{1}{30}$ of normal); the chief constituent of the urine is then sarcolactic acid, while in normal urine there is none; the ammonia is increased (*Minkowski*). This experiment goes to indicate that uric acid is formed in the liver. **Dog.**—If the liver be excluded from the portal circulation, by connecting the portal vein with the inferior vena cava, and ligaturing the hepatic artery, a dog will live in the former case three to six days, and in the latter one to two. The liver does not undergo necrosis, nor does bile cease to be secreted. The liver is nourished by the blood in the hepatic vein, the reflux in this vein being probably caused by the respiratory movements (*Stolnikow*). Noël Paton finds that in dogs, in a condition of nitrogenous balance, some drugs which increase the flow of bile (*e. g.*, salicylate and benzoate of soda, colchicum, perchloride of mercury, and euonymin) also increase the production of urea; hence, he concludes that the formation of urea in the liver bears a very direct relationship to the secretion of bile (§ 256).]

179. EXCRETION OF BILE.—[In this connection we must keep in view two distinct mechanisms. (1) The **bile-secreting mechanism** dependent upon the liver cells, which are always in a greater or less degree of activity;

(2) the **bile-expelling mechanism,** which is specially active at certain periods of digestion (§ 178).

Excretion of bile is due to (1) the continual pressure of the newly-formed bile within the inter-lobular bile ducts forcing onward the bile in the excretory ducts.

(2) The interrupted **periodic compression of the liver** from above, by the diaphragm, at every inspiration. Further, every inspiration assists the flow of blood in the hepatic veins, and every respiratory increase of pressure within the abdomen favors the current in the portal vein.

It is probable that the diminution of the secretion of bile, which occurs after bilateral division of the vagi, is to be explained in this way; still, it is to be remembered that the vagus sends branches to the hepatic plexus. It is not decided whether the biliary secretion is diminished after section of the phrenic nerves and paralysis of the abdominal muscles.

(3) The *contraction of the smooth muscles* of the larger bile ducts and the gall bladder. Stimulation of the spinal cord, from which the motor nerves for these structures pass, causes acceleration of the outflow, which is afterward followed by a diminished outflow. Under normal conditions, this stimulation seems to occur reflexly, and is caused by the passage of the ingesta into the duodenum, which, at the same time, excites movement of this part of the intestine.

(4) Direct stimulation of the liver, and reflex stimulation of the spinal cord, diminish the excretion; while extirpation of the hepatic plexus and injury to the floor of the fourth ventricle do not exert any disturbing influence.

(5) A relatively small amount of resistance causes bile to stagnate in the bile ducts.

Secretion Pressure.—A manometer, tied into the gall bladder of a guinea pig, supports a column of 200 millimetres of *water;* and secretion can take place under this pressure. If this pressure be increased, or too long sustained, the watery bile passes from the liver into the blood, even to the amount of four times the weight of the liver, thus causing solution of the red blood corpuscles by the absorbed bile; and very soon thereafter hæmoglobin appears in the urine. [This fact is of practical importance, as duodenitis may give rise to symptoms of jaundice, the resistance of the inflamed mucous membrane being sufficient to arrest the outflow of bile.]

Passage of Substances into the Bile.—Some substances which enter the blood pass into the bile; especially the metals, copper, arsenic, iron, etc.; potassium iodide, bromide, and sulphocyanide and turpentine; to a less degree, cane sugar and grape sugar; sodium salicylate, and carbolic acid. If a large amount of water be injected into the blood, the bile becomes albuminous; mercuric and mercurous chlorides cause an increase of the water of the bile. Sugar has been found in the bile in diabetes; leucin and tyrosin in typhus, lactic acid and albumin in other pathological conditions of this fluid.

180. **REABSORPTION OF BILE; JAUNDICE.—I. Absorption Jaundice.**—When resistance is offered to the outflow of bile into the intestine, *e. g.*, by a plug of mucus, or a gall stone which occludes the bile duct, or where a tumor or pressure from without makes it impervious—the bile ducts become filled with bile and cause an enlargement of the liver. The pressure within the bile ducts is increased. As soon as the pressure has reached a certain amount, which it soon does when the bile duct is occluded (in the dog 275 mm. of a column of bile), reabsorption of bile from the distended larger bile ducts takes place into the *lymphatics* (not the blood vessels) of the liver, the bile acids pass into the lymphatics of the liver. [The lymphatics can be seen at the portal fissure filled with yellow colored lymph.] The lymph passes into the thoracic duct, and so into the blood (*Fleischl*). Even when the pressure is very low within the portal vein, bile may pass into the blood without any obstruction to the bile duct being present. This is the case in Icterus neonatorum, as after ligature of the umbilical cord no more blood passes through the umbilical vein; further, in the icterus of hunger, "hunger jaundice" as the portal vein is relatively empty, owing to the feeble absorption from the intestinal canal (*Cl. Bernard*).

II. Cholæmia may also occur, owing to the excessive production of bile (hypercholia), the bile not being all excreted into the intestine, so that part of it is reabsorbed. This takes place when there is solution of a great number of blood corpsucles (§ 178, 6), which yield material for the formation of bile. Thick, inspissated bile accumulates in the bile ducts, so that stagnation, with subsequent reabsorption of the bile, takes place. The tranfusion of heterogeneous blood obtained by dissolving colored blood corpuscles acts in this direction. Icterus is a common phenomenon after too copious transfusion of the same blood. The blood corpuscles are dissolved by the injection into the blood of heterogeneous blood serum, by the injection of bile acids into the vessels, and by other salts, by

phosphoric acid, water, chloral, inhalation of chloroform and ether; the injection of dissolved hæmoglobin into the arteries or into a loop of the small intestine acts in the same way.

Icterus Neonatorum.—When, owing to compression of the placenta within the uterus, too much blood is forced into the blood vessels of the newly-born infant, a part of the surplus blood during the first few days becomes dissolved, part of the hæmoglobin is converted into bilirubin, thus causing jaundice (*Virchow, Violet*).

Absorption Jaundice.—When the jaundice is caused by the absorption of bile already formed in the liver, it is called hepatogenic or absorption jaundice. The following are the **symptoms:—**

(1) Bile pigments and bile acids pass into the tissues of the body; hence, the most pronounced external symptom is the yellowish tint or *jaundice*. The skin and the sclerotic become deeply colored **yellow.** In pregnancy the fœtus is also tinged.

(2) Bile pigments and bile acids pass into the **urine** (not into the saliva, tears, or mucus) (§ 177). When there is much bile pigment, the urine is colored a deep yellowish brown, and its froth is citron yellow; while strips of gelatin or paper dipped into it also become colored. Occasionally bilirubin (= hæmatoidin) crystals occur in the urine (§ 266).

(3) The **fæces** are "*clay colored*" (because the hydrobilirubin of the bile is absent from the fecal matter)—*very hard* (because the fluid of the bile does not pass into the intestine); contain much *fat* (in globules and crystals), because the fat is not sufficiently digested in the intestine without bile, so that 78 per cent. of the fat taken with the food reappears in the fæces (*v. Voit*); they have a very *disagreeable odor*, because the bile normally greatly limits the putrefaction in the intestine. [V. Voit finds that putrefaction does not take place if fats be withheld from the food.] The *evacuation of the fæces* occurs *slowly*, partly owing to the hardness of the fæces, partly because of the absence of the peristaltic movements of the intestine, owing to the want of the stimulating action of the bile.

(4) The **heart beats** are greatly diminished, *e.g.*, to 40 per minute. This is due to the action of the bile salts, which at first stimulate the cardiac ganglia, and then weaken them. Bile salts injected into the heart produce at first a temporary acceleration of the pulse, and afterward slowing (*Röhrig*). The same occurs when they are injected into the blood, but in this case the stage of excitement is very short. The phenomenon is not affected by section of the vagi. It is probable, that when the action of the bile salts is long continued, they act upon the heart muscle. In addition to the action on the heart, there is **slowing of the respiration** and **diminution of temperature.**

(5) That the **nervous system,** and perhaps also the muscles, are affected, either by the bile salts or by the accumulation of cholesterin in the blood, is shown by the very general relaxation, sensation of fatigue, weakness, drowsiness, and lastly, deep coma—sometimes there is sleeplessness, itchiness of the skin, even mania, and spasms. Löwit, after injecting bile into animals, observed phenomena referable to stimulation of the respiratory, cardio-inhibitory, and vasomotor nerve centres.

(6) In very pronounced jaundice there may be "*yellow vision*," owing to the impregnation of the retina and macula lutea with the bile pigment.

(7) The bile acids in the blood dissolve the red blood corpuscles. The hæmoglobin is changed into new bile pigment, and the globulin-like body of the hæmoglobin may form urinary cylinders or casts in the urinary tubules, which are ultimately washed out of the tubules by the urine.

[**Influence of Drugs on the Secretion of Bile.**—On animals one may make either a permanent or a temporary fistula. The latter is the more satisfactory method, and the experiments are usually made on fasting curarized dogs. A suitable cannula is introduced into the common bile duct (Fig. 197), the animal is curarized, artificial respiration being kept up, while the drug is injected into the stomach or intestine. Röhrig used this method, which was improved by Rutherford and Vignal. Röhrig found that some purgatives, croton oil, colocynth, jalap, aloes, rhubarb, senna, and other substances, increased the secretion of bile. Rutherford and Vignal investigated the action of a large number of drugs on the **bile-secreting mechanism.** They found that croton oil is a feeble hepatic stimulant, while podophyllin, aloes, colchicum, euonymin, iridin, sanguinarin, ipecacuan, colocynth, sodium phosphate, phytolaccin, sodium benzoate, sodium salicylate, dilute nitro-hydrochloric acid, ammonium phosphate, mercuric chloride (corrosive sublimate), are all powerful, or very considerable, hepatic stimulants. Some substances stimulate the intestinal glands, but not the liver, *e.g.*, magnesium sulphate, castor oil, gamboge, ammonium chloride, manganese sulphate, calomel. Other substances stimulate the liver as well as the intestinal glands, although not to the same extent, *e.g.*, scammony (powerful intestinal, feeble hepatic stimulant); colocynth excites both powerfully; jalap, sodium sulphate, and baptisin, act with considerable power both on the liver and the intestinal glands. Calabar bean stimulates the liver, and the increased secretion caused thereby may be reduced by sulphate of atropin, although the latter drug, when given alone, does not notably affect the secretion of bile. The injection of water or bile slightly increases the secretion. In all cases where purgation was produced by purely intestinal stimulants, such as magnesium sulphate, gamboge, and castor oil, the secretion of bile was diminished. In all such experiments it is most important that the *temperature of the animal be kept up*, else the secretion of bile diminishes. Paschkis's results on dogs differ considerably from those of Rutherford. He asserts that only the bile acids (salts) of all the substances he investigated excite a prompt and distinct cholagogue action.]

[As yet we cannot say definitely whether or not these substances stimulate the secretion of bile, by exciting the mucous membrane of the small intestine, and thereby inducing reflex excitement of the liver. Their action does not seem to be due to increase of the blood stream through the liver. More probably, as Rutherford suggests, these drugs act directly on the hepatic cells or their nerves. Acetate of lead directly depresses the biliary secretion, while some substances affect it indirectly.]

[**Cholesteræmia.**—Flint ascribes great importance to the excretion of cholesterin by the bile, with reference to the metabolism of the nervous system. Cholesterin, which is a normal ingredient of nervous tissue, is excreted by the bile; and if it be retained in the blood "cholesteræmia," with grave nervous symptoms, is said to occur. This, however, is problematical, and the phenomena described are probably referable to the retention of the bile acids in the blood.]

181. FUNCTIONS OF THE BILE.—[(1) Bile is concerned in the digestion of certain food stuffs; (2) part is absorbed; (3) part is excreted.]

(**A**) Bile plays an important part in the **absorption of fats**:—

(1) It *emulsionizes neutral fats*, whereby the fatty granules pass more readily through or between the cylindrical epithelium of the small intestine into the lacteals. It does *not* decompose neutral fats into glycerine and a fatty acid, as the pancreas does (§ 170, III).

When, however, fatty acids are dissolved in the bile, the bile salts are decomposed, the bile acids being set free, while the soda of the decomposed bile salts readily forms a soluble soap with the fatty acids. These soaps are soluble in the bile, and increase considerably the emulsifying power of this fluid. Bile can dissolve fatty acids to form an acid fluid, which has high emulsionizing properties (*Steiner*). Emulsification is influenced by a 1 per cent. solution of NaCl, or Na_2SO_4.

(2) As fluid fat flows more easily through capillary tubes moistened with bile, it is concluded that when the pores of the wall of the small intestine are moistened with bile, the fatty particles pass more easily through them.

(3) Filtration of fat takes place through a membrane moistened with bile or bile salts under less pressure than when it is moistened with water or salt solution (*v. Wistinghausen*).

(4) As bile, like a solution of soap, has a certain relation to watery solutions, as well as to fats, it permits diffusion to take place between these two fluids, as the membrane is moistened by both fluids.

It is clear, therefore, that the bile is of great importance in the absorption of fats. This is strikingly illustrated by experiments on animals, in which the bile is entirely discharged externally through a fistula. Dogs, under these conditions, absorbed at most 40 per cent. of the fat taken with the food [60 per cent. being given off by the fæces, while a normal dog absorbs 99 per cent. of the fat]. The chyle of such animals is very poor in fat, is not white but transparent; the fæces, however, contain much fat, and are oily; the animals have a ravenous appetite; the tissues of the body contain little fat, even when the nutrition of the animals has not been much interfered with. Persons suffering from disturbances of the biliary secretion, or from liver affections, ought, therefore, to abstain from fatty food. [The digestion of flesh and gelatin is not interfered with in dogs by the removal of the bile (*v. Voit*).]

(**B**) Fresh bile contains a **diastatic ferment**, which transforms starch into sugar, and also glycogen into sugar.

(**C**) Bile excites **contractions of the muscular coats** of the intestine, and contributes thereby to absorption.

(1) The bile acids act as a stimulus to the **muscles of the villi**, which contract from time to time, so that the contents of the origins of the lacteals are emptied toward the larger lymphatics, and the villi are thus in a position to absorb more. [The villi act like numerous small pumps, and expel their contents, which are prevented from returning by the presence of valves in the larger lymphatics.]

(2) The **musculature of the intestine** itself seems to be excited, perhaps through the agency of the plexus myentericus. In animals with a biliary fistula, and in which the bile duct is obstructed, the intestinal peristalsis is greatly diminished, while the salts of the bile acids administered by the mouth causes diarrhœa and vomiting. As contraction of the intestine aids absorption, bile is also necessary in this way for the absorption of the dissolved food stuffs.

(**D**) The presence of bile seems to be necessary to the vital activity of the intestinal epithelium in its supposed function of being concerned in the absorption of fatty particles (§ 190).

(**E**) Bile moistens the wall of the intestines, and gives to the fæces their normal

amount of water, so that they can be readily evacuated. Animals with biliary fistula, or persons with obstruction of the bile ducts, are very costive. The mucus aids the forward movement of the ingesta through the intestinal canal. [Thus, in a certain sense, bile is a *natural purgative*.]

(**F**) The bile diminishes putrefactive decomposition of the intestinal contents, especially with a fatty diet, § 190. [Thus, it is an **antiseptic**, although this is doubted by v. Voit.]

(**G**) When the strongly acid contents of the stomach pass into the duodenum, the glycocholic acid is precipitated by the gastric acid, and carries the pepsin with it (*Burkart*). Some of the albumin, which has been simply *dissolved* (but not peptone or propeptone), is also precipitated, by the taurocholic acid (*Maly and Emich*). The bile salts are decomposed by the acid of the gastric juice. When the mixture is rendered alkaline by the pancreatic juice and the alkali derived from the decomposition of the bile salts, the pancreatic juice acts energetically in this alkaline medium (*Moleschott*).

[Taurocholic acid and its soda salts precipitate albumin, but not peptone; glycocholic acid does not precipitate albumin, so that in the intestine the peptone is separated from the albumin (and syntonin), and may therefore be more readily absorbed, while the precipitate adhering to the intestinal wall can be further digested (*Maly and Emich*). Taurocholic acid behaves in the same way toward gelatin peptone.]

Bilious Vomit.—When bile passes into the stomach, as in vomitittg, the acid of the gastric juice unites with the bases of the bile salts; sodium chloride and free bile acids are formed, and the acid reaction is thereby somewhat diminished. The bile acids cannot carry on gastric digestion; the neutralization also causes a precipitation of the pepsin and mucin. As soon, however, as the walls of the stomach secrete more acid, the pepsin is redissolved. The bile which passes into the stomach deranges gastric digestion, by shriveling the proteids, which can only be peptonized when they are swollen up (p. 295).

182. **FATE OF THE BILE.**—Some of the biliary constituents are completely evacuated with the fæces, while others are reabsorbed by the intestinal walls.

(1) **Mucin** passes unchanged into the fæces.

(2) **The bile pigments** are reduced, and are partly excreted with the fæces as **hydrobilirubin**, and partly as the identical end-product **urobilin** by the urine (§ 177, 3 *g*).

From **meconium** hydrobilirubin is absent, while crystalline bilirubin and biliverdin, and an unknown red oxidation product of them, are present [bile acids, even taurocholic, and small trace of fatty acids] (*Zweifel*), so that it gives Gmelin's reaction. Hence, no reduction—but rather oxidation—processes occur in the fœtal intestine. [**Composition.**—Dary gives 72.7 per cent. water, 23.6 mucus and epithelium, 1 per cent. fat and cholesterin, and 3 per cent. bile pigments. Zweifel gives 79.78 per cent water, and solids 20.22 per cent. It does not contain lecithin, but so much bilirubin that Hoppe-Seyler uses it as a good source whence to obtain this pigment. It gives a spectrum of a body related to urobilin.]

(3) **Cholesterin** is given off with the fæces.

(4) The **bile salts** are for the most part reabsorbed by the walls of the jejunum and ileum, to be re-employed in the animal's economy. Tappeiner found them in the chyle of the thoracic duct—minute quantities pass normally from the blood into the urine. Only a very small amount of glycocholic acid appears unchanged in the fæces. The taurocholic acid, as far as it is not absorbed, is easily decomposed in the intestine, by the putrefactive processes, into cholalic acid and taurin; the former of these is found in the fæces, but the taurin at least seems not to be constantly present. Part of the cholalic acid is absorbed, and may unite in the liver either with glycin or taurin (*Weiss*).

(5) The fæces contain mere traces of **lecithin.**

Impaired Nutrition.—The greatest part of the most important biliary constituents, the bile acids, re-enter the blood, and thus is explained why animals with a biliary fistula, where all the bile is removed (without the animal being allowed to lick the bile), rapidly lose weight. This depends partly upon the digestion of the fats being interfered with, and also upon the direct loss of the bile salts. If

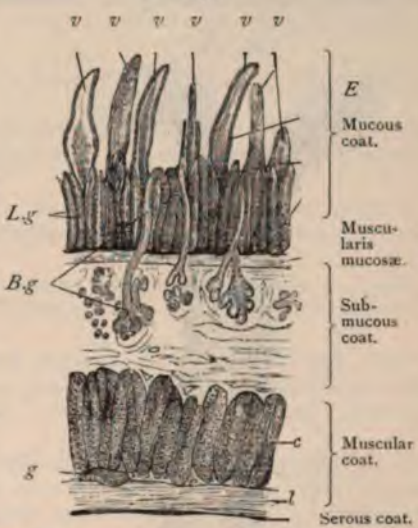
such dogs are to maintain their weight, they must eat twice as much food. In such cases, carbohydrates most beneficially replace the fats. If the digestive apparatus is otherwise intact, the animals, on account of their voracity, may even increase in weight, but the flesh and not the fat is increased.

Bile partly an Excretion.—The fact that bile is secreted during the fœtal period, while none of the other digestive fluids is, proves that it is an *excretion.*

The **cholalic acid** which is reabsorbed by the intestinal walls passes into the body and seems ultimately to be burned to form CO_2 and H_2O. The **glycin** (with hippuric acid) forms urea, as the urea is increased after the injection of glycin. The fate of **taurin** is unknown. When large quantities are introduced into the human stomach, it reappears in the urine as tauro-carbamic acid, along with a small quantity of unchanged taurin. When injected subcutaneously into a rabbit, nearly all of it reappears in the urine.

[**Practical.**—In practice it is important to remember that bile once in the intestine is liable to be absorbed unless it be carried down the intestine; hence, it is one thing to give a drug which will excite the secretion of bile, *i. e.*, a hepatic stimulant, and another to have the bile so secreted expelled. It is wise, therefore, to give a drug which will do both, or at least to combine a hepatic stimulant with one which will stimulate the musculature of the intestine as well. *Active exercise*, whereby the diaphragm is vigorously called into action to compress the liver, will aid in the expulsion of the bile from the liver (*Brunton*).]

FIG. 198.



Vertical section of duodenum (cat), × 30. *E*, epithelium; *c* and *l*, circular and longitudinal muscular fibres; *L.g*, Lieberkühn's glands; *B.g*, Brunner's glands, *g*, ganglion cells; *v*, villi.

183. THE INTESTINAL JUICE.—Length of Intestine.—The human intestine is ten times longer than the length of the body, as measured from the vertex to the anus. It is longer comparatively than that of the omnivora. Its minimum length is 507, its maximum 1194 centimetres [17 to 35 feet]; its capacity is relatively greater in children (*Beneke*).

The **succus entericus** is the digestive fluid secreted by the numerous glands of the intestinal mucous membrane. The largest amount is produced by Lieberkühn's glands, while in the duodenum there is added the scanty secretion of Brunner's glands.

Brunner's glands are small, branched, tubular glands, lying in the sub-mucosa of the duodenum. Their fine ducts run inward, pierce the mucous membrane, and open at the bases of the villi (Fig. 198). The acini are lined by cylindrical cells, like those lining the pyloric glands. In fact, Brunner's glands are structurally and anatomically identical with the pyloric glands of the stomach. During hunger, the cells are turbid and small, while during digestion they are large and clear. The glands receive nerve fibres from Meissner's plexus (*Drasch*).

I. The Secretion of Brunner's Glands.—The granular contents of the secretory cells of these glands, which occur singly in man, but form a continuous layer in the duodenum of the sheep, besides *proteids*, consist of *mucin* and a *ferment substance* of unknown constitution. The watery extract of the glands causes (1) Solution of proteids at the temperature of the body (*Krolow*). (2) It also has a diastatic action. It converts maltose into glucose (*Brown and Heron*). It does not appear to act upon fats.

On account of the smallness of the objects, such experiments are only made with great difficulty, and, therefore, there is a considerable uncertainty with regard to the action of the secretion.

Lieberkühn's glands are simply tubular glands resembling the finger of a glove [or a test-tube], which lie closely packed, vertically near each other, in the mucous membrane (Fig. 199); they are most numerous in the large intestine, owing to the absence of villi in this region. They consist of a structureless membrana propria lined by a single layer of low cylindrical epithelium, between which numerous goblet cells occur, the goblet cells being fewer in the small intestine and much more numerous in the large (Fig. 199). The glands of the small intestine yield a thin secretion, while those of

the large intestine yield a large amount of sticky mucus from their goblet cells (*Klose and Heidenhain*). [In a vertical section of the small intestine they lie at the base of the villi (Fig. 198). In transverse section they are shown in Fig. 200.]

II. The Secretion of Lieberkühn's Glands, from the duodenum onward, is the chief source of the intestinal juice.

Intestinal Fistula.—The intestinal juice is obtained by making a **Thiry's Fistula** (1864). A loop of the intestine of a dog is pulled forward (Fig. 201, 1), and a piece about 4 inches in length is cut out, so that the continuity of the intestinal tube is broken, but the mesentery and its blood vessels are not divided. One end of this tube is closed, and the other end is left open and stitched to the abdominal wall (Fig. 201, 3). The two ends of the intestine from which this piece was taken are brought together with sutures, so as to establish the continuity of the intestinal canal (Fig. 201, 2). The excised piece of intestine yields a secretion which is uncontaminated with any other digestive

Scheme of Thiry's Fistula. 1, 2, 3, 4, Vella's Fistula. AA' are stitched together; *Abd*, Abdominal wall (*Stirling*).

secretion. [Thiry's method is very unsatisfactory, as judged from the action of the separated loop in relation to medicaments, probably owing to its mucous membrane becoming atrophied from disuse, or injured by inflammation.]

[**Meade Smith** makes a small opening in the intestine, through which he introduces two small collapsed india-rubber balls, one above and the other below the opening, which are then distended by inflation until they completely block a certain length of the intestine. The loop thus blocked off, having been previously well washed out, is allowed to become filled with succus, which is secreted on the application of various stimuli. By means of Bernard's gastric cannula (§ 165) inserted into the fistula in the loop, the secretion can be removed when desired.]

[**Vella's Fistula.**—Open the belly of a dog, and pull out a loop (30 to 50 ctm.) [1 to 1½ feet] of small intestine, and ligature it; divide it above and below, re-establish the continuity of the rest of the intestine. Stitch *both* ends of the loop of intestine into the wound in the linea alba (Fig. 201, 4), so that there is a loop of intestine supplied by its blood vessels and nerves, isolated and with an upper and lower aperture.]

The intestinal juice of such fistulæ flows spontaneously in very small amount, and is increased during digestion; it is increased—especially its mucus—by mechanical, chemical, and electrical stimuli; at the same time, the mucous membrane becomes red, so that 100 centimetres yield 13 to 18 grammes of this juice in an hour (*Thiry*). The juice is light yellow, opalescent, thin, strongly alkaline, specific gravity 1011, evolves CO_2 when an acid is added; it contains albumin, ferments, and mucin—especially the juice of the large intestine. Its composition is—water, 97.59; proteids, 0.80; other organic substances = 0.73; salts, 0.88 per cent.; among these, sodium carbonate, 0.32 to 0.34 per cent.

[The intestinal juice obtained by Meade Smith's method contained only 0.39 per cent. of organic matter, and in this respect agreed closely with the juice which A. Moreau procured by dividing the mesenteric nerves of a ligatured loop of intestine. The secretion of the large intestine is much more viscid than that of the small intestine.]

Actions of Succus Entericus.—It is most active in the dog, and in other animals it is more or less inactive.

(1) It is less diastatic than the saliva and the pancreatic juice, but it does not form maltose; while the juice of the large intestine does not possess this property (*Eichhorst*).

(2) It converts maltose into grape sugar. It seems, therefore, to continue the diastatic action of saliva (§ 148) and pancreatic juice (§ 170), which usually form only maltose.

According to Bourquelot this action is due to the intestinal schizomycetes and not to the intestinal juice as such, the saliva, gastric juice or invertin. The greater part of the maltose appears, however, to be absorbed unchanged.

(3) Fibrin is slowly (by the trypsin and pepsin—*Kühne*) peptonized (*Thiry, Leube*); less easily albumin (*Masloff*), fresh casein, flesh raw or cooked, vegetable albumin; probably gelatin also is changed by a special ferment into a solution which does not gelatinize (*Eichhorst*).

(4) Fats are only partly emulsionized (*Schiff*), and afterward decomposed (*Vella*).

(5) According to Cl. Bernard, **invertin** occurs in intestinal juice (this ferment can also be extracted from yeast). It causes cane sugar ($C_{12}H_{22}O_{11}$) to take up water (+ H_2O), and converts it into invert-sugar, which is a mixture of left-rotating sugar (lævulose, $C_6H_{12}O_6$) and of grape sugar (dextrose, $C_6H_{12}O_6$). Heat seems to be absorbed during the process.

[Hoppe-Seyler has suggested that this ferment is not a natural product of the body, but is introduced from without with the food. Matthew Hay, however, finds it to be invariably present in the small intestine of the fœtus.]

[**Effect of Drugs.**—The subcutaneous injection of pilocarpin causes the mucous membrane of a Vella's fistula to be congested, when a strongly alkaline, opalescent, watery, and slightly albuminous secretion is obtained. This secretion produces a reducing sugar, converts cane sugar into invert-sugar, emulsifies neutral fats, ultimately splitting them up, peptonizes proteids, and coagulates milk, even although the milk be alkaline. The juice attacks the sarcous substance of muscle before the connective tissues—the reverse of the gastric juice. The mucous membrane in a Vella's fistula does not atrophy. K. B. Lehmann finds that the succus entericus obtained from the intestine of a *goat* by a Vella fistula has no digestive action.]

The Action of Nerves on the secretion of the intestinal juice is not well determined. Section or stimulation of the vagi has no apparent effect; while extirpation of the large sympathetic abdominal ganglia causes the intestinal canal to be filled with a watery fluid, and gives rise to diarrhœa. This may be explained by the paralysis of the vasomotor nerves, and also by the section of large lymphatic vessels during the operation, whereby absorption is interfered with and transudation is favored. **Moreau's Experiment.**—Moreau placed four ligatures on a loop of intestine at equal distances from each other (Fig. 202). The ligatures were tied so that three loops of intestine were shut off. The nerves (N) to the middle loop were divided, and the intestine was replaced in the abdominal cavity. After a time, a very small amount of secretion, or none at all, was found in two of the ligatured compartments of the gut, *i. e.*, in those with the nerves and blood vessels intact (1, 3),

FIG. 202.

Scheme of Moreau's experiment (*Stirling*).

but the compartment (2) whose nerves had been divided contained a watery secretion. Perhaps the secretion which occurs after section of the mesenteric nerves is a paralytic secretion. The secretion of the intestinal and gastric juices is **diminished** in man in certain nervous affections (hysteria, hypochondriasis, and various cerebral diseases); while in other conditions these secretions are increased.

Excretion of Drugs.—If an isolated intestinal fistula be made, and various drugs administered, the mucous membrane excretes iodine, bromine, lithium, sulphocyanides, but *not* potassium ferrocyanide, arsenious or boracic acid, or iron salts.

In **sucklings,** not unfrequently a large amount of acid is formed, when the fungi in the intestine split up milk sugar or grape sugar into lactic acid (*Leube*). Starch changed into grape sugar may undergo the same abnormal process; hence, infants ought not to be fed with starchy food.

[**Fate of the Ferments.**—Langley is of opinion that the digestive ferments are destroyed in the intestinal canal; the diastatic ferment of saliva is destroyed by the free HCl of the gastric juice; pepsin and rennet are acted upon by the alkaline salts of the pancreatic and intestinal juices, and by trypsin; while the diastatic and peptic ferments of the pancreas disappear under the influence of the acid fermentation in the large intestine.]

184. **FERMENTATION IN THE INTESTINE.**—Those processes which are to be regarded as fermentations or putrefactive processes, are quite different from those caused by the digestive enzymes or ferments just considered. The **putrefactive changes** are connected with the presence of lower organisms, so-called fermentation or putrefaction producers; and they may develop in suitable media outside the body. The lowly organisms which cause the intestinal fermentation are swallowed with the food and drink, and also with the saliva. When they are introduced, fermentation and putrefaction begin, and *gases are evolved.*

Intestinal Gases.—During the whole of the fœtal period, until birth, fermentation cannot occur; hence gases are never present in the intestine of the newly-born. The first air bubbles pass into the intestine with the saliva which is swallowed, even before food has been taken. The germs of organisms are thus introduced into the intestine, and give rise to the formation of gases. The evolution of intestinal gases goes hand-in-hand with the fermentations. Air is also swallowed, and an exchange of gases takes place in the intestine, so that the composition of the intestinal gases depends upon various conditions. Kolbe and Ruge collected the gases from the anus of a man, and found in 100 vols.:—

Food.	CO_2.	H.	CH_4.	N.	H_2S.
Milk, ...	16.8	43.3	0.9	38.3	Quantity not estimated.
Flesh, ...	12.4	2.1	27.5	57.8	
Peas, ...	21.0	4.0	55.9	18.9	

1. Air bubbles are swallowed with the food. The O is rapidly absorbed in the intestinal tract, so that in the lower part of the large intestine, even traces of O are absent. In exchange, the blood vessels in the intestinal wall give off CO_2 into the intestine, so that part of the CO_2 in the intestine is driven by diffusion from the blood.

2. H, CO_2, NH_3, and CH_4 are also formed from the intestinal contents by fermentation, which takes place even in the small intestine.

Fungi.—The chief agents in the production of fermentations, putrefaction and other similar decompositions are undoubtedly the group of fungi called **schizomycetes.** They are small unicellular organisms of various forms—globular, **micrococcus**; short rods, **bacterium**; long rods, **bacillus**; or spiral threads, **vibrio, spirillum, spirochæta** (Fig. 23). The mode of reproduction is by division, and they may either remain single or unite to form colonies. Each organism is usually capable of some degree of motion. They produce profound chemical changes in the fluids or media in which they grow and multiply, and these changes depend upon the vital activity of their protoplasm. These minute microscopic organisms take certain constituents from the "nutrient fluids" in which they live, and use them partly for building up their own tissues and partly for their own metabolism. In these processes, some of the substances so absorbed and assimilated undergo chemical changes, some *ferments* seem thereby to be produced, which in their turn may act upon material present in the nutritive fluid.

These fungi consist of a **capsule** enclosing protoplasmic **contents.** Many of them are provided with

excessively delicate cilia, by means of which they move about. The new organisms, produced by the division of pre-existing ones, sometimes form large colonies visible to the naked eye, the individual fungi being united by a jelly-like mass, the whole constituting **zoogloea**. In some fungi, reproduction takes place by **spores**; more especially when the nutrient fluids are poor in nutritive materials. The bacteria form longer rods or threads, which are jointed, and in each joint or segment small (1–2 μ), highly refractive globules or *spores* are developed (Fig. 203, 7). In some cases, as in the butyric acid fermentation, the rods become fusiform before spores are formed. When the envelope of the mother cell is ruptured or destroyed, the spores are liberated, and if they fall upon or into a suitable medium, they germinate and reproduce organisms similar to those from which they sprang. The process of **spore production** is illustrated in Fig. 203, 7, 8, 9, and in 1, 2, 3, 4 is shown the process of **germination** in the butyric acid fungus. The spores are very tenacious of life; they may be dried, when they resist death for a very long time; some of them are killed by being boiled. Some fungi exhibit their vital activities only in the presence of O (**ærobes**), while others require the exclusion of O (**anærobes**, *Pasteur*). According to the products of their action, they are classified as follows: Those that produce *fermentations* (**zymogenic** schizomycetes); those that produce *pigments* (**chromogenic**); those that produce disagreeable *odors*, as during putrefaction (**bromogenic**); and those that, when introduced into the living tissues of other organisms, produce *pathological conditions*, and even death (**pathogenic**). All these different kinds occur in the human body.

When we consider that numerous fungi are introduced into the intestinal canal with the food and drink—that the temperature and other conditions within this tube are specially favorable for their

FIG. 203.

development; that there also they meet with sufficient pabulum for their development and reproduction—we cannot wonder that a rich crop of these organisms is met with in the intestine, and that they produce there numerous fermentations.

I. Fermentation of Carbohydrates.—(1) **Bacillus acidi lactici** consists of biscuit-shaped cells, 1.5–3 μ in length, arranged in groups or isolated. They split up grape sugar into lactic acid;

$$1 \text{ grape sugar} = C_6H_{12}O_6 = 2(C_3H_6O_3) = 2 \text{ lactic acid.}$$

Milk sugar ($C_{12}H_{22}O_{11}$) can be split up by the same ferment causing it to take up H_2O, and forming 2 molecules of grape sugar, $2(C_6H_{12}O_6)$, which are again split into 4 molecules of lactic acid $4(C_3H_6O_3)$.

This fungus and its spores occur everywhere in the atmosphere, and are the cause of the spontaneous acidification and subsequent coagulation of milk (§ 230).

(2) **Bacillus butyricus**, which in the presence of starch is often colored blue by iodine, changes lactic acid into butyric acid, together with CO_2 and H (*Prazmowski*).

$$2(C_3H_6O_3) \text{ lactic acid} = \begin{cases} C_4H_8O_2 = 1 \text{ butyric acid.} \\ 2(CO_2) = 2 \text{ carbon dioxide.} \\ 4H = 4 \text{ hydrogen.} \end{cases}$$

This fungus (Fig. 203, B) is a true anærobe, and grows only in the absence of O. The lactic acid fungus uses O very largely, and is, therefore, its natural precursor. The butyric acid fermentation is the last change undergone by many carbohydrates, especially by starch and inulin. It takes place constantly in the fæces.

(3) Certain **micrococci** cause *alcohol* to be formed from carbohydrates. The presence of **yeast** may cause the formation of alcohol in the intestine, and in both cases also from milk sugar, which first becomes changed into dextrose.

(4) Bacterium aceti (Fig. 203, A) converts alcohol into acetic acid outside the body. Alcohol (C_2H_6O) + O = C_2H_4O (Aldehyd) + H_2O. Acetic acid ($C_2H_4O_2$) is formed from aldehyd by oxidation. According to Nägeli, the same fungus causes the formation of a small amount of CO_2 and H_2O. As the acetic fermentation is arrested at 35° C., this fermentation cannot occur in the intestine, and the acetic acid, which is constantly found in the fæces, must be derived from another source. During putrefaction of the proteids, with exclusion of air, acetic acid is produced (*Nencki*).

(5) **Starch** and **cellulose** are partly *dissolved* by the schizomycetes (Bac. butyricus and Vibrio rugula) of the intestine. If cellulose be mixed with cloacal mucus, or with the contents of the intestine, it passes into a saccharine carbohydrate which decomposes into equal volumes of CO_2 and CH_4 (*Hoppe-Seyler*).

(6) Fungi, whose rature is unknown, can partly transform *starch* (? and cellulose) into sugar.

(7) Others produce **invertin.** Invertin changes cane sugar into invert-sugar

FIG. 204.

(§ 183, II, 5). Cane sugar, $C_{12}H_{22}O_{11} + H_2O = C_6H_{12}O_6$ (Dextrose) + $C_6H_{12}O_6$ (Lævulose).

II. Fermentation of Fats (§ 251). During putrefaction, organisms of an unknown nature cause neutral fats to take up water and split into glycerine and their corresponding fatty acid (§ 170). **Glycerine** is capable of undergoing several fermentations, according to the fungus which acts upon it (§ 251). With a neutral reaction, in addition to succinic acid, a number of fatty acids, H and CO_2, are formed.

Fitz found that the *hay bacillus* (Bacillus subtilis, Fig. 204) formed alcohol with caproic, butyric, and acetic acids; in other cases, especially butylic alcohol, van de Velde found butyric, lactic, and traces of succinic acid with CO_2, H_2O, N.

The **fatty acids**, especially as chalk soaps, form an excellent material for fermentation. Calcium formiate mixed with cloacal mucus ferments and yields calcium carbonate, CO_2 and H; calcium acetate, under the same conditions, produces calcium carbonate, CO_2 and CH_4. Among the *oxy-acids*, we are acquainted with the fermentations of lactic, glycerinic, malic, tartaric, and citric acids.

According to Fitz, *lactic acid* (in combination with chalk) produces propionic and acetic acids, CO_2, H_2O. Other ferments cause the formation of valerianic acid. *Glycerinic acid*, in addition to

alcohol and succinic acid, yields chiefly acetic acid; *malic acid* forms succinic and acetic acid. The other acids above enumerated yield somewhat similar products.

III. Fermentation of Proteids (§ 249).—The undigested proteids and their derivatives appear to be acted upon by fungi. Many schizomycetes (hay bacillus and Bac. subtilis), however, can produce a peptonizing ferment. We have already seen that pancreatic digestion acts upon the proteids, forming, among other products, amido-acids, leucin, tyrosin, and other bodies (§ 170, II). Under normal conditions, this is the greatest decomposition produced by the pancreatic juice. The putrefactive fermentation of the large intestine causes further and more profound decompositions. **Leucin** ($C_6H_{13}NO_2$) takes up two molecules of water and yields valerianic acid ($C_5H_{10}O_2$), ammonia, CO_2 and $2(H_2)$; **glycin** behaves in a similar manner. **Tyrosin** ($C_9H_{11}NO_3$) is decomposed into **indol** (C_8H_7N), which is constantly present in the intestine along with CO_2, H_2O, H. If O be present, other decompositions take place. These putrefactive products are absent from the intestinal canal of the fœtus and the newly-born. During the putrefactive decomposition of proteids, CO_2, H_2S, H, and CH_4, are formed; the same result is obtained by boiling them with alkalies. **Gelatin**, under the same conditions, yields much leucin and ammonia, CO_2, acetic, butyric, and valerianic acids, and glycin. Mucin and nuclein undergo no change. Artificial pancreatic digestion experiments rapidly tend to undergo putrefaction.

The substance which causes the peculiar **fecal odor** is produced by putrefaction, but its nature is not known. It clings so firmly to indol and skatol that these substances were formerly regarded as the odorous bodies, but when they are prepared pure they are odorless (*Bayer*).

Among the solid substances in the large intestine formed *only by putrefaction* is **indol** (C_8H_7N), a substance which is also formed when proteids are heated with alkalies, or by superheating them with water to 200° C. It is the stage preceding the indican in the urine. If the products of the digestion of the proteids—the peptones—are rapidly absorbed, there is only a slight formation of indol; but when absorption is slight, and putrefaction of the products of pancreatic digestion occurs, much indol is formed, and indican appears in the urine.

Jaffé found much indican in the urine in strangulated hernia, and when the small intestine was obstructed.

Reactions for Indol.—Acidulate strongly with HCl, and shake vigorously after adding a few drops of turpentine. If there be an intense red color, the pigment is removed by ether. The substance which is formed after the digestion of fibrin by trypsin, and which gives a violet color with bromine water (§ 170, 2), can be removed by chloroform. In addition to the last pigment, there is a second one, which passes over during distillation, and which can be extracted from the distillate by ether. Both substances seem to belong to the indigo group (*Krukenberg*).

A. Bayer prepared indigo-blue artificially from ortho-phenyl-propionic acid, by boiling it with dilute caustic soda, after the addition of a little grape sugar. He obtained indol and skatol from indigo-blue. Hoppe-Seyler found that on feeding rabbits with ortho-nitrophenyl-propionic acid, much indican was present in the urine.

Phenol (C_6H_6O) is formed during putrefaction in the intestine, and it is also formed when fibrin and pancreatic juice putrefy outside the body, while Brieger found it constantly in the fæces. It seems to be increased by the same circumstances that increase indol, as an excess of indican in the urine is accompanied by an increase of phenylsulphonic acid in that fluid (§ 262).

From putrefying flesh and fibrin, amido-phenylpropionic acid is obtained, as a decomposition product of tyrosin. A part of this is transformed by putrefactive ferments into hydrocinnamic acid (phenylpropionic acid). The latter is completely oxidized in the body into benzoic acid, and appears as hippuric acid in the urine. Thus is explained the formation of hippuric acid from a purely albuminous diet.

Skatol (C_9H_9N = methyl-indol) is a constant human fecal substance, and has been prepared artificially by Nencki and Secretan from egg albumin, by allowing

it to putrefy for a long time under water. It also appears in the urine as a sulphur compound. The **excretin** of human fæces, described by Marcet, is related to cholesterin, but its history and constitution are unknown.

According to Salkowski, skatol and indol are both formed from a common substance which exists preformed in albumin, and which, when it is decomposed, at one time yields more indol, at another skatol, according as the hypothetical "*indol fungus*," or "*skatol fungus*," is the more abundant.

It is of the utmost importance, in connection with the processes of putrefaction, to determine whether they take place when oxygen is excluded, or not. When O is absent, **reductions** take place; oxy-acids are reduced to fatty acids, and H_2CH_4 and H_2S are formed; while the H may produce further reductions. If O be present, the nascent H separates the molecule of free ordinary oxygen ($=O_2$) into two atoms of active oxygen ($=O$). Water is formed on the one hand, while the second atom of O is a powerful oxidizing agent (*Hoppe-Seyler*).

It is remarkable that the putrefactive processes, after the development of phenol, indol, skatol, cresol, phenylpropionic and phenylacetic acids are subsequently limited, and after a certain concentration is reached, they cease altogether. The putrefactive process produces antiseptic substances which kill the micro-organisms, so we may assume that these substances limit to a certain extent the putrefactive processes in the intestine.

The **reaction** of the intestine immediately below the stomach is acid, but the pancreatic and intestinal juices cause a neutral and afterward an alkaline reaction, which obtains along the whole small intestine. In the large intestine, the reaction is generally acid, on account of the acid fermentation and the decomposition of the ingesta and the fæces.

185. PROCESSES IN THE LARGE INTESTINE.—Within the large intestine, the fermentative and putrefactive processes are certainly more prominent than the digestive processes proper, as only a very small amount of the intestinal juice is found in it. The **absorptive** function of the large intestine is greater than its secretory function, for at the beginning of the colon its contents are thin and watery, but in the further course of the intestine they become more solid. Water and the products of digestion in the solution are not the only substances absorbed, but under certain circumstances, unchanged fluid egg albumin, milk and its proteids, flesh juice, solution of gelatin, myosin with common salt, may also be absorbed. Experiments with acid albumin, syntonin, or blood serum gave no result. Toxic substances are certainly absorbed more rapidly than from the stomach. [In the dog the secretion of the large intestine has no digestive properties, but fats are absorbed in it. Klug and Koreck regard its Lieberkühnian glands not as secreting but as absorbing structures.] The fecal matters are *formed* or rather *shaped* in the lower part of the gut. The cæcum of many animals, *e. g.*, rabbit, is of considerable size, and in it fermentation seems to occur with considerable energy, giving rise to an acid reaction. In man, the chief function of the cæcum is absorption, as is shown by the great number of lymphatics in its walls. From the lower part of the small intestine and the cæcum onward, the ingesta assume the fecal odor.

The **amount of fæces** is about [5 oz. or] 170 grms. (60 to 250 grms.) in twenty-four hours; but if much indigestible food be taken, it may be as much as 500 grms. The amount is less, and the absolute amount of solids is less, after a diet of flesh and albumin, than after a vegetable diet. The fæces are rendered lighter by the evolution of gases, and hence they float in water.

The **consistence** depends on the amount of water present—usually about 75 per cent. The amount of water depends partly on the food—pure flesh diet causes relatively dry fæces, while substances rich in sugar yield fæces with a relatively large amount of water. The quantity of water taken has no effect upon the amount of water in the fæces. But the energy of the peristalsis has. The more energetic the peristalsis is, the more watery the fæces are, because sufficient

time is not allowed for absorption of the fluid from the ingesta. Paralysis of the blood and lymph vessels, or section of the nerves, leads to a watery condition of the fæces (§ 183).

The **reaction** is often acid, in consequence of lactic acid being developed from the carbohydrates of the food. Numerous other acids produced by putrefaction are also present (§ 184). If much ammonia be formed in the lower part of the intestine, a neutral or even alkaline reaction may obtain. A copious secretion of mucus favors the occurrence of a neutral reaction.

The **odor**, which is stronger after a flesh diet than after a vegetable diet, is caused by some fecal products of putrefaction, which have not yet been isolated; also by volatile fatty acids and by sulphuretted hydrogen, when it is present.

The **color** of the fæces depends upon the amount of altered bile pigments mixed with them, whereby a bright yellow to a dark brown color is obtained.

The color of the food is also of importance. If much blood be present in the food, the fæces are almost brownish-black, from hæmatin; green vegetables = brownish-green, from chlorophyll; bones (*dog*) = white, from the amount of lime; preparations of iron = black, from the formation of sulphide of iron.

The **fæces** contain—

(1) The unchanged residue of animal or vegetable tissues used as food; hairs, horny and elastic tissues; most of the cellulose, woody fibres, spiral vessels of vegetable cells, gums.

(2) Portions of digestible substances, especially when these have been taken in too large amount, or when they have not been sufficiently broken up by chewing. Portions of muscular fibres, ham, tendon, cartilage, particles of fat, coagulated albumin—vegetable cells from potatoes, and other vegetables, raw starch, etc.

All food yields a certain amount of residue—white bread, 3.7 per cent.; rice, 4.1 per cent.; flesh, 4.7 per cent.; potatoes, 9.4 per cent.; cabbage, 14.9 per cent.; black bread, 15 per cent.; yellow turnip, 20.7 per cent. (*Rubner*).

(3) The decomposition products of the bile pigments, which do not now give Gmelin's reaction; as well as the altered bile acids (§ 177, 2). This reaction, however, may be obtained in pathological stools, especially in those of a green color; unaltered bilirubin, biliverdin, glycocholic and taurocholic acids occur in meconium (§ 182).

[MacMunn found no unchanged bile pigments in the fæces. A substance called **stercobilin** is obtained from the fæces, and it closely resembles what has been called "febrile" urobilin, but it is certainly different from normal urobilin.]

(4) Unchanged mucin and nuclein—the latter occasionally after a diet of bread, together with partially disintegrated cylindrical epithelium from the intestinal canal, and occasionally drops of oil. Cholesterin is very rare. [Ten grains of a substance, **stercorin**, said to be a modification of cholesterin, occur in the fæces, (*Flint*).] The less the mucus is mixed with the fæces, the lower the part of the intestine from which it was derived (*Nothnagel*).

(5) After a milk diet, and also after a fatty diet, crystalline needles of lime combined with fatty acids and chalk soaps constantly occur, even in sucklings (*Wegscheider*). Even unchanged masses of casein and fat occur during the milk cure. Compounds of ammonia, with the acids mentioned as the result of putrefaction (§ 184, III), belong to the fecal matters (*Brieger*).

(6) Among **inorganic residues**, soluble salts rarely occur in the fæces because they diffuse readily, *e. g.*, common salt, and the other alkaline chlorides, the compounds of phosphoric acid, and some of those of sulphuric acid. The **insoluble compounds** of which ammoniaco-magnesic or triple phosphate, neutral calcic phosphate, yellow-colored lime salts, calcium carbonate, and magnesium phosphate are the chief, form 70 per cent. of the ash. Some of these insoluble substances are derived from the food, as lime from bones, and in part they are

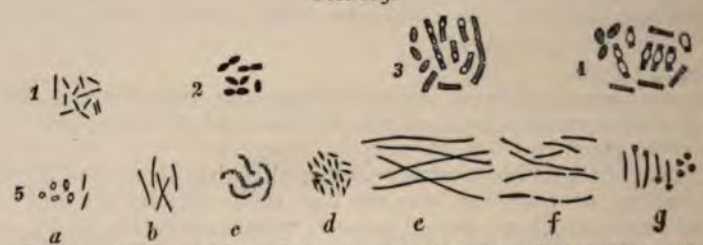
excreted after the food has been digested, as ashes are eliminated from food which has been burned.

Concretions.—The excretion of inorganic substances is sometimes so great, that they form incrustations around other fecal matters. Usually ammoniaco-magnesic phosphate occurs in large crystals by itself, or it may be mixed with magnesium phosphate.

(7) **Micro-organisms.**—A considerable portion of normal fecal matter consists of micrococci and micro-bacteria; yeast is seldom absent (*Frerichs, Nothnagel*).

To isolate the individual fungi, Escherich has made **pure cultivations** from the intestinal contents of sucklings, and Bienstock from adults. In the intestine of **sucklings** which have been nourished entirely on their mother's milk, the *Bacterium lactis aërogenes* (Fig. 205, 2) causes the lactic acid fermentation with the evolution of CO_2 and H, in the upper part of the canal where some milk sugar is still unabsorbed. In the **evacuations** is the characteristic slender *Bacterium coli commune* (Fig. 205, 1). In addition, occasionally there are other bacilli, cocci, spores of yeast, and a mould.

FIG. 205.



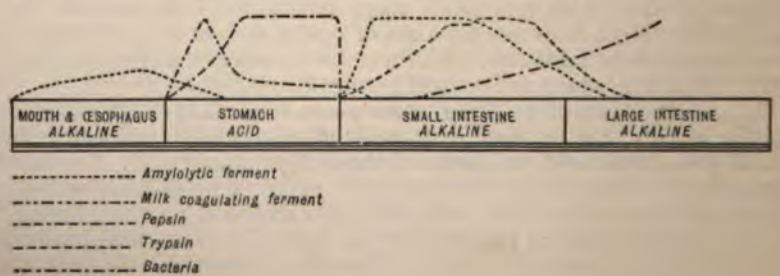
1, Bacterium coli commune; 2, bacterium lactis aërogenes; 3 and 4, the large bacilli of Bienstock, with partial endogenous spore formation: 5, the various stages in the development of the bacillus which causes the fermentation of albumin.

In the fæces of an **adult**, Bienstock detected two large forms of bacilli (Fig. 205, 3, 4), closely resembling Bacillus subtilis in form and size, but distinguished from it only by the form of its pure cultivation, by the mode of growth of its spores, and by the absence of movements. These two forms can be distinguished microscopically by the mode of their cultivation, which is either in the form of a grape or a flat membrane. These two do not excite a fermentative action. A third micrococcus-like, small, very slowly developing bacillus occurs in three-fourths of all stools. A fourth kind (absent in sucklings) is the specific bacillus (§ 184, III), causing the decomposition of albumin, resulting in the products of putrefaction and a fecal odor. This is the only bacillus that excites these processes in the intestine; but it does not decompose casein and alkali albumin. In Fig. 205, 5, *a–g*, the stages in the development of this bacillus are represented, but the stages from *c* and *g* are absent in the fæces, and are found only in artificial cultivations.

If the fæces are simply investigated microscopically and without special precautions, there are other fungi, some of which may be introduced through the anus. In stools that contain much starch, the bacillus butyricus, which is tinged blue with iodine, occurs (§ 184), and other small globular or rod-like fungi, which give a similar reaction (*Nothnagel, Uffelmann*).

The changes of the intestinal contents have been studied on persons with an accidental intestinal fistula, or an artificial anus.

[The following scheme from Krukenberg shows graphically the reaction of the contents of the various parts of the alimentary canal, and also the distribution of the ferments.]



186. PATHOLOGICAL VARIATIONS.—A. The **taking of food** may be interfered with by spasm of the muscles of mastication (usually accompanied by general spasms), stricture of the œsophagus, by cicatrices after swallowing caustic fluids (*e.g.*, caustic potash, mineral acids), or by the presence of a tumor, such as cancer. Inflammation of all kinds in the mouth or pharynx interferes with the taking of food. Inability to swallow occurs as part of the general phenomena in disease of the medulla oblongata, in consequence of paralysis of the motor centre (superior olives) for the facial, vagus, and hypoglossal nerves, and also for the afferent or sensory fibres of the glosso-pharyngeal, vagus, and trigeminus. Stimulation or abnormal excitation of these parts causes spasmodic swallowing, and the disagreeable feeling of a constriction in the neck (globus hystericus).

B. The **secretion of saliva is diminished** during inflammation of the salivary glands; occlusion of their ducts by concretions (salivary calculi); also by the use of atropin, daturin, and during fever, whereby the secretory (not the vasomotor) fibres of the chorda appear to be paralyzed (§ 145). When the fever is very high, no saliva is secreted. The saliva secreted during moderate fever is turbid and thick, and usually acid. As the fever increases, the diastatic action of the saliva diminishes. The secretion is **increased** by stimulation of the buccal nerves (inflammation, ulceration, trigeminal neuralgia), so that the saliva is secreted in great quantity. Mercury and jaborandi cause secretion of saliva, the former causing stomatitis, which excites the secretion of saliva reflexly. Even diseases of the stomach accompanied by vomiting cause secretion of saliva. A very thick, tenacious, sympathetic saliva occurs when there is violent stimulation of the vascular system during sexual excitement, and also during certain psychical conditions. The *reaction* of the saliva is acid in catarrh of the mouth, in fever in consequence of decomposition of the buccal epithelium, and in diabetes mellitus in consequence of acid fermentation of the saliva which contains sugar. Hence, diabetic persons often suffer from carious teeth. Unless the mouth of an infant be kept scrupulously clean, the saliva is apt to become acid.

C. Disturbances in the activity of the **musculature of the stomach** may be due to paralysis of the muscular layers, whereby the stomach becomes distended, and the ingesta remain a long time in it. A special form of paralysis of the stomach is due to non-closure of the pylorus (*Ebstein*). This may be due to disturbances of innervation of a central or peripheral nature, or there may be actual paralysis of the pyloric sphincter, or anæsthesia of the pyloric mucous membrane, which acts reflexly upon the sphincter muscle; and lastly, it may be due to the reflex impulse not being transferred to the efferent fibre within the nerve centre. Abnormal activity of the gastric musculature hastens the passage of the ingesta into the intestine; vomiting often occurs.

D. Gastric digestion is **delayed** by violent bodily or mental exercise, and sometimes it is arrested altogether. Sudden mental excitement may have the same effect. These efforts are very probably caused through the vasomotor nerves of the stomach. Feeble and imperfect digestion may be of a purely nervous nature (Dyspepsia nervosa—*Leube;* Neurasthenia gastrica—(*Burkart*). An excessive formation of acid may be due to nervous disturbance, and is called "nervous gastroxynsis" by Rossbach.

[**Action of Alcohol, Tea, etc., in Digestion.**—According to J. W. Fraser, all infused beverages, tea, coffee, cocoa, retard the peptic digestion of proteids, with few exceptions. The retarding action is less with coffee than with tea. The tannic acid and volatile oil seem to be the retarding ingredients in teas. Distilled Spirits—brandy, whisky, gin—have but a trifling retarding effect on the digestive processes; and when one considers their action on the secretory glands, it follows that in moderate dietetic doses they promote digestion. Wines are highly inimical to salivary digestion, but this is due to their acidity; and this effect can be removed by the addition of an alkali. Wines retard peptic digestion, the sparkling less than the still wines. Tea has an intensely inhibitory action on salivary digestion; in fact a small quantity paralyzes the action of saliva, while coffee has only a slight effect. This action of tea is due to the tannin. Tea, coffee, and cocoa all retard peptic digestion, when they form 20 per cent. of the digestive mixture (*W. Roberts*).]

Inflammatory or catarrhal affections of the stomach, as well as ulceration and new formations, interfere with digestion, and the same result is caused by eating too much food which is difficult of digestion, or taking too much highly spiced sauce or alcohol. In the case of a dog suffering from chronic gastric catarrh, Grützner observed that the secretion took place continuously, and that the gastric juice contained little pepsin, was turbid, sticky, feebly acid, and even alkaline. The introduction of food did not alter the secretion, so that in this condition the stomach really obtains no rest. The chief cells of the gastric glands were turbid. Hence, in gastric catarrh, we ought to eat frequently, but take little at a time, while at the same time dilute hydrochloric acid ought to be administered (0.4 per cent.). Small doses of common salt seem to aid digestion.

[**Absence of HCl.**—HCl is almost always absent in carcinoma of the stomach (*van de Velde*), amyloid degeneration of the gastric mucous membrane (*Edinger*), and sometimes in fever. In all these cases the acid reaction is due to lactic or butyric acid. The absence of HCl in cancer of the stomach is an important diagnostic and prognostic symptom. It is not absent in simple dilatation of the stomach. Test the contents of the stomach for free HCl with tropæolin (red color), methyl violet (blue), and with ferric chloride and carbolic acid (*Uffelmann*). $\frac{1}{20}$ per cent. of free HCl causes the

amethyst blue of the last to become steel gray, while somewhat more discharges the color altogether. [In testing for the presence of **free lactic acid** in the gastric contents use Uffelmann's reaction (§ 163). The lactic acid is easily extracted by ether from the gastric contents, and the reaction can then be performed with the residue obtained after evaporating the ether. A solution of 1 drop of the liquor perchloride in 50 c. c. of water is made yellow by lactic acid.]

Feeble digestion may be caused either by imperfect formation of acid or pepsin, so that both substances may be administered in such a condition. [It may also be due to deficient muscular power in the wall of the stomach.] In other cases, lactic, butyric, and acetic acids are formed, owing to the presence of lowly organisms. In such cases, small doses of salicylic acid, together with some hydrochloric acid, are useful. Pepsin need not be given often, as it is rarely absent, even from the diseased gastric mucous membrane. Albumin has been found in the gastric juice in cases of gastric catarrh and cholera.

E. Digestion during fever and Anæmia.—Beaumont found that in the case of Alexis St. Martin, when fever occurred, a small amount of gastric juice was secreted; the mucous membrane was dry, red, and irritable. Dogs suffering from septicæmic fever, or rendered anæmic by great loss of blood, secrete gastric juice of feeble digestive power and containing little acid (*Manassein*). [In acute diseases accompanied by fever, the inner cells of the fundus glands of the human stomach may disappear (*C. Kupffer*).] Hoppe-Seyler investigated the gastric juice of a typhus patient in which van de Velde found no free acid. Usually no free hydrochloric acid is found in cancer of the stomach. The gastric juice of the typhus patient did not digest artificially, even after the addition of hydrochloric acid. The diminution of acid, under these circumstances, favors the occurrence of a neutral reaction, so that, on the one hand, digestion cannot proceed, and on the other, fermentative processes (lactic and butyric acid fermentations with the evolution of gases) occur. These results are associated with the presence of micro-organisms and *Sarcina ventriculi* (*Goodsir*). Uffelmann found that the secretion of a peptone-forming gastric juice ceased in fever, when the fever is severe at the outset, when a feeble condition occurs, or when the temperature is very high. The amount of juice secreted is certainly diminished during fever. The excitability of the mucous membrane is increased, so that vomiting readily occurs. The increased excitability of the vasomotor nerves during fever is disadvantageous for the secretion of the digestive fluids (*Heidenhain*). Beaumont observed that fluids are rapidly absorbed from the stomach during fever, but the absorption of peptones is diminished on account of the accompanying catarrhal condition of the stomach, and the altered functional activity of the muscular mucosæ (*Leube*).

Many **salts**, when given in *large* amount, disturb gastric digestion, *e. g.*, the sulphates. While the alkaloids, morphia, strychnia, digitalin, narcotin, veratria have a similar action, quinine favors it (*Wolberg*). In some nervous individuals "peristaltic unrest of the stomach," conjoined with a dyspeptic condition, occurs (*Kussmaul*). [Professor James directs attention to the value of peptic and pancreatic salts, which are preparations of common salt mixed with pepsin and the ferments of the pancreas respectively.]

[**Artificial Digestion** is affected by various salts according to their nature and dilution. The digestion of *fibrin by pepsin* goes on best without the addition of salts, being diminished by magnesic sulphate, sodic carbonate, and sulphate. The digestion of fibrin by pancreatic extract is accelerated by sodic carbonate (*Heidenhain*), and retarded by $MgSO_4$ and Na_2SO_4. The diastatic action of the saliva and pancreas on starch is greatly accelerated by NaCl (2 per cent.), while Na_2CO_3, Na_2SO_4, and $MgSO_4$ hinder it (*Pfeiffer*).] According to Schütz, artificial gastric digestion is retarded by a 2 per cent. solution of alcohol, and also by a solution of salicylic acid (.06 to .1 per cent.). Buchner, however, finds that 10 per cent. of alcohol does not affect artificial gastric digestion, while above 20 per cent. arrests it. Beer hinders digestion.

F. In acute diseases, the **secretion of bile** is affected; it becomes less in amount and more watery, *i. e.*, it contains fewer specific constituents. If the liver undergoes great structural change, the secretion may be arrested.

G. Gall Stones.—When decomposition of the bile occurs, gall stones are formed in the *gall bladder* or in the *bile ducts*. Some are *white*, and consist almost entirely of stratified layers of crystals of **cholesterin.** The *brown* forms consist of bilirubin-lime, and calcium carbonate, often mixed with iron, copper, and manganese. The gall stones in the gall bladder become facetted by rubbing against each other. The nucleus of the white stones often consists of chalk and bile-coloring matters, together with nitrogenous residues, derived from shed epithelium, mucin, bile salts, and fats. Gall stones may occlude the bile duct and cause cholæmia. When a small stone becomes impacted in a duct, it gives rise to excessive pain, constituting hepatic colic, and may even cause rupture of the bile duct with its sharp edges.

H. Nothing certain has been determined regarding the **pancreatic secretion** in disease, but in fever it appears to be diminished in amount and digestive activity. The suppression of the pancreatic secretion [as by a cancerous tumor of the head of the pancreas], is often accompanied by the appearance of fat, in the form of globules or groups of crystals in the fæces.

I. Constipation is a most important derangement of the digestive tract. It may be caused by—(1) Conditions which *obstruct the normal channel, e. g.*, constriction of the gut from stricture—in the

large gut after dysentery, tumors, rotation on its axis of a loop of intestine (volvulus), or invagination, occlusion of a coil of gut in a hernial sac, or by the pressure of tumors or exudations from without, or congenital absence of the anus. (2) Too great *dryness* of the contents, caused by too little water in the articles of diet, diminution of the amount of the digestive secretions, *e. g.*, of bile in icterus; or in consequence of much fluid being given off by other organs, as after copious secretion of saliva, milk, or in fever. (3) Variations in the functional activity of the *muscles* and *motor nervous apparatus* of the gut may cause constipation, owing to imperfect peristalsis. This condition occurs in inflammations, degenerations, chronic catarrh, and diaphragmatic inflammation. Affections of the spinal cord, and sometimes also of the brain, are usually accompanied by slow evacuation of the intestine. Whether diminished mental activity and hypochondriasis are the cause of or are caused by constipation, is not proved. Spasmodic contraction of a part of the intestine may cause temporary retention of the intestinal contents, and, at the same time, give rise to great pain or colic; the same is true of spasm of the anal sphincter, which may be excited reflexly from the lower part of the gut. The fecal masses in constipation are usually hard and dry, owing to the water being absorbed; hence they form large masses or *scybala* within the large intestine, and these again give rise to new resistance. Among the reagents which prevent evacuation of the bowels, some paralyze the motor apparatus temporarily, *e. g.*, opium, morphia; some diminish the secretion of the intestinal mucous membrane, and cause constriction of the blood vessels, as tannic acid, vegetables containing tannin, alum, chalk, lead acetate, silver nitrate, bismuth nitrate.

J. Increased *evacuation of the intestinal contents* is usually accompanied by a watery condition of the fæces, constituting **diarrhœa.** The causes are:—

1. A too rapid movement of the contents through the intestine, chiefly through the large intestine, so that there is no time for the normal amount of absorption to take place. The increased peristalsis depends upon stimulation of the motor nervous apparatus of the intestine, usually of a reflex nature. Rapid transit of the contents through the intestine causes the evacuation of certain substances which cannot be digested in so short a time.

2. The stools become thinner from the presence of much water, mucus, and the admixture with fat, and by eating fruit and vegetables. In rare cases, when the evacuations contain much mucin, Charcot's crystals occur (Fig. 144, *c*). In ulceration of the intestine, leucocytes (pus) are present (*Nothnagel*).

3. Diarrhœa may occur as a consequence of disturbance of the diffusion processes through the intestinal walls, as in affections of the epithelium, when it becomes swollen in inflammatory or catarrhal conditions of the intestinal mucous membrane. [Irritation over the abdomen, as from the subcutaneous injection of small quantities of saline solutions, causes diarrhœa.]

4. It may also be due to increased secretion into the intestine, as in capillary diffusion, when magnesium sulphate in the intestine attracts water from the blood.

The same occurs in cholera, when the stools are copious and of a rice-water character, and are loaded with epithelial cells from the villi. The transudation into the intestine is so great that the blood in the arteries becomes very thick, and may even on this account cease to circulate.

Transudation into the intestine also takes place as a consequence of paralysis of the vasomotor nerves of the intestine. This is perhaps the case in diarrhœa following upon a cold. Certain substances seem directly to excite the secretory organs of the intestines or their nerves, such as the drastic purgatives (§ 180). Pilocarpin injected into the blood causes great secretion (*Masloff*).

During **febrile conditions,** the secretion of the intestinal glands seems to be altered quantitatively and qualitatively, with simultaneous alteration of the functional activity of the musculature and the organs of absorption, while the excitability of the mucous membrane is increased (*Uffelmann*). It is important to note that in many acute febrile diseases the amount of common salt in the urine diminishes, and increases again as the fever subsides.

187. **COMPARATIVE.—Salivary Glands.**—Among **mammals,** the herbivora have larger salivary glands than the carnivora; while midway between both are the omnivora. The whale has no salivary glands. The pinnipedia have a small parotid, which is absent in echidna. The dog and many carnivora have a special gland lying in the orbit, the *orbital* or *zygomatic gland*. In **birds** the salivary glands open at the angle of the mouth, but the parotid is absent. Among **reptiles** the parotid of some species is so changed as to form poison glands; the tortoise has sub-lingual glands; reptiles have labial glands. The **amphibia** and **fishes** have merely small glands scattered over the mouth. The salivary glands are large in **insects**; some of them secrete formic acid. The salivary glands are well developed in mollusks, and the saliva of Dolium galea contains more than 3 per cent. of free sulphuric acid (?). The cephalopods have double glands.

A **crop** is not present in any mammal; the stomach is either *simple*, as in man, or, as in many rodents, it is divided into two halves, into a cardiac and a pyloric portion. The *intestine* is short in flesh-eating animals and long in herbivora. The stomach of ruminants is **compound,** and consists of four cavities. The first and largest is the **paunch** or rumen, then the **reticulum.** In these two cavities, especially the former, the ingesta are softened and undergo fermentation. They are then returned to the mouth by the action of the voluntary muscular fibres, which reach to the stomach. This is the process of **rumination.** The ingesta are chewed again in the mouth, and are again

swallowed, but this time they enter the third cavity or **psalterium**—(which is absent in the camel)—and thence into the fourth stomach or **abomasum**, in which the fermentative digestion takes place. The cæcum is a very large and important digestive organ in herbivora and in most rodents; it is small in man, and absent in carnivora. The œsophagus in grain-eating **birds** not unfrequently has a blind diverticulum or *crop* for softening the food. In the crop of pigeons during the breeding season, there is formed a peculiar secretion—"pigeon's milk," which is used to feed the young (*J. Hunter*). The stomach consists of a glandular *proventriculus* and a strong *muscular stomach* which is covered with horny epithelium and triturates the food. There are usually two fluid diverticula on the small intestine near where it joins the large gut. In **fishes** the intestinal canal is generally simple; the stomach is merely a dilatation of the tube; and at the pylorus there may be one, but usually many, blind glandular appendages (the appendices pyloricæ). They are generally longitudinal folds in the intestinal mucous membrane, but in some fishes *e. g.*, the shark, there is a *spiral valve*. [The inversive (cane sugar) ferment is wanting in the herbivora, as the cow, horse, and sheep, but is present in the dog and cat. It is also met with in birds and reptiles, and in many of the invertebrates, as the ordinary earth-worm (*M. Hay*).]

In **amphibia** and **reptiles** the stomach is a simple dilatation; the gut is larger in vegetable feeders than in flesh feeders. The **liver** is never absent in vertebrates, although the gall bladder frequently is. The **pancreas** is absent in some fishes.

Digestion in Plants.—The observations on the albumin digesting power of some plants are extremely interesting (*Canby*, 1869; *Ch. Darwin*, 1875). The sundew or drosera has a series of tentacles on the surface of its leaves, and the tentacles are provided with glands. When an insect alights upon a leaf, it is suddenly seized by the tentacles; the glands pour out an acid juice over the prey, which is gradually digested, all except the chitinous structures. The secretion, as well as the subsequent absorption of the products of digestion, are accomplished by the activity of the protoplasm of the cells of the leaves The digestive juice contains a pepsin-like ferment and formic acid. Similar phenomena are manifested by the Venus flytrap (Dionæa), by pinguicula, as well as by the cavity of the altered leaves of nepenthes. About fifteen species of these "insectivorous" or carnivorous plants are known. [Papain, and other ferments analogous in their action to trypsin, are referred to in § 170.]

188. HISTORICAL.—Digestion in the Mouth.—The older observers regarded the *saliva* as a solvent, and in addition, many bad qualities, especially in starving animals, were ascribed to it. This arose from the knowledge of the saliva of mad animals, and the parotid saliva of poisonous snakes. The salivary glands have been known for a long time. Galen (131–203 A. D.) was acquainted with Wharton's duct, and Aëtius (270 A. D.) with the sub-maxillary and sub-lingual glands. Hapel de la Chenaye (1780) obtained large quantities of saliva from a horse, in which he was the first to make a salivary fistula. Spallanzani (1786) asserted that food mixed with saliva was more easily digested than food moistened with water. Hamberger and Siebold investigated the reaction, consistence, and specific gravity of saliva, and found in it mucus, albumin, common salt, calcium and sodium phosphates. Berzelius gave the name *ptyalin* to the characteristic organic constituent of saliva, but Leuchs (1831) was the first to detect its diastatic action.

Gastric Digestion.—Digestion was formerly compared to "coction," whereby solution was effected. According to Galen, only substances that have been dissolved passed through the pylorus into the intestine. He described the movements of the stomach and the peristalsis of the intestines. Aelian gave names to the four stomachs of the ruminants. Vidius († 1567) noticed the numerous small apertures of the gastric glands. Van Helmont († 1644) expressly notices the *acidity* of the stomach. Reaumur (1752) knew that a juice was secreted by the stomach, which effected solution, and with which he and Spallanzani performed experiments on digestion outside the body. Carminati (1785) found that the stomachs of carnivora during digestion secreted a very acid juice. Prout (1824) discovered the hydrochloric acid of the gastric juice, Sprott and Boyd (1836) the glands of the gastric mucous membrane, while Wasmann and Bischoff noted the two kinds of gastric glands. After Beaumont (1834) had made his observations upon Alexis St. Martin, who had a gastric fistula caused by a gunshot wound, Bassow (1842) and Blondlot (1843) made the first artificial gastric fistulæ upon animals. Eberle (1834) prepared artificial gastric juice. Mialhe called albumin, when altered by gastric digestion, albuminose; Lehmann, who investigated this substance more carefully, gave it the name *peptone*. Schwann isolated *pepsin* (1836), and established the fact of its activity in the presence of hydrochloric acid.

Pancreas, Bile, Intestinal Digestion.—The pancreas was known to the Hippocratic School; Maur. Hoffmann (1642) demonstrated its duct (fowl), and Wirsung described it in man. Regner de Graaf (1664) collected the pancreatic juice from a fistula, and Tiedemann and Gmelin found it to be alkaline, while Lauret and Lassaigne found that it resembled saliva. Valentin discovered its diastatic action, Eberle its emulsionizing power, and Cl. Bernard (1846) its tryptic and fat-splitting properties. The last mentioned function was referred to by Purkinje and Pappenheim (1836). Aristotle characterized the **bile** as a useless secretion; according to Erasistratus (304 B. C.), fine invisible channels conduct the bile from the liver into the gall bladder. Arëtaeus ascribed icterus to obstruction of the bile duct. Benedetti (1493) described gall stones. According to Jasolinus (1573), the

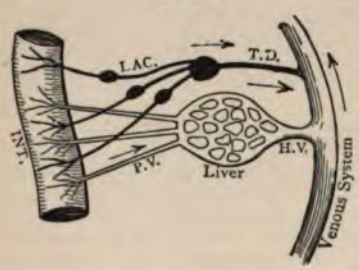
gall bladder is emptied by its own contractions. Sylvius noticed the lymphatics of the liver (1640); Walaeus, the connective tissue of the so called capsule of Glisson (1641). Haller indicated the uses of bile in the digestion of fats. The liver cells were described by Henle, Purkinje, and Dutrochet (1838). Heynsius discovered the urea and Cl. Bernard (1853) the sugar in the liver, and he and Hensen (1857) found glycogen in the liver. Kiernan gave a more exact description of the hepatic blood vessels (1834). Beale injected the lymphatics, and Gerlach the finest bile ducts. Schwann (1844) made the first biliary fistula; Demarcay particularly referred to the combination of the bile acids with soda (1838); Strecker discovered the soda compounds of both acids, and isolated them. Celsus mentions nutrient enemata (3–5 A.D.). Fallopius (1561) described the valvulæ conniventes and villi of the intestinal mucous membrane, and the nervous plexus of the mesentery. The agminated glands or patches of Peyer were known to Severinus (1645).

PHYSIOLOGY OF ABSORPTION.

189. THE ORGANS OF ABSORPTION.—[As most substances in the state in which they are used for food are either insoluble, or diffuse but imperfectly through membranes, the whole drift of the complicated digestive processes is to render these substances **soluble** and **diffusible**, and thus fit them for absorption; while most of the fats are emulsionized.]

The **mucous membrane** of the whole intestinal tract, as far as it is covered by a single layer of columnar epithelium, *i. e.*, from the cardiac orifice of the stomach to the anus—is adapted for absorption. The mouth and œsophagus, lined as they are by stratified squamous epithelium, are much less adapted for this purpose. Still, poisoning is caused by placing potassium cyanide in the mouth. The channels of absorption in the intestinal tract are (Fig. 206)—(1) the **capillaries** [*direct*], and (2) the **lacteals** [*indirect*] of the mucous membrane. Almost the whole of the substances absorbed by the former pass into the rootlets of the portal vein, *and traverse the liver*, while those that enter the lacteals really pass into lymphatics, so that the chyle passes through the thoracic duct and is poured by it into the blood, where the thoracic duct joins the subclavian vein.

FIG. 206.



Scheme of Intestinal Absorption. LAC., lacteals; T. D., thoracic duct; P.V. and H.V., portal and hepatic veins; INT., intestine.

Watery solutions of salts, grape sugar, peptone, poisons, and in a still higher degree alcoholic solutions of poisons, are absorbed **in the stomach.** The empty stomach absorbs more rapidly than one filled with food; gastric catarrh delays absorption. After a copious diet of milk, fatty granules have been found in the protoplasm of the goblet cells; so that according to this view, the goblet cells have a double function, to secrete mucus and to absorb nutriments.

The greatest area of absorption is undoubtedly the **small intestine**, especially its *upper* half, owing to the presence of the **valvulæ conniventes** and the **villi.**

190. STRUCTURE OF THE SMALL AND LARGE INTESTINES.—[The wall of the **small intestine** consists of **four coats**; which, from without inward, are named serous, muscular, sub-mucous, and mucous (Fig. 207).]

(1) The **serous coat** has the same structure as the peritoneum, *i. e.*, a thin basis of fibrous tissue covered on its outer surface by endothelium.

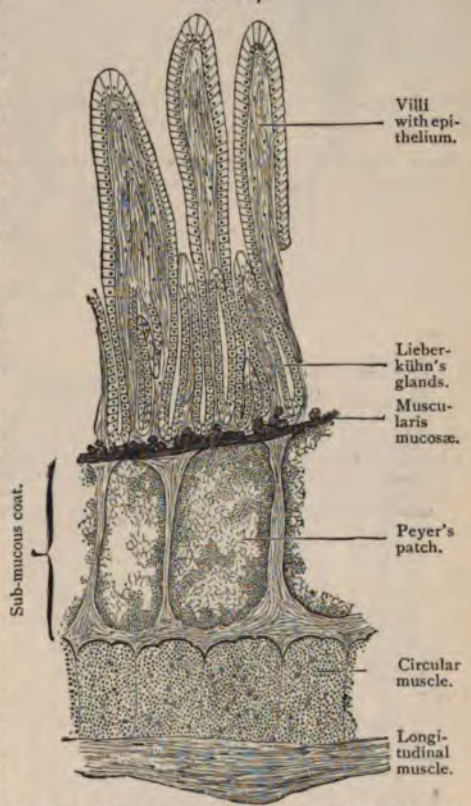
(2) The **muscular coat** consists of a thin **outer longitudinal** and an **inner** thicker **circular** layer of non-striped muscular fibres (Fig. 207).

(3) The **sub-mucous coat** consists of loose connective tissue containing large blood vessels and nerves, and it connects the muscular with the mucous coat.

(4) The **mucous coat** is the most internal coat, and its absorbing surface is largely increased by the presence of the valvulæ conniventes and villi. [The **valvulæ conniventes** are peramnent folds of the mucous membrane of the small intestine, arranged across the long axis of the gut. They pass round a half or more of the inner surface of the gut. They begin a little below the commence-

ment of the duodenum, and are large and well marked in the duodenum, and remain so as far as the upper half of the jejunum, where they begin to become smaller, and finally disappear about the lower part of the ileum.] The **villi** are characteristic of the small intestine, and are confined to it; they occur everywhere as closely-set projections over and between the valvulæ conniventes (Fig. 207). When the inner surface of the mucous membrane is examined in water, it has a velvety appearance owing to their presence. [They vary in length from $\frac{1}{50}$ to $\frac{1}{30}$ of an inch, are largest and most numerous in the upper part of the intestine, duodenum, and jejunum, where absorption is most active, but they are less abundant in the ileum. Their total number has been calculated at four millions by Krause.] Each villus is a projection of the entire mucous membrane, so that it contains within itself representatives of all the tissue elements of the mucosa. The orifices of the glands of Lieberkühn open between the bases of villi (Fig. 207).

FIG. 207.



Longitudinal section of the small intestine of a dog through a Peyer's patch.

Each **villus**, be it cylindrical or conical in shape, is covered by a single layer of **columnar epithelium**, whose protoplasm is reticulated, and contains a well-defined nucleus with an intranuclear plexus of fibrils. The ends of the epithelial cells directed toward the gut are polygonal, and present the appearance of a mosaic (Fig. 208, D). When looked at from the side, their free surface is seen to be covered with a clear, highly refractive **disk** or "**cuticula**," which is marked with vertical striæ. These striæ were supposed by Kölliker to represent pores for the absorption of fatty particles, but this has not been confirmed, while Brettauer and Steinach regarded them as produced by prisms placed side by side.

According to v. Thanhoffer, however, this clear disk is comparable to the thickened flange around the bottom of a vessel, such as is used for collecting gases. On this supposition, the upper end of each cell is open, and from it there project pseudopodia-like bundles of protoplasmic processes (Fig. 208, B). These processes are supposed to be extended beyond the margin of the cell, and again rapidly retracted, and in so acting they are said to carry the fatty particles into the interior of the cells, much as the pseudopodia of an amœba entangle its food. [This view has not been confirmed by a sufficient number of observers.] Between the epithelial cells are the so-called **goblet cells** (Fig. 208, C). [Each goblet cell is more or less like a chalice, narrower above and below, and broad in the middle, with a tapering fixed extremity. The outer part of these cells is filled with a clear substance or **mucigen**, which, on the addition of water, yields mucus. The mucigen lies in the intervals of a fine network of fibrils, which pervades the cell protoplasm, while the protoplasm, containing a globular or triangular nucleus, is pushed into the lower part of the cell. Those goblet cells are simply altered columnar epithelial cells, which secrete mucus in their interior. They are more numerous under certain conditions. Not unfrequently in a section of the mucous membrane of the gut, after it is stained with logwood, we may see a deep blue plug of mucus partly exuded from these cells. When looked at from above they give the appearance seen in Fig. 208, D.] The epithelial cells are shed in enormous numbers in cholera, and in poisoning with arsenic and muscarin (*Böhm*).

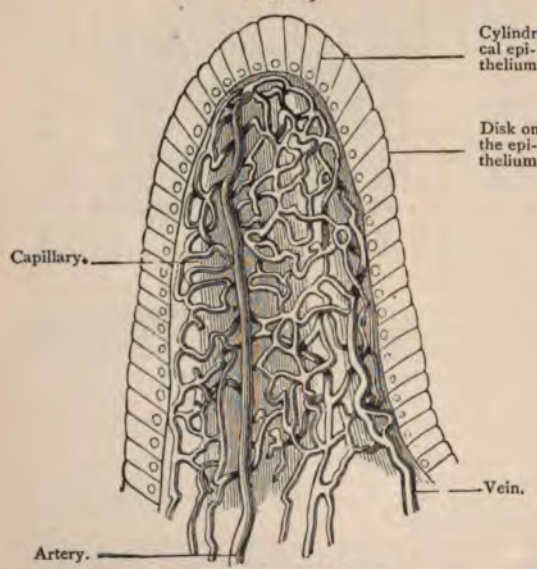
[The epithelial cells covering the villus are placed upon a layer of squamous epithelium (**basement membrane**)—the sub-epithelial membrane of Dêbove. This basement membrane is said to be connected by processes with the so-called branched cells of the adenoid tissue of the villus, while it also sends up processes between the epithelial covering.]

The villus itself consists of a basis of **adenoid tissue**, containing in its centre one or more lacteals, closely invested with bundles of longitudinal smooth muscular fibres, derived from the muscularis mucosæ, and a plexus of blood vessels. The adenoid tissue of the villus consists of a reticulum of fibrils with endothelial plates at its nodes. The spaces of the adenoid tissue form a spongy network

FIG. 208.

B, scheme of a cell with processes projected from its interior. C, columnar epithelium after the absorption of fatty granules. D, columnar epithelium of a villus seen from above with a goblet cell in the centre.

FIG. 209.



Injected blood vessels of a villus.

of inter-communicating channels containing stroma cells or leucocytes (Fig. 208, A, *e*, *e*). These leucocytes or lymph corpuscles have been seen to contain fatty granules, and they are perhaps concerned in the absorption of fatty particles.

The lymphatic or **lacteal** lies in the axis of the villus (Fig. 210, *d'*). Some regard the lacteal merely as a space in the centre of the villus, but more probably it has a distinct wall composed of endothelial cells, with apertures or stomata here and there between the cell plates. These stomata place the interior of the lacteal in direct communication with the spaces of the adenoid tissue. Perhaps, white blood corpuscles wander out of the blood vessels of the villi into the spaces of the adenoid tissue where they become loaded with fatty granules, and pass into the central lacteal. Zuwarykin and Wiedersheim suppose that the leucocytes pass from the parenchyma of the villus toward the epithelial layer, and even between the epithelial cells, from which they return toward the axis of the villus, laden with substances which they have taken into their interior (§ 192, II).

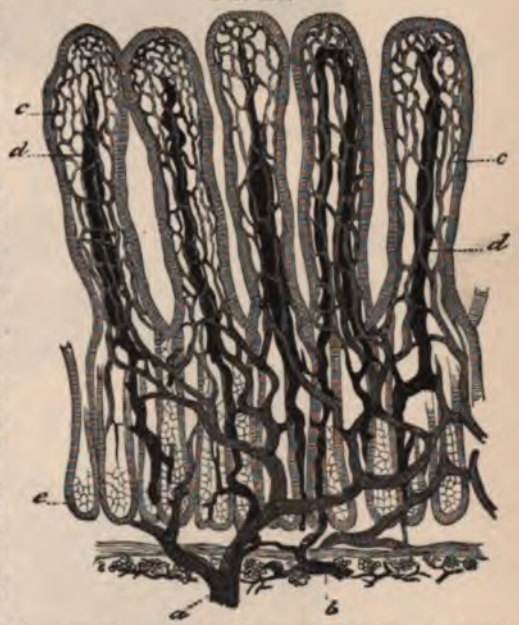
A small **artery** placed eccentrically passes into each villus (Fig. 209). In man it begins to divide about the middle of the villus, but in animals it usually runs to the apex before it divides. The capillaries resulting from the division of the artery form a fine dense network placed *superficially*, immediately under the epithelium of the surface. The blood is carried out of a villus by one or two veins (Figs. 207, 209).

Non-striped muscular fibres are present in villi. They are arranged longitudinally in several bundles from base to apex, immediately outside the central lacteal. When they contract they tend to empty the lacteal. A few muscular fibres are placed more superficially, and run in a more transverse direction. [The longitudinal bundles of non-striped muscle in the villi are connected together by oblique strands; while the longitudinal bundles shorten the villus, the oblique fibres keep the lacteal open; thus the parenchyma of the villus is also compressed transversely, whereby the products of absorption are forced into the lacteal. The muscles are fixed by cement to the sub-epithelial basal membrane. The muscular fibres of the villi are direct prolongations of the muscularis mucosæ.]

Nerves pass into the villi from Meissner's plexus lying in the sub-mucous coat. The nerves to the villi are said to have small granular ganglionic cells in their course, and they terminate partly in the muscular fibres and partly in the arteries of the villi.

[On making a vertical section of the **mucous membrane** of the small intestine, it is seen to consist of a network of adenoid tissue loaded with leucocytes. This tissue forms its basis, and in it are placed vertically, side by side, like test-tubes in a stand, immense numbers of simple tubular glands—the **crypts of Lieberkühn** (Fig. 207).] [Kultschitzki finds that the connective-tissue framework of the mucous membrane of the small intestine is not true adenoid tissue, but a transition form between the latter and loose fibrous tissue.] Lieberkühn's glands open above at the bases of the villi, while their closed lower extremity reaches almost to the muscularis mucosæ. Each tube consists of a basement membrane lined by a single layer of columnar epithelium, leaving a wide lumen, the cells lining them being continuous with those that cover the mucous membrane. Some goblet cells are often found between the columnar epithelium. Immediately below the bases of the follicles of Lieberkühn is the **muscularis mucosæ**, consisting of two or three narrow layers of non-striped muscular fibres arranged circularly and longitudinally. [It is continuous with the muscularis mucosæ of the stomach, and extends throughout the whole intestine, not as a continuous layer, but as a close network of bundles of smooth muscle. It sends fibres upward into the villi (Fig. 212, *e*).]

FIG. 210.



Mucous membrane of the small intestine of the dog; the lacteals are black, and the blood vessels lighter. *a*, artery; *b*, lymphatic; *c*, plexus of capillaries in the villi; *d*, lacteal; *e*, Lieberkühn's glands.

[**Brunner's Glands** are compound tubular glands lying in and confined to the submucous coat of the **duodenum** (Fig. 198). Their ducts perforate the muscularis mucosæ to open on the surface. They seem to be the homologues of the pyloric glands of the stomach.]

[**Solitary Follicles** are small round or oval white masses of adenoid tissue, with their deeper parts embedded in the submucosa, and their apices projecting into the mucosa of the intestine. They begin at the pyloric end of the stomach and are found throughout the whole intestine. They consist of small masses of adenoid tissue loaded with leucocytes (Fig. 214). They are well supplied with blood vessels (§ 197), although no lymphatic vessels enter them. They are surrounded by lymphatics, and, in fact, they may be said to hang into a lymph stream. The distribution of solitary follicles is fairly uniform in the small intestine; their number generally increases from the stomach to the large intestine; although there are considerable variations in different individuals, there seems to be the same number of solitary follicles and Peyer's patches in the infant as in the adult (*Passow*).]

[**Peyer's glands**, or agminated glands, consist of groups of lymph follicles like the foregoing (Figs. 207, 213). The masses are often more or less fused together, their bases lie in the sub-mucosa,

while their summits project into the mucosa, where they are covered merely by the columnar epit
of the intestine. The lymph corpuscles often pass between the epithelial cells. The patc
formed have their long axis in the axis of the intestine, and they are always placed opposite the

ment of the mesentery. Like the solitary glands, they are well supplied with blood vessels
around them is a dense plexus of lymphatics or lacteals. They are most abundant in the low
of the ileum. These glands are specially affected in typhoid fever.]

Nerves of the Intestine.—Throughout the whole intestinal tract there exists the **plexus of Auerbach,** lying between the longitudinal and circular muscular coats (Figs. 174, 175). This

FIG. 213.

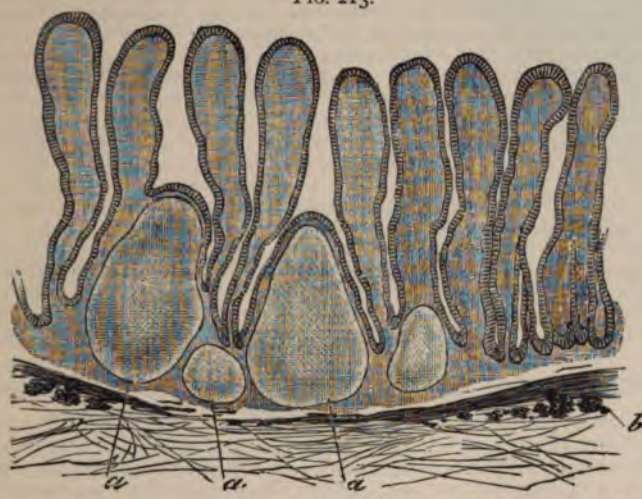

Diagram of a vertical section of the mucous membrane of the small intestine of a dog, showing the closed follicles, *aa*; *b*, muscularis mucosæ.

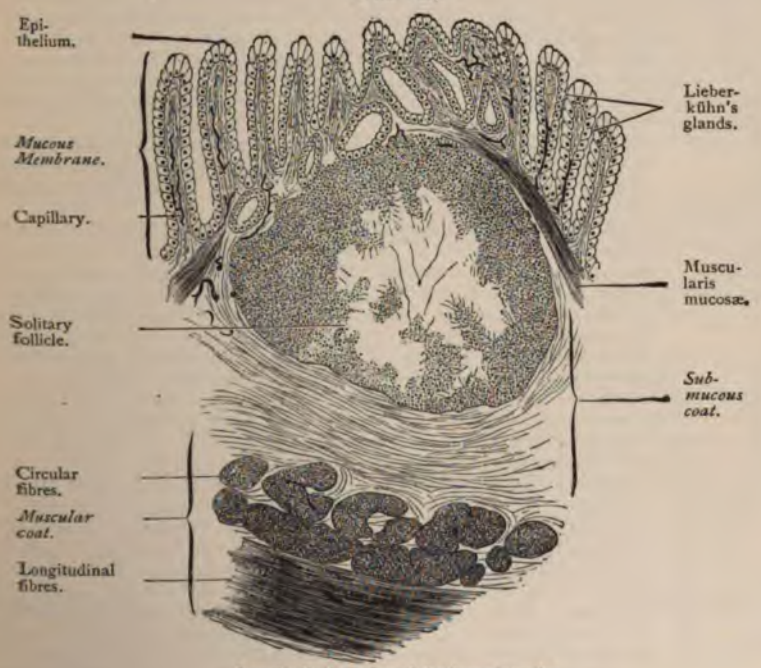
FIG. 214.



Longitudinal section of the large intestine.

plexus consists of non-medullated nerves with groups of ganglionic cells at the nodes. Fibres are given off by it to the muscular coats. Connected by branches with the foregoing, and lying in the sub-

mucosa, is the **plexus of Meissner,** which is much finer, the meshes being wider, the nodes smaller, but also provided with ganglionic cells. It supplies the muscular fibres and arteries of the mucosa, including those of the villi. It also sends branches to Lieberkühn's glands (Fig. 176).

[**Structure of the Large Intestine.**—It has **four coats,** like those of the small intestine. The **serous** coat has the same structure as that of the small intestine. The **muscular** coat has external *longitudinal* fibres occurring all round the gut, but they form three flat, ribbon-like longitudinal bands in the cæcum and colon (Fig. 214). Inside this coat are the *circular* fibres. The **sub-mucosa** is practically the same as that of the small intestine. The **mucosa** is distinguished by negative characters. It has no villi and no Peyer's patches, but otherwise it resembles structurally the small intestine, consisting of a basis of adenoid tissue with the simple tubular **glands of Lieberkühn** (Fig. 199). These glands are very numerous and somewhat longer than those of the small intestine, and they always contain far more goblet cells—about ten times as many. The cells lining them are devoid of a clear disk. **Solitary glands** occur throughout the entire length of the large intestine. At the basis of Lieberkühn's glands is the **muscularis mucosæ.** The blood vessels and nerves have a similar arrangement to those in the stomach.]

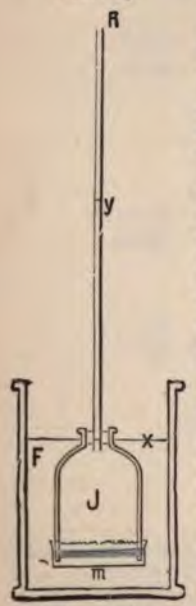
[**Blood Vessels.**—On looking down on an opaque injection of the mucous membrane of the stomach, one sees a dense meshwork of polygonal areas of unequal size, with depressions here and there. The orifices are the orifices of the gastric glands, each surrounded by a capillary. A somewhat similar appearance is seen in an opaque injection of the mucous membrane of the large intestine, but in the latter the meshwork is *uniform*, all the orifices (of Lieberkühn's glands) being of the same size.]

191. ABSORPTION OF THE DIGESTED FOOD.—The physical forces concerned are endosmosis, diffusion, and filtration.

All the constituents of the food, with the exception of the fats, which in part are changed into a fine emulsion, are brought into a state of **solution** by the digestive processes. These substances pass through the walls of the intestinal tract, either into the blood vessels of the mucous membrane or into the beginning of the lymphatics. In this passage of the fluids two physical processes come into play —*endosmosis* and *diffusion*, as well as *filtration*.

I. Endosmosis and **diffusion** occur between two fluids which are capable of forming an intimate mixture with each other, *e. g.*, hydrochloric acid and water, but never between two fluids which do not form a perfect mixture, such as oil and water. If two fluids capable of mixing with each other, but of different compositions, be separated from each other by means of a septum with physical pores (which occur even in a homogeneous membrane), an exchange of the constituents in the fluids occurs until both fluids have the same composition. This exchange of fluids is termed *endosmosis* or *diosmosis*.

FIG. 215.



Endosmometer.

Diffusion.—If the two mixable fluids are placed in a vessel, the one fluid over the other, but without being separated by a porous septum, an exchange of the particles of the fluids also occurs, until the whole mixture is of uniform composition. This process is called *diffusion*.

Conditions Influencing Diffusion.—Graham's investigations showed that the rapidity of diffusion is influenced by (1) The nature of the fluids themselves; acids diffuse most rapidly; the alkaline salts more slowly; and most slowly, fluid albumin, gelatin, gum, dextrin. These last do not crystallize, and perhaps do not form true solutions. (2) The more concentrated the solutions, the greater the diffusion. (3) Heat accelerates, while cold retards, the process. (4) If a solution of a body which diffuses with difficulty be mixed with an easily diffusible one, the former diffuses with still greater difficulty. (5) Dilute solutions of several substances diffuse into each other without any difficulty, but if concentrated solutions are employed the process is retarded. (6) Double salts, one constituent of which diffuses more readily than the other, may be chemically separated by diffusion.

Endosmometer.—The exchange of the fluid particles takes place *independently of the hydrostatic pressure.* An endosmometer (Fig. 215) consists of a glass cylinder filled with distilled water, and into this is placed a flask, J, without a bottom, instead of which a membrane, *m*, is tied on. A glass tube, R, is fixed firmly, by means of a cork, into the neck of the flask. The flask is filled up to the lower end of the tube with a concentrated salt solution, and is then placed in the cylindrical vessel until both fluids are on the same level, *x*. The fluid in the tube, R, soon begins to rise, because water passes through the membrane into the concentrated solution in the flask, and this independently of the hydrostatic pressure. Particles of the concentrated salt solution pass into the cylinder and mix with the water, F. These outgoing and ingoing currents continue until the fluids without and within J are of uniform composition, whereby the fluid in R always stands higher (*e. g.*, at *y*), while it is lowered in the cylinder. The circumstance of the level

of the fluid within the tube being so high, and remaining so, is due to the fact that the pores in the membrane are too fine to allow the hydrostatic pressure to act through them.

Endosmotic Equivalent.—Experiment has shown that equal weights of different soluble substances attract different amounts of distilled water through the membrane *i. e.*, a known weight of a soluble substance (in the flask) can be exchanged by endosmosis for a definite weight of water. The term "endosmotic equivalent" indicates the weight of distilled water that passes into the flask of the endosmometer, in exchange for a known weight of the soluble substance (*Jolly*). For 1 grm. alcohol 4.2 grms. water were exchanged; while for 1 grm. NaCl, 4.3 grms. water passed into the endosmometer. The following numbers give the endosmotic equivalent of—

Acid potassium sulphate,	= 2.3	Magnesium sulphate,	= 11.7
Common salt,	= 4.3	Potassium sulphate,	= 12.0
Sugar,	= 7.1	Sulphuric acid,	= 0.39
Sodium sulphate,	=11.6	Potassium hydrate,	=215.0

The amount of the substance which passes through the membrane into the water of the cylinder is proportional to the concentration of the solution. If the water in the cylinder, therefore, be repeatedly renewed, the endosmosis takes place more rapidly, and the process of equilibration is accelerated. The larger the pores of the membrane, and the smaller the molecules of the substance in solution, the more rapid is the endosmosis. Hence, the rapidity of endosmosis of different substances varies, *e. g.*, the rapidity of sugar, sodium sulphate, common salt, and urea is in the ratio of 1 : 1.1 : 5 : 9.5.

The endosmotic equivalent is not constant for each substance. It is influenced by (1) The temperature, which, as it increases, generally increases the endosmotic equivalent. (2) It also varies with the degree of concentration of the osmotic solutions, being greater for dilute solutions of the substances.

If a substance other than water be placed in the cylinder, an endosmotic current occurs on both sides until complete equality is obtained. In this case, the currents in opposite directions disturb each other. If two substances be dissolved in the water in the flask at the same time, they diffuse into water without affecting each other. (3) It also varies with membranes of varying porosity. Common salt, which gives an endosmotic equivalent with a pig's bladder = 4.3, gives 6.4 when an ox bladder is used; 2.9 with a swimming bladder; and 20.2 with a collodion membrane.

Colloids.—There are many fluid substances which, on account of the great size of their molecules, do not pass, or pass only with difficulty, through the pores of a membrane impregnated with gelatinous bodies, which diffuse slowly. These substances are not actually in a true state of solution, but exist in a very dilute condition of imbibition. Such substances are the fluid proteids, starches, dextrin, gum, and gelatin. These diffuse when no septum is present, but diffuse with difficulty, or not at all, through a porous septum. Graham called these substances **colloids,** because, when concentrated, they present a glue-like or gelatinous appearance; further, they do not crystallize, while those substances which diffuse readily are crystalline, and are called **crystalloids.** Crystallizable substances may be separated from non-crystallizable by this process, which Graham called **dialysis.** Mineral salts favor the passage of colloids through membranes.

That **endosmosis** takes place in the intestinal tract, through the mucous membrane and the delicate membranes of the blood and lymph capillaries, cannot be denied. On the one side of the membrane, within the intestine, are relatively concentrated solutions of highly diffusible salts, peptones, sugar and soaps, and within the blood vessels are the colloids which are scarcely diffusible, *e.g.*, the proteids of blood and lymph.

II. Filtration is the passage of fluids through the **coarse** intermolecular pores of a membrane **owing to pressure.** The greater the pressure, and the larger and more numerous the pores, the more rapid does the fluid pass through the membrane; increase of temperature also accelerates it. Those substances which are imbibed by the membrane filter most rapidly, so that the same substance filters through different membranes with varying rapidity. The filtration is usually slower, the greater the concentration of the fluid. The filter has the property of retaining some of the substances from the solution passing through it, *e.g.*, colloid substances—or water (in dilute solutions of nitre). In the former case the filtrate is more dilute, in the latter more concentrated, than before filtration. Other substances filter without undergoing any change of concentration. Many membranes behave differently, according to which surface is placed next the fluid; thus the shell membrane of an egg permits filtration only from without inward; [and the same is true to a much less extent with filter paper; the smooth side of the filter paper ought always to be placed next the fluid to be filtered. The intact skin of the grape prevents the entrance of fungi into the fruit]. There is a similar difference with the gastric and intestinal mucous membrane.

[By using numerous layers of filter paper, many colloids and crystalloids are retained in the filter, *e.g.*, hæmoglobin, albumin, and many coloring matters, especially aniline colors, the last being arrested by glass wool (*Krysinski*).]

[**Filtration of Albumin.**—Runeberg finds that the amount of albumin in pathological transudations varies with (1) the *capillary area*, being least in œdema of the subcutaneous tissue. (2) The

presence or absence of *inflammatory processes* in the vascular wall, non-inflammatory pleuritic effusion containing 2 per cent., and inflammatory 6 per cent., of albumin. (3) The condition and amount of *albumin in the blood.* The amount of albumin in the transudate never reaches, although it sometimes approaches, that in blood. In ascites in general dropsy the amount is .03 to .04 per cent. (4) The *duration* of the transudation. (5) Perhaps the blood pressure and the condition of the circulation.]

Filtration of the soluble substance may take place from the canal of the digestive tract when: (1) The *intestine contracts* and thus exerts pressure upon its contents. This is possible when the tube is narrowed at two points, and the musculature between these two points contracts upon the fluid contents. (2) Filtration, under **negative pressure**, may be caused by the **villi** (*Brücke*). When the villi contract energetically, they empty their contents toward the blood and lymph vessels. The lacteal remains empty, as the chyle is prevented from passing backward into the origin of the lacteal within the villi, owing to the presence of numerous valves in the lymphatics. When the villi relax, they are refilled with fluids from the intestine.

192. **ABSORPTION BY THE INTESTINAL WALL.—I. True solutions** undoubtedly pass by endosmosis into the blood vessels and lymphatics of the intestinal walls, but numerous facts indicate that the protoplasm of the cells takes an active part in the process of absorption. The forces concerned have not as yet been proved to be purely physical and chemical in their nature.

(1) **Inorganic Substances.—Water** and the **soluble salts** necessary for nutrition are easily absorbed, the latter especially by the **blood** and **lymph vessels.** When saline solutions pass by endosmosis into the vessels, water must pass from the intestinal vessels into the intestine. The amount of water, however, is small, owing to the small endosmotic equivalent of the salts to be absorbed. More salts are absorbed from concentrated than from dilute solutions. If large quantities of salt, with a high endosmotic equivalent, *e. g.*, magnesiun or sodium sulphate, are introduced into the intestine, these salts retain the water necessary for their solution, and may thus cause diarrhœa. Conversely, when these substances are injected into the blood, a large quantity of water passes from the intestine into the blood, so that constipation occurs, owing to the dryness of the intestinal contents (*Aubert*).

[M. Hay concludes from his experiments (§ 161), that salts, when placed in the intestines, do not abstract water from the blood, or are themselves absorbed, in virtue of an endosmotic relation being established between the blood and the saline solution in the intestines. Absorption is probably due to the filtration and diffusion, or processes of inhibition other than endosmosis, as yet little understood. The result obtained by Aubert, which is not constant, is mostly caused by the great diuresis which the injected salt excites.] The absorption of fluids takes place best at a medium pressure of 80 to 140 c. cm. of water within the intestine; higher pressure compresses the blood vessels and diminishes the absorption. During digestion, owing to the dilatation of the vessels, absorption is more rapid. The fact that 0.5 per cent. solution of NaCl is absorbed better than water, and soda solution than potash solution, seems to show that physical forces are not the only factors concerned.

Numerous inorganic substances, which do not occur in the body, are absorbed by endosmosis from the intestine, *e.g.*, dilute sulphuric acid, potassium iodide, chlorate and bromide, and many other salts.

(2) The **soluble carbohydrates**, such as the **sugars**, of which the chief representatives are **dextrose** and **maltose**, with a relatively high endosmotic equivalent. Cane sugar is changed by a special ferment into invert-sugar (§ 183, 5). Absorption appears to take place somewhat slowly, as only very small quantities of grape sugar are found in the chyle vessels, or the portal vein, at any time. According to v. Mering, the *sugar passes from the intestine into the rootlets of the portal vein*; dextrin also occurs in the portal vein. When the blood of the portal vein is boiled with dilute sulphuric acid, the amount of sugar is increased. The amount of sugar absorbed depends upon the concentration of its solution in the intestine; hence the amount of sugar in the blood is increased after a diet containing much of this substance, so that it may appear in the urine; in which case

the blood must contain at least 0.6 per cent. of sugar. A small amount of **cane sugar** has also been found in the blood (*Cl. Bernard*). The sugar is used up in the bodily metabolism; some of it is perhaps oxidized in the muscles (§ 176).

(3) The **peptones** have a small endosmotic equivalent, a 2 to 9 per cent. solution = 7 to 10. Owing to their great diffusibility they are readily absorbed, and they are the chief representatives of the proteids which are absorbed. The amount absorbed depends upon the concentration of their solution in the intestine. When animals are fed on peptones (with the necessary fat or sugar), they serve to maintain the body weight. [According to Plósz and Györgyai, Drosdorff and Schmidt-Mulheim, peptones occur only in traces in the blood of the portal vein. Neumeister, however, using the best methods, finds that although peptones are abundant in the intestine, not a trace of peptone or of the albumoses is found either in the blood or lymph. This coincides with Hofmeister's researches, and is, of course, opposed to the results of the above-named observers. As no peptones or albumoses have been found in the blood, and as they can compensate for the total metabolism of the proteids within the body, we must assume that they are rapidly converted into albuminous bodies.] Hofmeister supposes that the leucocytes absorb the peptones and act as their carriers, much as the red corpuscles are oxygen carriers. They carry the peptones into the mucous membrane of the stomach and small intestine, which are very rich in peptone at the fourth hour of digestion. [The number of leucocytes is greatly increased in the mucous membrane, especially in the stomach and upper part of the duodenum, during digestion, and diminished during fasting in dogs and cats. The same is the case with the lymph follicles, the cells of which are formed by the division of the pre-existing cells.] It is asserted by Salvioli that the mucous membrane possesses the property of changing peptone into albumin.

[**Injection of Peptone into Blood.**—When peptone is injected into the blood of an animal, within twenty minutes thereafter no trace of the peptone is to be found in the blood, although it has not been excreted by any of the organs. Peptones so injected prevent the blood of the dog (not of the rabbit or pig) from coagulating. In large quantity they are fatal. Fano asserts that the peptone is taken up by the red blood corpuscles, which thus become of greater specific gravity, and change it into globulin. After three or more hours the corpuscles return the globulin to the blood, so that the corpuscles represent a reserve store of proteid. The peptones used in these experiments were really a mixture of peptones and albumoses. Neumeister finds that in the dog, when **albumoses** are injected into the blood they reappear in the urine, but somewhere in the body they undergo hydration in the sense in which peptic digestion causes hydration. The two primary albumoses reappear almost completely as deutero-albumose, and deutero-albumose, when introduced, reappears as peptone. Peptone, however, reappears unchanged. In rabbits, albumose reappears unchanged in the urine.]

(4) **Unchanged true proteids** filter with great difficulty, and much albumin remains upon the filter. On account of their high endosmotic equivalent they pass with extreme slowness, and only in traces, through membranes. Nevertheless, it has been conclusively proved that unchanged proteids can be absorbed (*Brücke*), *e. g.*, casein, soluble myosin, alkali-albuminate, albumin mixed with common salt, gelatin (*Voit, Bauer, Eichhorst*). They are absorbed even from the large intestine (*Czerny and Latschenberger*), although the human large intestine cannot absorb more than 6 grms. daily. But the amount of unchanged proteids absorbed is always very much less than the amount of peptone.

Egg albumin without common salt, syntonin, serum albumin, and fibrin are not absorbed (*Eichhorst*). Landois observed in the case of a young man who took the whites of 14 to 20 eggs along with NaCl, that albumin was given off by the urine for 4 to 10 hours thereafter. The amount of albumin given off rose until the third day, and ceased on the fifth day. The more albumin taken, the sooner the albuminuria appeared, and the longer it lasted. The unchanged egg albumin reappeared in the urine. If egg albumin be injected into the blood, part of it reappears in the urine (§ 41, 2) (*Stokvis, Lehmann*).

(5) The soluble **fat soaps** represent only a fraction of the fats of the food which are absorbed; the greater part of the neutral fats being absorbed in the

form of very fine particles—as an emulsion (§ 192, II). The *absorbed soaps have been found in the chyle*, and as the blood of the portal vein contains more soaps during digestion than during hunger, it has been assumed that the soaps pass into the intestinal blood capillaries. The investigations of Lenz, Bidder, and Schmidt, render it probable that the organism can absorb only a limited amount of fat within a given period; the amount perhaps bears a relation to the amount of bile and pancreatic juice. The maximum per kilo. (cat) was 0.6 grm. of fat per hour.

Perhaps the soaps reunite with glycerine in the parenchyma of the villi, to form neutral fats, as Perewoznikoff and Will found neutral fats, after injecting these two ingredients into the intestinal canal, while Ewald found that fat was formed when soaps and glycerine were brought into contact with the fresh intestinal mucous membrane. Perhaps this is the explanation of the observation of Bruch, who found fatty particles within the blood vessels of the villi. No **fatty acids** are found in blood, or chyle.

Absorption of other Substances.—Of soluble substances which are introduced into the intestinal canal, some are absorbed and others are not. The following are absorbed: alcohol, part of which appears in the urine (not in the expired air), viz., that part which is not changed into CO_2 and H_2O, within the body; tartaric, citric, malic, and lactic acids; glycerine, inulin; gum and vegetable mucin, which give rise to the formation of glycogen in the liver.

Among **coloring matters**, alizarin (from madder), alkannet, indigo-sulphuric acid, and its soda salt are absorbed; hæmatin is partly absorbed, while chlorophyll is not. **Metallic salts** seem to be kept in solution by proteids, are perhaps absorbed along with them, and are partly carried by the blood of the portal vein to the liver (ferric sulphate has been found in chyle). Numerous **poisons** are very rapidly absorbed, *e. g.*, hydrocyanic acid after a few seconds; potassium cyanide has been found in the chyle. [If salts (KI, sulphocyanide of ammonium) be injected into a ligatured loop of intestine (dog, cat, rabbit), these substances are absorbed both by the blood and lymph vessels, and in both nearly simultaneously.] Even for the absorption of completety fluid substances, endosmosis and filtration seem to be scarcely sufficient. An active participation of the protoplasm of the cells seems here also—in part at least—to be necessary, else it is diffiult to explain how very slight disturbances in the activity of these cells, *e. g.*, from intestinal catarrh, cause sudden variations of absorption, and even the passage of fluids into the intestine.

If absorption were due to diffusion alone, when alcohol is injected into the intestine, water ought to pass into the intestine, but this does not occur. Brieger found that the injection of a 0.5 to 1 per cent. solution of salts into a ligatured loop of intestine did not cause water to pass into the intestine; but it appeared when a 20 per cent. solution was injected.

II. Absorption of the Smallest Particles.—The largest amount of the fats is absorbed in the form of a milk-like **emulsion**, formed by the action of the bile and the pancreatic juice, and consisting of excessively small granules of uniform size (§ 170, III; § 181). The fats themselves are not chemically changed, but remain as undecomposed neutral fats. The particles seem to be surrounded by a delicate albuminous envelope, or haptogen membrane, partly derived from the pancreatic juice [probably from its alkali-albuminate]. The **villi** of the small intestine are the chief organs concerned in the absorption of the fatty emulsion, but the epithelium of the stomach and that of the large intestine also take a part. The fatty granules are recognized in the villi (1) Within the delicate canals? (§ 190) in the clear band of the epithelium (*Kölliker*). [It is highly doubtful if the vertical lines seen in the clear disk of the epithelium of the intestine are due to pores.] (2) The protoplasm of the epithelial cells is loaded with fatty granules of various sizes during the time of absorption, while the nuclei of the cells remain free, although, from the amount of fat within the cells, it is often difficult to distinguish them. (3) The granules pass into the spaces of the parenchyma of the villi; these spaces communicate freely with each other. (4) The origin of the **lacteal** in the axis of the villus is found to be filled with fatty granules. The amount of fat in the chyle of a dog, after a fatty meal, is 8 to 10 per cent., while the fat disappears from the blood within thirty hours.

With regard to the **forces concerned in the absorption of fats**, v. Wistinghausen proved, that when a porous membrane is moistened with bile, the

passage of fatty particles through it is thereby facilitated, but this fact alone does not explain the copious and rapid absorption of fats. It is possible that the protoplasm of the epithelial cells is actively concerned in the process, and that it takes the particles into its interior. Perhaps a fine protoplasmic process is thrown out by these cells, just as pseudopodia are thrown out and retracted by lower organisms. It is possible that absorption may take place through the open mouths of the goblet cells. The protoplasm of the epithelial cells is in direct communication with the numerous protoplasmic lymph cells within the reticulum of the villi, so that the particles may pass into these, and from them through the stomata (?) between the endothelial cells into the central lacteal of the villus. According to this view, the absorption of fatty particles, and perhaps also the absorption of true proteids, is due to an active vital process, as indicated by the observations of Brücke and v. Thanhoffer. This view is supported by the observation of Grünhagen, that the absorption of fatty particles in the frog is most active at the temperature at which the motor phenomena of protoplasm are most lively. That it is due to simple filtration alone is not a satisfactory explanation, for the amount of fatty particles in the chyle is independent of the amount of water in it. If absorption were chiefly due to filtration, we would expect that there would most probably be a direct relation between the amount of water and fat (*Ludwig and Zawilsky*). [The observations of Watney have led him to suppose that the fatty particles do not pass through the cell protoplasm to reach the lacteal, but that they pass through the *cement substance* between the epithelial cells covering a villus. If this view be correct, the absorbing surface is thereby greatly diminished. Zuwarykin and Schäfer suggest that the leucocytes, which have been observed between the columnar cells of the villi of the small intestine, are carriers of at least part of the fat from the lumen of the gut to the lacteal; they also, perhaps, alter it for further use in the economy. According to Zuwarykin, Peyer's patches in the rabbit seem to be especially active in the absorption of fat, so that he attaches great importance to the leucocytes of the adenoid tissue in the absorption of fat.]

[According to Grünhagen, there are several channels for the absorption of fats, but they are different in different animals. Some are absorbed by the columnar epithelium cells themselves, and some passes between them.]

The activity of the cells of the intestine with pseudopodial processes may be studied in the intestinal canal of Distomum hepaticum. Sommer has figured these pseudopodial processes actively engaged in the absorption of particles from the intestine.

193. **INFLUENCE OF THE NERVOUS SYSTEM.**—With regard to the influence of the nervous system upon intestinal absorption, we know very little. After extirpation of the semilunar ganglion, as well as after section of the mesenteric nerves (*Moreau*), the intestinal contents become more fluid, and are increased in amount (§ 183). This may be partly due to diminished absorption. V. Thanhoffer states that he observed the protrusion of threads from the epithelial cells of the small intestine only after the spinal cord, or the dorsal nerves, had been divided for some time.

194. **"NUTRIENT ENEMATA."**—In cases where food cannot be taken by the mouth, *e.g.*, in stricture of the œsophagus, continued vomiting, etc., food is given per rectum. As the digestive activity of the large intestine is very slight, fluid food ought to be given in a condition ready to be absorbed, and this is best done by introducing it into the rectum through a tube with a funnel attached, and allowing the food to pass in slowly by its own weight. The patient must endeavor to retain the enema as long as possible. When the fluid is slowly and gradually introduced, it may pass above the ileo-cæcal valve.

Solutions of grape sugar, and perhaps a small amount of soap solution, are useful; and among nitrogenous substances the commercial flesh-, bread-, or milk peptones of Sanders-Ezn, Adamkiewicz, in Germany, and Darby's fluid meat, and Carnrick's beef peptonoids in this country, are to be recommended. The amount of peptone required is 1.11 grm. per kilo. of body weight (*Catillon*); less useful are buttermilk, egg albumin with common salt. Leube uses a mixture of 150 grms. flesh with 50 grms. pancreas and 100 grms. water, which he slowly injects into the rectum, where the proteids

are peptonized and absorbed. [Peptonized food prepared after the method of Roberts is very useful (§ 172).] The method of nutrient enemata only permits imperfect nutrition, and at most only ¼ of the proteids necessary for maintaining the metabolism of the body is absorbed (*v. Voit, Bauer*).

195. **CHYLE VESSELS AND LYMPHATICS.—Lymphatics.**—Within the tissues of the body, and even in those tissues which do not contain blood vessels, *e. g.*, the cornea, or in those which contain few blood vessels, there exists a system of vessels or channels which contain the juices of the tissues, and within these vessels the fluid always moves in a centripetal direction. These canals arise within the tissues in a variety of ways, and unite in their course to form delicate and afterward thicker tubes, which ultimately terminate in two large trunks which open at the junction of the jugular and subclavian veins; that on the left side is the **thoracic duct,** and that on the right, **the right lymphatic trunk.**

With regard to the **lymph** and its movements in different organs, it is to be noticed that this occurs in different ways in different places. (1) In many tissues the lymphatics represent the **nutrient channels** by which the fluid that transudes through the neighboring vessels is distributed, as in the cornea and in many connective tissues. (2) In many tissues, as in glands, *e. g.*, the salivary glands and the testis, the lymph spaces are the chief **reservoirs for fluid,** from which the cells during the act of secretion derive the fluid necessary for that process. (3) The lymphatics have the general function of collecting the fluid which saturates the tissues, and carrying it back again to the blood. The capillary blood system may be regarded as an **irrigation system,** which supplies the tissues with nutrient fluids, while the lymphatic system may be regarded as a **drainage apparatus,** which conducts away the fluids that have transuded through the capillary walls. Some of the decomposition products of the tissues, proofs of their retrogressive metabolism, become mixed with the lymph stream, so that the lymphatics are at the same time **absorbing vessels.** Substances introduced into the parenchyma of the tissues in other ways, *e. g.*, by subcutaneous injection, are partly absorbed by the lymphatics. A study of these conditions shows that the lymphatic system represents an **appendix to the blood-vascular system,** and further that there can be no lymph system when the blood stream is completely arrested; it acts only as a part of the whole, and with the whole.

Lacteals.—When we speak of the lymphatics proper as against the *chyle vessels* or *lacteals*, we do so from anatomical reasons, because the important and considerable lymphatic channels coming from the whole of the intestinal tract are, in a certain sense, a fairly independent province of the lymphatic vascular area, and are endowed with a *high absorptive activity*, which, from ancient times, has attracted the notice of observers. The contents of the chyle vessels or lacteals are mixed with a large amount of fatty granules, giving the **chyle** a *white* color, which distinguishes them at once from the true lymphatics with their clear, watery contents. From a physiological point of view, however, the lacteals must be classified with the lymphatics, for, as regards their structure and function, they are true lymphatics, and their contents consist of true lymph mixed with a large amount of absorbed substances, chiefly fatty granules. [The contents of the lacteals are white only during digestion; at other times they are clear, like lymph.]

196. **ORIGIN OF THE LYMPHATICS.**—(1) **Origin in Spaces.**—Within the connective tissues (connective tissue proper, bone) are numerous stellate, irregular or branched spaces, which communicate with each other by numerous tubular processes (Fig. 216, 1); in these communicating spaces lie the cellular elements of these tissues. These spaces, however, are not completely filled by the cells, but an interval exists between the body of the cell and the wall of the space, which is greater or less according to the condition of movement of the protoplasmic cell. These spaces are the so-called "**juice canals**" or "**Saft-canälchen,**" and they represent the origin of the lymphatic vessels (*v. Recklinghausen*). As they communicate with neighboring spaces, the movement of the lymph is provided for. The cells which lie in the spaces exhibit amœboid movements. Some of these cells remain permanently, each in its own space, within which, however, it may change its form—these are the so-called "**fixed connective-tissue corpuscles,**" and bone corpuscles—while others merely wander or pass into these spaces, and are called "**wandering cells,**"

or "**leucocytes**;" but the latter are merely lymph corpuscles, or colorless blood corpuscles which have passed out of the blood vessels into the origin of the lymphatics. These cells exhibit amœboid movements. These spaces communicate with the small tubular lymphatics—the so-called *lymph capillaries* (L). The spaces lie close together where they pass into a lymph capillary (*a*). The lymph capillary, which is usually of greater diameter than the blood capillary, generally lies in the middle of the space within the capillary arch (B). The finest lymphatics are lined by a layer of delicate, nucleated, endothelial cells (*e*, *e*), with characteristic **sinous margins**, whose characters are easily revealed by the action of silver nitrate (Fig. 217, L). This substance blackens the cement substance which holds the endothelial cells together. Between the endothelial cells are small holes, or **stomata**, by means of which the lymph capillaries communicate (at *x*) with the juice canals.

It is assumed by Arnold that the blood vessels communicate with the juice canals, and that fluid passes out of the thin-walled capillaries through their stomata into these spaces (§ 65). This fluid nourishes the tissues, the tissues take up the substances appropriate to each, while the effete materials pass back into the spaces, and from these reach the lymphatics, which ultimately discharge them into the venous blood.

FIG. 216.

Origin of lymphatics from the central tendon of the diaphragm stained with nitrate of silver. *s*, the juice canals, communicating at *x* with the lymphatics; *a*, origin of the lymphatics by the confluence of several juice canals.

Whether the cells within these spaces are actively concerned in the pouring out of the blood plasma, or take part in its movement, is matter of conjecture. We can imagine that by contracting their body, after it has been impregnated with fluid, this fluid may be propelled from space to space toward the lymphatics. The leucocytes wander through these spaces until they pass into the lymphatics. Fine particles which are contained in these spaces—*e.g.*, after tattooing the skin, and even fatty particles after inunction—are absorbed by the leucocytes and carried by them to other parts of the body. [The pigment particles used to tattoo the finger are usually found within the first lymphatic gland at the elbow.]

The migration of cellular elements from the blood vessels into the origin of the lymphatics is to be considered as a normal process. *Granular coloring matter* passes from the blood into the protoplasmic body of the cells within the lymph spaces; and only when the granular pigment is in large amount, does it appear as a granular injection in the branches of the juice spaces.

FIG. 217.

(2) **Origin within villi**—*i. e.*, of the chyle vessel or **lacteal**—has been described (§ 190).

(3) **Origin in perivascular spaces** (Fig. 218).—The smallest blood vessels of bone, the central nervous system, retina and the liver, are completely surrounded by wide lymphatic tubes, so that the blood vessels are completely bathed by a lymph stream. In the brain these lymphatics are partly composed of delicate connective-tissue fibres, which traverse the lymph space and become attached to the wall of the included blood vessel. Fig. 218, B, represents a transverse section of a small blood vessel, B, from the brain; *p* is the divided perivascular space. This space is called the **perivascular space** of His, but in addition to it the blood vessels of the brain have a lymph space within the adventitia of the blood vessels (*Virchow-Robin's space*). It is partly lined by well-defined endothelium. Where the blood vessels begin to increase considerably in diameter, they pass through the wall of the lymphatics, and the two vessels afterward take separate courses. In all cases, where there is a perivascular space, the passage of lymph and blood corpuscles into the lymphatics is greatly facilitated. In the tortoise the large blood vessels are often surrounded with perivascular lymphatics. Fig. 218, A, gives a representation of the aorta surrounded by a perivascular space which is visible to the unaided eye. In mammals the perivascular spaces are microscopic.

(4) **Origin in the form of interstitial slits within organs.**—Within the testis the lymphatics begin simply in the form of numerous slits, which occur between the coils and twists of the seminal tubules. They take the form of elongated spaces bounded by the curved cylindrical surfaces of the tubules. The surfaces, however, are covered with endothelium. The lymphatics of the testis get independent walls after they leave the parenchyma of the organ. In many other glands the gland

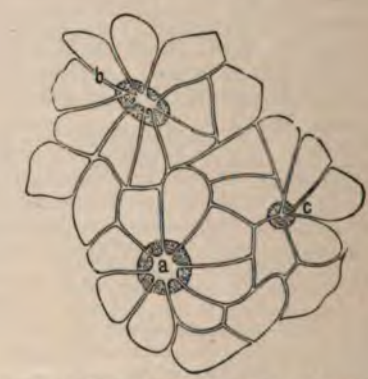
FIG. 219.



Stomata in the great lymph sac (frog). *a*, open; *b*, half-closed; *c*, closed.

substance is similarly surrounded by a lymph space. The blood vessels pour the lymph into these spaces, and from them the secretiug cells obtain the materials necessary for the formation of their secretion.

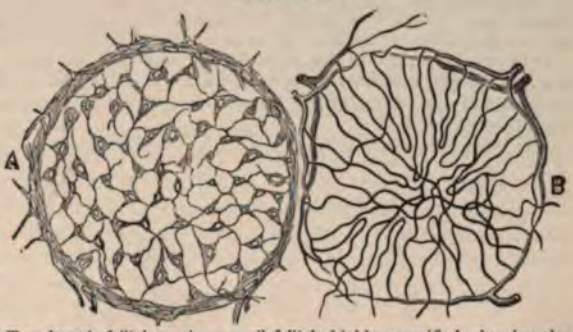
(5) **Origin by means of free stomata** on the walls of the larger **serous cavities**, which (Fig. 219, *a*) communicate freely with the lymphatics. The investigation of the serous surfaces is most easily accomplished on the septum of the great abdominal lymph sac of the frog. Silver nitrate reveals the presence of relatively large free openings or **stomata** lying between the endothelium. Each stoma is bounded by several **germinating cells**, which have a granular appearance, and undergo a change of shape, so that the size of the stoma depends upon the degree of contraction of these cells; thus the stoma may be open (*a*), half-open (*b*), or completely closed (*c*). These stomata are the origin of the lymphatics. The serous cavities belong therefore to the lymphatic system, and fluids placed in the serous cavities readily pass into the lymphatics. The cavities of the peritoneum, pleura, pericardium, tunica vaginalis, testis, arachnoid space, aqueous chambers of the eye, and the labyrinth of the ear, are true lymph cavities, and the fluid they contain is to be regarded as lymph. [Hoffmann has found that a nerve fibre surrounds the stomata in the frog and sends branches between the germinal epithelium.]

(6) **Free open pores** have been observed on some *mucous membranes*, which are regarded as the origin of lymphatics, *e. g.*, in the bronchi, nasal mucous membrane, trachea and larynx.

Structure.—The larger lymphatics resemble in structure the veins of corresponding size. The valves are particularly numerous in the lymphatics, so that a distended lymphatic resembles a chain of pearls. [Lymphatics have dilations here and there in their course (Fig. 217).]

197. THE LYMPH GLANDS.—The **lymphatic glands** belong to the lymph apparatus. They are incorrectly termed glands, as they are merely much-branched lacunar labyrinthine spaces composed of adenoid tissue, and intercalated in the course of the lymphatic vessels. There are **simple** and **compound** lymph glands.

FIG. 220.

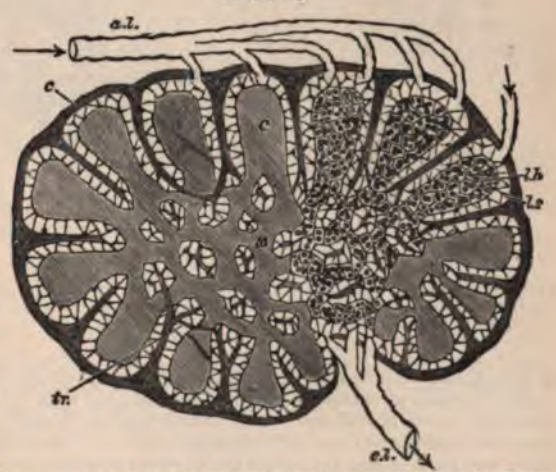


Two lymph follicles. A, a small follicle highly magnified, showing the adenoid reticulum; B, a follicle less highly magnified, showing injected blood vessels.

(1) The simple **lymph glands**, or, more correctly, **lymph follicles**, are small rounded bodies, about the size of a pin head. They consist of a mass of adenoid tissue (Fig. 220, A), *i. e.*, of a very delicate network of fine reticular fibres with nuclei at their points of intersection, and in the spaces of the meshwork lie the lymph and the lymph corpuscles. Near the surface, the tissue is somewhat denser, where it forms a capsule, which is not, however, a true capsule, as it is permeated with numerous small sponge-like spaces. Small lymphatics come directly into contact with these lymph follicles, and often cover their surface in the form of a close network. The surface of the lymph follicles is not unfrequently placed in the wall of a lymph vessel, so that it is directly bathed by the lymph stream. Although no direct canal-like opening leads from the follicle into the lymphatic stream in relation with it, a communication must exist, and this is obtained by the numerous spaces in the follicle itself, so that a lymph follicle is a true lymphatic apparatus whose juices and lymph corpuscles can pass into the nearest lymphatic. The follicles are surrounded by a network of blood vessels which sends loops of capillaries into their interior (Fig. 220, B). We may assume that lymph corpuscles pass from these capillaries into the follicle.

In connection with these follicles, including those of the back of the tongue, the solitary glands of the intestine and the adenoid tissue in the bronchial tract, the tonsils, and Peyer's patches, it is important to remember that enormous numbers of leucocytes pass out between the epithelial cells covering these follicles. The extruded leucocytes undergo disintegration subsequently.

FIG. 221.



Diagrammatic section of a lymphatic gland. *a. l.*, afferent, *e. l.*, efferent lymphatics; C, cortical substance: M, reticular cords of medulla; *l. s.*, lymph sinus; *c*, capsule, with trabeculæ, *tr.*

(2) The **compound lymph glands**—the **lymphatic glands**—represent a collection of lymph follicles, whose form is somewhat altered. Every lymph gland is covered externally with a connective-tissue **capsule** (Fig. 221, *c*), which contains numerous non-striped muscular fibres. From its inner surface, numerous **septa** and trabeculæ (*tr.*) pass into the interior, so that the gland substance is divided into a large number of **compartments**. These compartments in the *cortical* portion of the gland have a somewhat rounded form, and constitute the alveoli, while in the medullary portion they have a more elongated and irregular form. [On making a section of a lymph gland we can readily distinguish the **cortical** from the **medullary** portion of the gland,] All the compartments are of equal dignity, and they all communicate with each other by means of openings, so that the septa bound a rich network of spaces within the gland, which communicate on all sides with each other.

These spaces are traversed by the follicular threads (Fig. 222, *f, f*). These represent the con-

tents of the spaces, but are smaller than the spaces in which they lie, and do not come into contact anywhere with the walls of the spaces. If we imagine the spaces to be injected with a mass, which ultimately shrinks to one-half of its original volume, we obtain a conception of the relation of these follicular threads to the spaces of the gland. The **blood vessels** of the gland (*b*) lie within these follicular threads. They are surrounded by a tolerably thick crust of adenoid tissue, with very fine meshes (*x*, *x*) filled with lymph corpuscles, and with its surface (*o*, *o*) covered by the cells of the adenoid reticulum, in such a way as to leave free communications through the narrow meshes.

Between the surface of the follicular threads and the inner wall of all the spaces of the gland, lies the **lymph channel** or **lymph path** (B, B), which is traversed by a reticulum of adenoid tissue, containing relatively few lymph corpuscles. It is very probable that these lymph paths are lined by endothelium.

The **vasa afferentia** (Fig. 221, *a. l.*), of which there are usually several, expand upon the surface

FIG. 222.

Part of a lymphatic gland. A, vas afferens; B, B, lymph paths; *a*, *a*, trabeculæ seen on edge; *f*, *f*, follicular strand from the medulla; *x*, *x*, its adenoid reticulum; *b*, its blood vessels; *o*, *o*, narrow-meshed part limiting the follicular strands from the lymph path.

of the gland, perforate the outer capsule, and pour their contents into the lymph paths of the gland (C). The **vasa efferentia**, which are less numerous than the afferentia, and come out at the hilum, form large, wide, almost cavernous dilatations, and they anastomose near the gland (*e. l.*). Through them the lymph passes out at the opposite surface of the gland. The lymph percolates through the gland, and passes along the lymph paths, which represent a kind of rete mirabile interposed between the afferent and efferent lymph vessels.

During its passage through this complicated branched system of spaces, the movement of the lymph through the gland is retarded, and, owing to the numerous resistances which occur in its path, it has very little propulsive energy. The lymph corpuscles which lie in the meshes of the adenoid reticulum are washed out of the gland by the lymph stream. The lymph corpuscles lying within the follicular threads pass through the narrow meshes (*o*) into the lymph paths. The formation of lymph corpuscles either occurs locally, from division of the pre-existing cells, or new leuco-

tes wander out into the follicular threads. The movement of the lymph through the gland is ored by the muscular action of the capsule. When the capsule contracts energetically, it must mpress the gland like a sponge, and the direction in which the fluid moves is regulated by the sition and arrangement of the valves.

Chemistry.—In addition to the constituents of lymph, the following chemical substances have en found in lymphatic glands: leucin and xanthin.

198. PROPERTIES OF CHYLE AND LYMPH.—**Chyle** and **ymph** are albuminous, colorless, clear juices, containing **lymph corpuscles,** hich are identical with the colorless blood corpuscles (§ 9). In some places, *e.g.*, n the lymphatics of the spleen, especially in starving animals, and in the thoracic luct, a few colored blood corpuscles have been found. The lymph corpuscles are upplied to the lymph and chyle from the lymphatic glands and the adenoid issue. As to their source see § 200, 2. They also pass out of the blood vessels nd wander into the lymphatics. As red blood corpuscles have also been seen to ass out of the blood vessels, this explains the occasional presence of these cor- uscles in some lymphatics; but when the pressure within the veins is high, near he **central** orifice of the thoracic duct, red blood corpuscles may pass into the horacic duct. But we are not entitled to conclude from their presence that mph cells form red blood corpuscles. In addition, the **chyle** contains merous **fatty granules,** each surrounded with an albuminous envelope. Thus the chyle, in addition to the constituents of the lymph, contains, especially ring digestion, a very large amount of fat, in the form of the finely emul- sified fat of the food, which gives it its characteristic *white* or milky appearance. ring hunger, the fluid in the lacteals resembles ordinary lymph. The fine fat anules constitute the so-called "**molecular basis**" of the chyle.]

Composition of Lymph.—The lymph consists of **lymph plasma** with **mph corpuscles** suspended in it. The corpuscles or leucocytes are described § 24. The **lymph plasma** contains the three so-called fibrin factors, derived ry probably from the breaking up of lymph corpuscles (§ 29). When lymph is thdrawn from the body, these substances cause it to **coagulate.** Coagulation curs slowly, owing to the formation of a soft, jelly-like, small "**lymph clot,**" hich contains most of the lymph corpuscles. The exuded fluid or **lymph** rum contains *alkali albuminate* (precipitated by acids), *serum albumin* (coagu- ted by heat), and *paraglobulin*—the two latter occurring in the same proportion in blood serum; 37 per cent. of the coagulable proteids is paraglobulin.

(1) **Chyle,** which occurs within the lacteals of the intestinal tract, can only be btained in very small amount before it is mixed with lymph, and hence the diffi- lty of investigating it. A few *lymph corpuscles* occur even in the origin of cteals within the villi, but their number increases in the vessels beyond the testine, more especially after the chyle has passed through the mesenteric glands. he amount of **solids,** which undergoes a great increase during digestion, on e contrary, diminishes when chyle mixes with lymph. After a diet rich in tty matters, the chyle contains innumerable *fatty granules* (2–4 μ in size). [This the so-called "molecular basis" of the chyle.] The amount of *fibrin factors* creases with the increase of lymph corpuscles, as they are formed from the break- g up of the lymph-corpuscles; a *diastatic ferment* absorbed from the intestine; casionally *sugar* (to 2 per cent.); after much starchy food, *lactates;* peptone the leucocytes (§ 192, I, 3), and traces of urea and leucin.

The **Chyle** of a person who was executed contained 90.5 per cent. of water.

Solids,	9.5	Fibrin,	trace
		Albumin,	7.1
		Fats,	0.9
		Extractives,	1.0
		Salts,	0.5

Schmidt found the following **inorganic** substances in 1000 parts of chyle :—

Sodic chloride,	5.84	Sulphuric acid,	0.05	Magnesic phosphate,	0.05
Soda,	1.17	Phosphoric acid,	0.05	Iron,	trace.
Potash,	0.13	Ca'cic phosphate.	0.20		(Horse.)

(2) **The lymph** obtained from the beginning of the lymphatic system contains very few lymph corpuscles; it is clear, transparent, and colorless, and closely resembles the fluids of serous cavities. That the lymph coming from different tissues varies somewhat, is highly probable, but this has not been proved. After lymph has passed through lymphatic glands, it contains more corpuscles, and also more solids, especially albumin and fat. Ritter counted 8200 lymph corpuscles in 1 cubic centimetre of the lymph of a dog.

Pure lymph obtained from a lymphatic fistula in the leg of a man has an alkaline reaction and a saline taste, and the following composition :—

Pure Lymph (*Hensen & Dähnhardt*).	Cerebro-spinal Fluid (*Hoppe-Seyler*).	Pericardial Fluid (*v. Gorup-Besanez*).
Water, 98.63	98.74	95 51
Solids, 1.37	1.25	4.48
Fibrin, 0.11	...	0.08
Albumin, 0 14	0.16	2.46
Alkali-albuminate, 0.09	...	...
Extractives, ...	...	1.26
Urea, Leucin, 1.05	The cerebro-spinal fluid and abdominal lymph contain a kind of sugar (without the property of rotating polarized light—*Hoppe-Seyler*).	
Salts, 0.88		
70 vol. per cent. of absorbed CO_2, 50 per cent. could be pumped out, and 20 per cent. by the addition of an acid.		

100 parts of the **ash** of **lymph** contained the following substances :—

Sodium chloride,	74.48	Lime,	0.98	Sulphuric acid,	1.28
Soda,	10.36	Magnesia,	0.27	Carbonic acid,	8.21
Potash,	3.26	Phosphoric acid,	1.09	Iron oxide,	0.06

Just as in blood, **potash** and **phosphoric acid** are most abundant in the **corpuscles**; while **soda** (chiefly sodium chloride) is most abundant in the **lymph serum.** The potash and phosphoric acid compounds are most abundant in cerebro-spinal fluid, according to C. Schmidt. The amount of **water** in the lymph rises and falls with that of the blood. **Gases.**—Dog's lymph contains much CO_2—more than 40 vols. per cent., of which 17 per cent. can be pumped out, and 23 per cent. expelled by acids, while there are only traces of O and 1.2 vols. per cent. N (*Ludwig, Hammersten*).

[The **cerebro-spinal fluid** contains a substance which reduces an alkaline solution of cupric hydrate. The potassic are in excess of the soda salts, while the fluid of the meningoceles and chronic hydrocephalus contains proto-albumose, some serum globulin, no serum albumin, but the last is present in acute hydrocephalus fluid. No albumose is found in pericardial or pleuritic fluids (*Halliburton*).]

199. QUANTITY OF LYMPH AND CHYLE.—When it is stated that the total **amount** of the lymph and chyle passing through the large vessels in twenty-four hours is equal to the amount of the blood, it must be remembered that this is merely a conjecture. Of this amount one-half may be lymph and the other half chyle. The formation of lymph in the tissues takes place continually, and without interruption. Nearly 6 kilos. of lymph were collected in twenty-four hours from a lymphatic fistula in the arm of a woman, by Gubler and Quevenne; 70 to 100 grms. were collected in 1½ to 2 hours from the large lymph trunk in the neck of a young horse. The following conditions affect the **amount** of chyle and lymph :—

(1) The amount of chyle undergoes very considerable **increase during digestion,** more especially after a full meal, so that the lacteals of the mesentery and intestine are distended with white or milky chyle. During hunger the lymph vessels are collapsed, so that it is difficult to see the large trunks.

(2) The amount of lymph **increases** especially with the **activity of the organ** from which it proceeds. Active or passive muscular movements greatly increase its amount. Lesser obtained in this way 300 cubic centimetres of lymph from a fasting dog, whereby its blood became so inspissated as to cause death.

(3) All conditions which increase the **pressure** upon the juices of the tissues *increase* the amount of lymph, and *vice versâ*. These conditions are:—

(*a*) An **increase of the blood pressure,** not only in the whole vascular system, but also in the vessels of the corresponding organ, augments, the amount of lymph and *vice versâ* (*Ludwig, Tomsa*). This, however. is doubtful, as has been shown by Paschutin and Emminghaus. [In order to increase the amount of lymph depending upon pressure within the vessels, what must happen is increased pressure within the capillaries and veins.]

(*b*) **Ligature** or **obstruction** of the efferent **veins** greatly increases the amount of lymph which flows from the corresponding parts (*Bidder, Emminghaus*). It may be doubled in amount. Tight bandages cause a swelling of the parts on the peripheral side of the bandage, owing to a copious effusion of lymph into the tissue (congestive œdema).

(*c*) An increased **supply of arterial blood** acts in the same way, but to a less degree. Paralysis of the vasomotor nerves, or stimulation of vaso-dilator fibres, by increasing the supply of blood increases the amount of lymph; while diminution of the blood supply, owing to stimulation of vaso-motor fibres or other causes, diminishes the amount. Even after ligature of both carotids, as the head is still supplied with blood by the vertebrals, the lymph stream in the large cervical lymphatic does not cease.

(4) When the **total amount of the blood** is increased, by the injection of blood or serum into the arteries, much fluid passes into the tissues and increases the formation of lymph.

(5) The formation of lymph still goes on for a short time after death, and after complete cessation of the action of the heart, but only to a slight extent. If fresh blood be caused to circulate in the body of an animal, while it is still warm, more lymph flows from the lymphatics. It appears as if the tissues obtained plasma from the blood for a time after the stoppage of the circulation. This perhaps explains the circumstance that some tissues, *e. g.*, connective tissues, contain more fluid after death than during life, while the blood vessels have given out a considerable amount of their plasma after death.

(6) The amount of lymph is increased under the influence of **curara**, and so is the amount of solids in the lymph (*Lesser*). A large amount of lymph collects in the lymph sacs [especially the sub-lingual] of frogs poisoned with curara, which is partly explained by the fact that the lymph hearts are paralyzed by curara. The amount of lymph is also increased in inflamed parts.

200. ORIGIN OF LYMPH.—(1) Source of the Lymph Plasma.— The lymph plasma may be regarded as fluid which has been pressed through the walls of the blood vessels by the blood pressure, *i. e.*, by **filtration** into the tissues. The *salts* which pass most readily through membranes, go through nearly in the same proportion as they exist in blood plasma—the *fibrin factors* to about two-thirds, and *albumin* to about one-half of that in the blood. As in the case of other filtration processes, the amount of lymph must increase with increasing pressure.

This was proved by Ludwig and Tomsa, who found that when they passed blood serum under varying pressures through the blood vessels of an excised testis, the amount of transuded fluid which flowed from the lymphatics varied with the pressure. This "**artificial lymph**" had a composition similar to that of the natural lymph. Even the amount of al umin increased with increasing pressure. The lymph plasma is mixed in the different tissues with the decomposition products, the results of the metabolism of the tissues.

When the **muscles act,** not only is the lymph poured out more rapidly, but more lymph is formed. The tendons and fasciæ of the muscles of the skeleton, which are provided with numerous small stomata, absorb the lymph from the muscles. By the alternate contraction and relaxation of these fibrous structures, act like suction pumps, whereby the lymphatics are alternately filled and while the lymph is propelled onward. Even **passive movements**

act in the same way. If solutions be injected under the fascia lata, they may be propelled onward to the thoracic duct by passive movements of the limb (*Ludwig, Schweigger-Seidel*).

(2) **The source of the lymph corpuscles** varies.—(1) A very considerable number of lymph corpuscles are derived from the **lymphatic glands**; they are washed out of these glands into the vas efferens by the lymph stream, hence, the lymph always contains more corpuscles after it has passed through a lymph gland. Small isolated lymph follicles permit corpuscles to pass through their limiting layer into the lymph stream. (2) Those organs whose basis consists of **adenoid tissue**, and in whose meshes numerous lymph corpuscles occur, *e. g.*, the mucous membrane of the entire intestinal tract, red marrow of bone, and the spleen (§ 103). The cells reach the origin of the lymph stream by their own amœboid movements. (3) As lymph corpuscles are returned to the blood stream, where they appear as colorless blood corpuscles, so they again pass out of the **blood capillaries** into the tissues, partly owing to their amœboid movements, and they are partly expelled by the blood pressure. In rare cases lymph corpuscles wander from lymphatic spaces back again into the blood vessels.

Fine particles of cinnabar or milk globules introduced into the blood soon pass into the lymphatics. The extrusion of particles is greater during venous congestion than when the circulation is undisturbed, just as with diapedesis (§ 95); inflammatory affections of the vascular wall also favor their passage. The vessels of the portal system are especially pervious.

(4) By division **of the lymph corpuscles**, and also by **proliferation of the fixed connective-tissue corpuscles.** This process certainly occurs during inflammation of many organs. This has been proved for the excised cornea kept in a moist chamber; the nuclei of the cornea corpuscles also proliferate.

That the connective-tissue corpuscles proliferate is shown by the enormous production of lymph corpuscles in acute inflammations (with the formation of pus), *e. g.*, in extensive erysipelas, and inflammatory purulent effusions into serous cavities, where the number of corpuscles is too great to be explained by the wandering of blood corpuscles out of the blood vessels.

Decay of Lymph Corpuscles.—The lymph corpuscles disappear partly where the lymphatics arise. The presence of the fibrin factors in the lymph—formed as they are from the breaking up of lymph corpuscles—seems to indicate this. In inflammation of connective tissue, in addition to the formation of numerous new lymph corpuscles, a considerable number seems to be dissolved; hence the lymph, and also the blood, in this case contains more fibrin. Lymph corpuscles are also dissolved within the blood stream, and help to form the fibrin factors.

201. **MOVEMENT OF CHYLE AND LYMPH.**—The **ultimate cause** of the movement of the chyle and lymph depends upon the difference of the pressure at the origin of the lymphatics, and the pressure where the thoracic duct opens into the venous system.

(1) The forces which are active at the **origin of the lymphatics** are concerned in moving the lymph, but these must vary according to the place of origin. (*a*) The **lacteals** receive the first impulse toward the movements of their contents—the chyle—from the contraction of the **muscular fibres of the villi** (pp. 339, 344). When these contract and shorten, the axial lacteal is compressed, and its contents are forced in a centripetal direction toward the large lymphatic trunks. When the villi relax, the numerous valves prevent the return of the chyle into the villi. (*b*) Within those lymphatics which take the form of perivascular spaces, every time the contained *blood vessel* is *dilated* the surrounding lymph will be pressed onward. (*c*) In the case of the pleural lymphatics with open mouths, every **inspiratory movement** acts like a suction pump upon the lymph, and the same is the case with the openings or stomata of the lymphatics on the abdominal side of the *diaphragm*. (*d*) In the case of those vessels which begin

by means of fine juice canals, the movement of the lymph must largely depend upon the **tension of the juices of the parenchyma**, and this again must depend upon the tension or *pressure in the blood capillaries*, so that the blood pressure acts like a *vis a tergo* in the rootlets of the lymphatics.

[In some organs peculiar **pumping arrangements** are brought into action. The abdominal surface of the **central tendon** of the **diaphragm** is provided with stomata, or open communications between the peritoneal cavity and the lymphatics in the substance of the tendon. Von Recklinghausen found that milk put upon the peritoneal surface of the central tendon showed little eddies, caused by the milk globules passing through the stomata and entering the lymphatics. The central tendon consists of two layers of fibrous tissue arranged in different directions (Fig. 223, *b*, *c*). When the

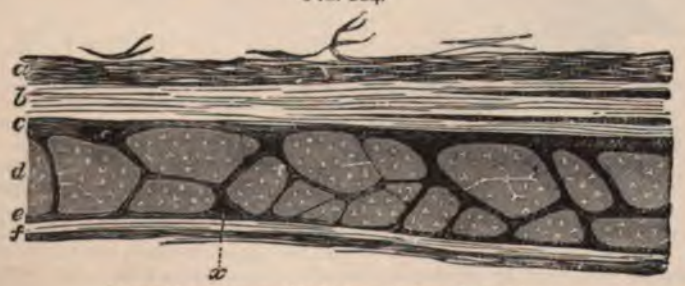
FIG. 223.

Section of central tendon of diaphragm. The injected lymph spaces, *h* and *h*, are black. At *f* the walls of the space have collapsed.

diaphragm moves during respiration, these layers are alternately pressed together and pulled apart. Thus the spaces are alternately dilated and contracted, lymph being drawn into the lymphatics through the stomata (Fig. 223, *h*). The same kind of pumping mechanism exists over the **costal pleura.** The fascia covering the muscles is another similar mechanism. The fascia consists of two layers of fibrous tissue, with intervening lymphatics (Fig. 224). When a muscle contracts, lymph is forced out from between the layers of the fascia, while when it relaxes, the lymph from the muscle, carrying with it some of the waste products of muscular action, passes out of the muscle into the fascia, between the now partially separated layers.]

[**Ludwig's Experiment.**—Tie a respiration cannula in the trachea of a dead rabbit; cut across the body of the animal immediately below the diaphragm; remove the viscera, and ligature the vessels passing between the thorax and abdomen; tie the thorax to an iron ring, and hang it up with the head downward; pour a solution of Berlin blue upon the peritoneal surface of the diaphragm;

FIG. 224.



Injected lymph spaces (black) from the fascia lata of the dog.

connect the respiration cannula either with a pair of bellows or an apparatus for artificial respiration, and imitate the respiratory movements. After a few minutes the lymphatics are filled with a blue injection showing a beautiful plexus.]

(2) Within the lymph trunks themselves, the **independent contraction of their muscular fibres** partly aids the lymph stream. Heller observed in the mesentery of the guinea pig that the peristaltic movement of the lymphatic wall passed in a centripetal direction. The numerous **valves** prevent any reflux. The **contraction of the surrounding muscles,** and **pressure** upon the vessels and the tissues, aid the current. If the outflow of blood from the veins is interfered with, lymph flows copiously from the corresponding tissues. [If a

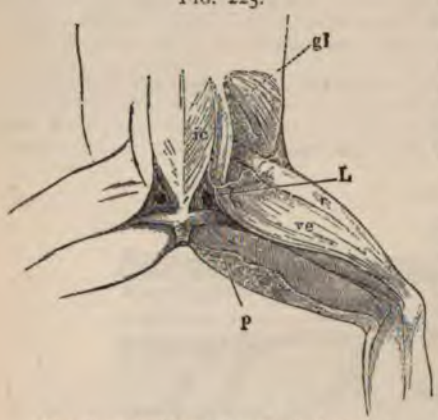
cannula be tied in a lymphatic of a dog, a few drops of lymph flow out at long intervals. But if even *passive* movements of the limb be made, *e. g.*, simply flexing and extending the limb, the outflow becomes very considerable and continuous.]

(3) The **lymph glands,** which occur in the course of the lymphatics, offer very considerable resistance to the lymph stream, which must pass through the lymph paths, whose spaces are traversed by adenoid tissue, and contain a few lymph corpuscles. But this is, to a certain extent, compensated for by the non-striped muscle which exists in the capsule and trabeculæ of the glands. When they contract they force on the lymph, while the valves prevent its reflux. Enlarged lymphatic glands have been seen to contract when stimulated electrically. [Botkin has stimulated enlarged lymphatic glands with electricity in cases of leukæmia.]

(4) The lymph vessels gradually join to form larger vessels, and finally end in one trunk. Thus the *sectional area* diminishes, so that the **velocity** of the current and the pressure are increased. Nevertheless, the velocity is always small; it varied from 230 to 300 millimetres per minute in the large lymphatic in the neck of a horse, a fact which enables us to conclude that the movement must be very slow in small vessels. The *lateral pressure* at the same place was 10 to 20 mm., and in the dog 5 to 10 mm. of a weak solution of soda, although it was 12 mm. Hg in the thoracic duct of a horse.

(5) The **respiratory movements** exercise a considerable influence upon the lymph stream in the thoracic duct, and in the right lymphatic duct; every inspiration favors the passage of the venous blood, and also of the lymph toward the heart, whereby the tension in the thoracic duct may even become negative. [The *diastolic suction of the heart*, by diminishing the pressure in the subclavian vein, also favors the inflow of lymph into the thorax.]

FIG. 225.



Posterior pair of lymph hearts (L) of the frog.

(6) **Lymph hearts** exist in certain cold-blooded animals. The frog has two *axillary* hearts (above the shoulder near the vertebral column), and two *sacral* hearts, one on each side of the coccyx near the anus (Fig. 225, L). They beat, but not synchronously, about sixty times per minute, and contain 10 cubic centimetres of lymph. They have transversely striped muscular fibre in their walls, and are also provided with *nerve ganglia*. The posterior pair pump the lymph into the branch of the vena iliaca communicans, and the anterior pair into the vena subscapularis. Their pulsation depends partly, but not exclusively, upon the spinal cord, for if the cord be rapidly destroyed, they may cease to pulsate, but not unfrequently they continue to pulsate after removal of the cord. [And if the cord be destroyed gradually, they continue to beat (*Kabrhel*).] A second source of their pulsatile movements is to be sought for in Waldeyer's ganglia. Stimulation of the skin, intestine, or blood heart influences them reflexly—partly accelerating and partly retarding them [most frequently arresting them in diastole, so that there seems to be an inhibitory mechanism in the cord, but it is not affected by atropine (*Kabrhel*)]. If the coccygeal nerve, which connects the sacral hearts to the spinal cord be divided, these effects do not occur. *Strychnia* accelerates their movements, and so does heating of the spinal cord; but if the cord be cooled, they are retarded. A lymph heart arrested by being exposed, or after the action of muscarin, can be caused to beat by filling it under pressure, but this is not the case when the arrest is caused by destruction of its nerves. *Antiarin* paralyzes the lymph heart and the blood heart at the same time, while *curara* paralyzes the former alone. In other amphibians there are two lymph hearts; in the ostrich and cassowary and some swimming birds, and in the embryo chick, 1 or 2. They occur in some fishes, *e. g.*, near the caudal vein of the eel.

(7) The **nervous system** has a direct effect upon the lymph stream, on account of its connection with the muscles of the lymphatics and lymph glands, and with the lymph hearts where these exist. Kühne observed that the cornea corpuscles contracted when the corneal nerves were stimulated [and Hoffman has described the termination of nerves in connective tissue corpuscles]. Goltz also observed that, when a dilute solution of common salt was injected under the skin of a frog, it was rapidly absorbed, but if the central nervous system had been destroyed, it was not absorbed.

If inflammation be produced in the hind legs of a dog, and if the sciatic nerve be divided on one side, œdema and a simultaneous increase of the lymph stream occur on that side. [A combination of congestion and inflammation greatly increases the lymph stream, and this is still more the case when the nerves are divided at the same time.]

Ligature the leg of a frog, except the nerves, so as to arrest the circulation, and place the leg in water; it swells up very rapidly, but a dead limb does not swell up. So that absorption is independent of the continuance of the circulation. Section of the sciatic nerve, or destruction of the spinal cord (but not section of the brain), arrests absorption.

202. **ABSORPTION OF PARENCHYMATOUS EFFUSIONS.**—Fluids which pass from the blood vessels into the spaces in the tissues, or those injected subcutaneously, are absorbed chiefly by the blood vessels, but also by the lymphatics. Small particles, as after tattooing with cinnabar or China ink, may pass from the tissue spaces into the lymphatics—and so do blood corpuscles from extravasations of blood, and fat granules from the marrow of a broken bone. If all the lymphatics of a part are ligatured, absorption takes place quite as rapidly as before; hence, absorbed fluid must pass through the thin membranes of the blood vessels. The corresponding experiment of ligaturing all the blood vessels, when no absorption of the parenchymatous juices takes place, does not prove that the lymphatics are not concerned in absorption, for, after ligaturing the blood vessels of a part, of course the formation of lymph, and also the lymph stream, must cease. When fluids are injected under the skin, absorption takes place very rapidly—more rapidly than when the substance is given by the mouth. The **subcutaneous injection** of drugs is extensively used, but of course the substances used must not corrode, irritate, or coagulate the tissues. Some substances do not act when given by the mouth, as snake poison, poisons from dead bodies, or putrid things, although they act rapidly when introduced subcutaneously. If **emulsin** be given by the mouth, and **amygdalin** be injected into the veins of an animal, hydrocyanic acid is not formed, as the emulsin seems to be destroyed in the alimentary canal. If the emulsin, however, be injected into the blood, and the amygdalin be given by the mouth, the animal is rapidly poisoned, owing to the formation of hydrocyanic acid, as the amygdalin is rapidly absorbed from the intestinal canal. The amygdalin, a glucoside ($C_{20}H_{27}NO_{11}$), is acted upon by fresh emulsin like a ferment; it takes up $2(H_2O)$ and yields hydrocyanic acid (CHN), + oil of bitter almonds (C_7H_6O), + sugar $2(C_6H_{12}O_6)$. **Serum** injected subcutaneously is rapidly absorbed; it is decomposed within the blood stream, and increases the amount of urea. Albuminous solutions, oil, peptones, and sugars are also absorbed.

203. **ŒDEMA, DROPSY, AND SEROUS EFFUSIONS.**—[**Dropsy.**—As aptly illustrated by Lauder Brunton, the lymph spaces may be represented by cisterns, each of which is provided with supply pipes—the arteries and capillaries; while there are two exit pipes—the veins and lymphatics. In health, the balance between the inflow and outflow is such that the spaces are merely moistened with fluid. When a cannula is placed in a lymphatic vessel in a dog, only a few drops of lymph flow out at long intervals, but if the veins of the limb be ligatured, the lymph flows much more quickly. This is in part due to the increased transudation of fluid from the small blood vessels, but it may also be due to fluid passing away by the lymphatics when it can no longer be carried away by the veins. We cannot say what is the relative share of the veins and the lymphatics, nor in the above experiment do we know how much is due to increased transudation or diminished absorption. When there is an undue accumulation of fluid more or less like serum in the lymph spaces, we have the condition termed **dropsy.** When there is general dropsy it is called **anasarca.**]

Œdema.—If the efferent veins and lymphatics of an organ be ligatured, or if resistance be offered to the outflow of their contents, congestion and a copious transudation of lymph into the tissue take place. These are most marked in the skin and subcutaneous cellular tissue. The soft parts swell up, without pain or redness, and a doughy swelling, which **pits** on **pressure** with the finger, results. These are the signs of lymph congestion, which is called **œdema** when the fluid is *watery* and localized.

Under similar circumstances lymph is effused in the **serous cavities.** [In the peritoneum it is **ascites**—thorax, **hydrothorax**—pericardium, **hydro-pericardium**—cranium, **hydrocephalus**—tunica vaginalis, **hydrocele**—joints, **hydrarthrosis,** etc.] If, at the same time, a large number of colorless blood corpuscles pass out of the blood vessels into the cavity, the fluid becomes more and more like pus. In order that these corpuscles may proliferate, a considerable percentage of albumin is necessary. When the pressure within the serous cavity rises above that in the small blood vessels,

water may pass into the blood. These sero-purulent effusions not unfrequently undergo changes, and yield decomposition products, such as leucin, tyrosin, xanthin, kreatin, kreatinin (?), uric acid (?), urea. Endothelium from the serous cavity, sugar in pleuritic effusions and in œdemas with little albumin, cholesterin frequently in hydrocele fluid, and succinic acid in the fluid of echinococci, have all been found in these effusions. The effusion of lymph may arise not only from pressure upon the lymphatics, but also from inflammation and thrombosis of the lymphatics themselves, in which cases not unfrequently new lymphatics are formed, so that the communication is reëstablished. Sometimes the ductus thoracicus bursts, and lymph is poured directly into the abdomen or thorax. [Ligature of the thoracic duct results in rupture of the receptaculum chyli and escape of chyle and lymph into the large serous cavities (*Ludwig*).

When dropsy or effusion of fluids occurs into serous cavities, there is always a greater transudation of fluid through the blood vessels. The abdominal blood vessels, and those which yield a watery effusion under normal circumstances, are those most liable to be affected.

Transudation is favored by (1) **Venous congestion,** so as to raise the **blood pressure**, in which case the effusion usually contains little albumin and few lymph corpuscles, while the colored corpuscles, on the contrary, are more numerous the greater the venous obstruction. Ranvier produced œdema artificially by ligaturing the vena cava in a dog, and at the same time dividing the sciatic nerve. The paralytic dilatation of the blood vessels thereby produced caused an increased amount of blood to pass to the limb, while the blood pressure was raised, and both factors favored the transudation of fluid. [Ranvier's experiment proves that mere ligature of the venous trunk of a limb *by itself* is not sufficient to cause œdema. The œdema is due to the concomitant paralysis of the vasomotor nerves. If the motor roots of the sciatic nerve alone be divided along with ligature of the vena cava, no œdema occurs, but if the vasomotor fibres are divided at the same time the limb rapidly becomes œdematous. There is such an increased transudation through the vascular walls that the veins and lymphatics cannot remove it with sufficient rapidity, and œdema occurs. If there be weakness of the vasomotor nerves, slight obstruction is sufficient to produce œdema.] When the leg veins are occluded with an injection of gypsum, œdema occurs. (2) Some unknown **physical changes** occur in the **protoplasm** of the endothelium of the capillaries and blood vessels, which favor the transudation of albumin, hæmoglobin, and even blood corpuscles. This occurs when abnormal substances accumulate in the blood—*e. g.*, dissolved hæmoglobin—and when the blood contains little O or albumin. The same has been observed after exposure to too high temperatures, and the swelling of soft parts in the neighborhood of an inflammatory focus seems due to the transudation of fluid through the altered vascular wall. It is probable that a nervous influence may affect particular areas through its action on the blood vessels of the part (it may be upon the protoplasm of the blood capillaries). The transudations of this nature usually contain much albumin and many lymph corpuscles. (3) When the **blood** contains a very large **amount of water,** the tendency to transudation of fluid is increased. After a time it may produce the changes indicated in (2), and when long continued may increase the permeability of the vascular wall. Watery lymphatic effusions from watery blood—"**cachectic œdema**"—occur in feeble and badly-nourished individuals. [One of the commonest forms of dropsy is the slight œdema of the legs in anæmic persons, in whom the heart and lungs are healthy. Many factors are involved—the blood pressure, watery condition of the blood, the condition of nutrition of the capillaries, and probably a tendency to vasomotor paresis (*Brunton*).]

[The fluid poured out varies according to the rapidity with which this occurs. In acute inflammations effusion or **exudation** takes place rapidly, and the fluid contains the fibrin factors, so that it tends to coagulate spontaneously. There is every gradation between the non-coagulable hydrocele fluid and the coagulable exudation in inflammation. The fluids in different dropsies vary in composition, and some have more cells in them, depending on local causes, as in some situations absorption is more active than in others. The pleural fluid contains most solids, then ascitic, cerebro-spinal, and lastly that in the subcutaneous tissue. Transudation corresponds to the process of filtration through animal membranes, *i. e.*, the transudation contains only those substances already present in the blood plasma. The filtrate may even contain more salts than the original fluid, as is often the case with fluids containing cry-talloid and colloid bodies. Senator finds, in cases of œdema of the leg, that increase of the venous pressure increases the proteids in the transudation, but causes no essential change in the amount of the salts.]

[(4) Ostroumoff found that stimulation of the lingual nerve not only causes the blood vessels of the tongue to dilate, but that the corresponding side of the tongue becomes œdematous. If a solution of dilute hydrochloric acid or quinine (§ 145) be injected into the duct of the sub-maxillary gland, and the chorda tympani stimulated, there is no secretion of saliva, but the gland becomes œdematous. In an animal poisoned with atropin, stimulation of the chorda causes dilatation of the blood vessels, although there is no secretion of saliva, nevertheless the gland does not become œdematous (*Heidenhain*). As Brunton suggests, this experiment points to some action of atropin on the blood vessels which has hitherto been entirely overlooked.]

204. COMPARATIVE PHYSIOLOGY.—In the **frog** large lymph sacs, lined with endothelium, exist under the skin, while large lymph sacs lie in relation with the vertebral column—one on each side—separated from the abdominal cavity by a thin membrane, perforated with stomata.

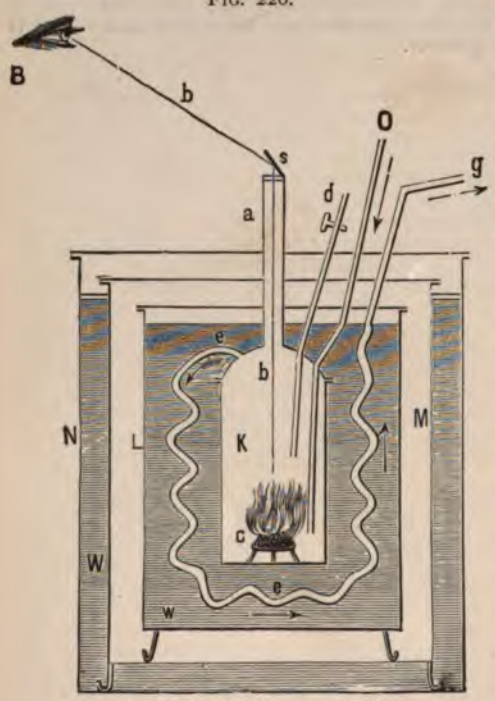
: **cysterna lymphatica magna** of Panizza. Some amphibians and many reptiles have skin large lymph spaces, which occupy the whole of the dorsal region of the body. All d the tailed amphibians have large elongated reservoirs for lymph along the course of the ıe lymph apparatus of the tortoise (Fig. 218) is very extensive. The **osseous fishes** e lateral parts of their backs an elongated lymph trunk, which reaches from the tail to the ns, and is connected with the dilated lymphatic rootlets in the base of the tail and in the largest internal lymph sinus is in the region of the œsophagus. Many **birds** possess a dilatation or lymph space in the region of the tail. The lymph spaces communicate with ı system—with valves properly arranged—usually in connection with the upper vena cava. :arts have already been referred to (§ 201, 6). In **carnivora** the lymph glands of the are united into one large compact mass, the so-called "pancreas Asellii."

ISTORICAL.—Although the Hippocratic School was acquainted with the lymph glands becoming swollen from time to time, and although Herophilus and Erasistratus had seen teric glands, yet Aselli (1662) was the first who accurately described the lacteals of the with their valves. Pecquet (1648) discovered the receptaculum chyli; Rudbeck and rtholinus the lymphatic vessels (1650–52); Eustachius (1563) was acquainted with the ıct, which Gassendus (1654) maintained that he was the first to see; Lister noticed that ɔecame blue when indigo was injected into the intestine (1671); Sömmering observed the of fibrin when lymph coagulated; Reuss and Emmert discovered the lymph corpuscles. ıical investigations date from the first quarter of this century; they were carried out by Tiedemann, Gmelin, and others. The two last-named observers noticed that the white ıyle was due to the presence of fatty granules.

PHYSIOLOGY OF ANIMAL HEAT.

206. SOURCES OF HEAT.—The heat of the body is an uninterrupted evolution of kinetic energy, which we must represent to ourselves as due to vibrations of the corporeal atoms. The **ultimate source** of the heat is contained in the potential energy taken into the body with the food, and with the O of the air absorbed during respiration. The **amount** of heat formed depends upon the amount of energy liberated.

FIG. 226.



Water calorimeter of Favre and Silbermann.

The energy of the food stuffs may be called **"latent heat,"** if we assume that when they are used up in the body, chiefly by a process of combustion, kinetic energy is liberated only in the form of heat. As a matter of fact, however, mechanical energy and electrical energy are developed from the potential energy. In order to obtain a unit measure for the energy liberated, it is advisable to express all the potential energy as **heat units.**

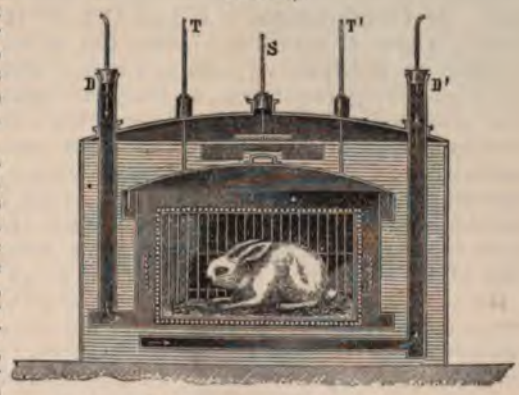
The Calorimeter.—This instrument enables us to transform the potential energy of the food into heat, and, at the same time, to measure the number of heat units produced.

Favre and Silbermann used a **water calorimeter** (Fig. 226). The substance to be burned is placed in a large cylindrical combustion chamber (K), suspended in a large cylindrical vessel (L) filled with water (*w*), so that the combustion chamber is completely surrounded by the water. Three tubes open into the upper part of the chamber; one of them (O) supplies the air which is necessary for combustion, it reaches almost to the bottom of the chamber; the second (*a*) is fixed in the middle of the lid, and is closed above with a thick glass plate, and on this is placed, at an angle, a small mirror (*s*), which enables an observer to look into the chamber, and observe the process of combustion at *c*. The third tube (*d*) is used only when combustible gases are to be burned in the chamber. It can be closed by means of a stop-cock. A lead tube (*e*, *e*), with many twists, passes from the upper part of the chamber through the water, and finally opens at *g*. The gaseous products of combustion pass out through this tube, and in doing so h
The cylindrical vessel with the water is closed with a lid which transm
cylinder stands on four feet within a large cylinder (M), whi
ductor of heat, and this again is placed in a large v
any heat reaching the inner cylinder from with
investigated is placed in the combustion c

inner water must be repeatedly stirred, the temperature of the water is ascertained by means of a delicate thermometer. If the increase of the temperature and the amount of water are known, then it is easy to calculate the number of **heat units** produced by the combustion of a known weight of substance (see *Introduction*).

The **ice calorimeter** may also be used. The inner cylinder is filled with ice and not with water, and ice is also placed in the outer cylinder to prevent any heat from without from acting upon the inner ice. The heat given off from the combustion chamber causes a certain amount of the ice to melt, and the water thereby produced is collected and measured. It requires 79 heat units to melt 1 grm. of ice to 1 grm. of water at 0° C.

FIG. 227.



Water calorimeter of Dulong.

[The amount of heat produced by a **living animal** is similarly measured. The animal (Fig. 227), in a cage, is placed in a large vessel, which is placed within another vessel, and the inter-space filled with water. The whole should be enclosed in a large box packed with fur, shavings, feathers, or other bad conductor of heat. A tube, D, opens into the inner space, and from it there is an exit tube, D′, which winds many times in the water space beneath. Air passes in through D and out by D′. The temperature of the water is ascertained by thermometers T and T′, while the water is moved by a stirrer (S) placed between the two.]

Just as in a calorimeter, although *much more slowly*, the food stuffs within our body are burned up, oxygen being supplied, and thus potential energy is transformed into kinetic energy, which, in the case of a person at *rest*, almost completely appears in the form of heat.

Heat Units.—Favre, Silbermann, Frankland, Rechenberg, B. Danilewsky, and others have made calorimetric experiments on the heat produced by food. According to Danilewsky, 1 gramme of the following dry substances yields heat units:—

Casein, ... 5855	Olein, ... 8958	Woman's milk, . 4837	Alcohol, ... 6980
Fibrin, ... 5772	Stearin, ... 9036	Egg yelk, . . . 4479	Urea, ... 2537
Peptone, ... 4876	Ox-fat, ... 9686	Potatoes, . . . 4234	Muscle Extractives (Liebig's) 4400
Gluin, ... 5493	Glycerine, . . . 4179	Rye bread, . . 4471	
Ox-blood, . . . 5900	Starch, ... 4479	Wheat bread, . . 4351	
Ox-flesh, ... 5724	Dextrose, . . . 3939	Rice, ... 4806	Flesh extract, . . 3216
Vegetable fibrin, . 6231	Maltose, ... 4163	Peas, ... 4889	Acetic acid, . . 3318
Gluten, ... 6141	Milk sugar, . . . 4162	Buckwheat, . . 4288	Butyric acid, . . 5647
Legumin, . . . 5573	Cane sugar, . . . 4173	Maize, ... 5188	Palmitic acid, . . 9316
Palmitin, ... 8883	Cow's milk, . . 5733		

As albumin is only oxidized to the stage of urea, we must deduct the heat units obtainable from urea from those of albumin, and as 1 part of albumin yields in round numbers about ⅓ of urea, we obtain about 5100 calories [= 2170 kilogram-metres] for 1 grm. of albumin.

Isodynamic foods, *i. e.*, those that produce an equal amount of heat; 100 grms. animal albumin (after deducting the heat units of urea) = 52 fat = 114 starch = 129 dextrose; 100 grms. fat are isodynamic with 243 dry flesh or 225 of dry syntonin (*Rubner*); 100 grms. of vegetable albumin = 55 fat = 121 starch = 137 dextrose (*Danilewsky*). Rubner calculated that in man, with a mixed diet, the *available* heat units for 1 grm. of albumin = 4100; 1 grm. fat = 9300; and for 1 grm. carbohydrate = 4100 calories.

[illegible] know the weight of any of the above-named substances consumed by
four hours, a simple calculation enables us to determine how
rmed in the body by oxidation, *i. e.*, provided the substance

[**Several sources of heat production or thermogenesis** are to be found in all tissues wherever oxidation is going on. The metabolism of protoplasm is always associated with the evolution of heat.]

(1) *In the transformation of the chemical constituents of the food, endowed with a large amount of potential energy, into such substances as have little or no energy.* The organic substances used as food consist of C, H, O, N, so that there takes place (*a*) **Combustion** of C into CO_2, of H into H_2O, whereby heat is produced; 1 grm. C burned to produce CO_2 yields 8080 heat units, while 1 grm. H oxidized to H_2O yields 37,460 heat units. The O necessary for these purposes is absorbed during respiration, so that, to a certain extent at least, the amount of heat produced may be estimated from the amount of O consumed. The same consumption of O gives rise to the same amount of heat whether it is used to oxidize H or C (*Pflüger*). There is a relation, amounting to cause and effect, between the amount of heat produced in the body and the O consumed. The cold-blooded animals, which consume little O, have a low temperature; among warm-blooded animals, 1 kilo. of a living rabbit takes up within an hour 0.914 grm. O, and its body is heated to a mean of 38° C. 1 kilo. of a living fowl uses 1.186 grms. O, and gives a mean temperature of 43.9° C. The amount of heat produced is the same whether the combustion occurs slowly or quickly; the rapidity of the metabolism, therefore, affects the rapidity, but not the absolute amount of heat production. The combustion of inorganic substances in the body *e.g.*, of the sulphur into sulphuric acid, the phosphorus into phosphoric acid, is another, although very small, source of heat.

[The **muscles** form about the half of the whole mass of the body and the bones nearly the other half. In the latter, oxidation does not go on actively, so that the muscles must be the great seats of heat production or thermogenesis in the body. This view is supported by the fact that the blood leaving a muscle at rest contains more CO_2 than the blood in the right ventricle. Muscular exercise greatly increases the metabolism and the CO_2 excreted (§ 127), but at the same time, there is a great increase in heat production. The muscles, therefore, are the great thermogenic tissues, and they yield $\frac{3}{5}$ of the heat in health. The several **secreting glands**, especially the liver, and the alimentary canal, during digestion, are also foci of heat formation.]

(*b*) In addition to the processes of combustion or oxidation, all those **chemical processes** in our body, by which the amount of the available potential energy which is present is diminished, in consequence of a greater satisfaction of atomic affinities, lead to the production of heat. In all cases where the atoms assume more stable positions with their affinities satisfied, chemical energy passes into kinetic thermal energy, as in the alcoholic fermentation of grape sugar and other similar processes.

Heat is also developed during the following chemical processes:—

(*a*) During the union of bases with acids. The nature of the base determines the amount of heat produced, while the nature of the acid is without effect. Only in those cases where the acid, *e.g.*, CO_2, is unable to set aside the alkaline reaction, the amount of heat produced is less. The formation of compounds of chlorine (*e.g.*, in the stomach) produces heat.

(β) When a neutral salt is changed into a basic one. In the blood the sulphuric and phosphoric acids derived from the combustion of S and P are united with the alkalies of the blood to form basic salts. The decomposition of the carbonates of the blood by lactic and phosphoric acids forms a double source of heat, on the one hand, by the formation of a new salt, and on the other, by the liberation of CO_2, which is partly absorbed by the blood.

(γ) The combination of hæmoglobin with O (§ 36).

During those chemical processes, whereby the heat of the body is produced, heat-absorbing intermediate compounds are not unfrequently formed. Thus, in order that the final stage of more complete saturation of the affinities be reached,

intermediary atomic groups are formed, whereby heat is absorbed. Heat is also absorbed when the solid aggregate condition is dissolved during retrogressive processes. But these intermediary processes, whereby heat is lost, are very small compared with the amonnt of heat liberated when the end products are formed.

(2) Certain **physical processes** are a **second source** of heat. (*a*) The **transformation of the kinetic mechanical energy** of internal organs, when the work done is not transferred outside the body, produces heat. Thus the whole of the kinetic energy of the heart is changed into heat, owing to the resistance opposed to the blood stream (§ 93). The same is true of the mechanical energy evolved by many muscular viscera. The torsion of the costal cartilages, the friction of the current of air in the respiratory organs, and the ingesta in the digestive tract, all yield heat.

An excessively minute amount of the mechanical energy of the heart is transferred to surrounding bodies by the cardiac impulse and the superficial pulse beats, but this is infinitesimally small. During respiration, when the respiratory gases and other substances are expired, a very small amount of energy disappears externally, which does not become changed into heat. If we assume that the daily work of the circulation exceeds 86,000 kilogram-metres, the heat evolved is equal to 204,000 calories, in twenty-four hours (§ 93), which is sufficient to raise the temperature of a person of medium size 2° C.

(*b*) When, owing to muscular activity, the body produces work which is transferred to external objects, *e. g.*, when a man ascends a tower or mountain, or throws a heavy weight, a portion of the kinetic energy passes into heat, owing to friction of the muscles, tendons, and the articular surfaces, as well as to the shock and pressure of the ends of the bones against each other.

(*c*) The electrical currents which occur in muscles, nerves, and glands very probably are changed into heat. The chemical processes which produce heat evolve electricity, which is also changed into heat. This source of heat, however, is *very small.*

(*d*) Other processes are the formation of heat from the *absorption of* CO_2, by the *concentration of water* as it passes through membranes, in *imbibition, and the formation of the solids, e. g.*, of chalk in the bones. After death, and in some pathological processes during life, the *coagulation of blood* and the production of *rigor mortis* are sources of heat.

207. HOMOIOTHERMAL AND POIKILOTHERMAL ANIMALS.—In place of the old classification of animals into "**cold-blooded**" and "**warm-blooded,**" another basis of classification seems desirable, viz., the relation of the temperature of the body to the temperature of the surrounding medium. Bergmann introduced the word **homoiothermal** for the **warm-blooded** animals (mammals and birds), because these animals can maintain a very uniform temperature, even although the surrounding temperature be subject to considerable variations. The so-called **cold-blooded** animals are called **poikilothermal,** because the temperature of their bodies rises or falls, within wide limits, with the heat of the surrounding medium.

When **homoiothermal animals** are kept for a long time in a cold medium, their heat production is increased, and when they are kept for a long time in a warm medium it is diminished.

Fordyce gave a proof of the nearly uniform temperature in man. A man remained ten minutes in an oven containing very dry hot air (§ 218), and yet the temperature of the palm of his hand, mouth, and urine was increased only a few tenths of a degree. Becquerel and Brechet investigated the temperature of the human biceps (by means of thermo-electric needles), when the arm had been one hour in iced water, and yet the temp rature of the muscular tissue was cooled only 0.2° C. The same muscle did not undergo any increase in temperature, or at most 0.2° C., when the man's arm was placed for a quarter of an hour in water at 42° C.

If heat be rapidly abstracted (§ 225) or rapidly supplied (§ 221) to the body, so as to produce rapid variation of the temperature, life is endangered.

Poikilothermal animals behave very differently; the temperature of their bodies generally follows, although with considerable variations, the temperature of the surroundings. When the temperature of the surroundings is increased, the amount of heat produced is increased, and when the surrounding temperature falls, the amount of heat evolved within the body also falls.

The following table shows very clearly the characters of **poikilothermal animals**, *e.g.*, **frogs**, which were placed in air and water of varying temperatures. They were immersed up to the mouth. The temperature was measured by means of a thermometer introduced through the mouth into the stomach.

In Water.		In Air.	
Temperature of the Water.	Temperature of Frog's Stomach.	Temperature of the Air.	Temperature of Frog's Stomach.
41.0° C.	38.0° C.	40.4° C.	31 7° C.
30.0	29.6	27.4	19.7
20.6	20.7	16.4	14.6
5.9	8.0	6.2	7.6
2.8	5.3	5.9	8.6

[**Temperature of Different Animals.**

Birds.	Temp.		Temp.		Temp.
Thalassidroma,	40.30	Swallow,	44.03	Panther,	38.90
Procellaria,	40.80	Gull,	37.8	Mouse,	41.1
Goose,	41.70	**Mammals.**		Dolphin,	35.5
Sparrow,	39.08–42.10	Tiger,	37.20	Sheep,	37.30–40.00; 39.50–40.00; 40.00–40 50
Pigeon,	41.80–42.50	Horse,	36.80–37.50	Ape,	35.50
Turkey,	42.70	Rat,	38.80	Guinea pig,	35.76–38.00
Guinea fowl,	43.90	Hare,	37.80	Rabbit,	37.50–38.00
Duck,	43.90–42.50	Cat,	38.30–38.90	Ox,	37.50
Crow,	41.17	Guinea pig,	38.80	Ass,	36 95
		Dog,	37.40; 39.00; 39.60	(*Gavarret & Rosenthal*).]	

Reptiles—Snakes, 10°–12°, but higher when incubating. *Amphibians and fishes*—0.5°–3° above the temperature of the surroundings. *Arthropoda*—0.1°–5.8° above the surroundings. Bees in a hive, 30°–32°, and when swarming, 40°. The following animals have a temperature higher than the surrounding temperature: Cephalopods, 0.57°; mollusks, 0.46°; echinoderms, 0.40; medusæ, 0.27°; polyps, 0.21° C.

208. **ESTIMATION OF TEMPERATURE.**—By using thermometric apparatus, we are enabled to obtain information regarding the degree of heat of the body to be investigated. For this purpose the following **methods** are employed:—

A. The Thermometer.—Celsius (1701–1744) divided his thermometer into 100 parts, and each part was again divided into 10 parts, so that $\frac{1}{10}$° C. could be easily read off. All thermometers which have been used for a long time give too high readings; hence they should be compared, from time to time, with a normal thermometer. When taking the temperature, the bulb ought to be surrounded for fifteen minutes, and during the last five minutes the mercury column ought not to vary. A very sensitive thermometer will indicate the temperature after seven seconds if the urine stream be directed upon its bulb. **Minimal** and **maximal** thermometers are often of use to the physician.

[**Clinically**, one of the thermometers shown in Fig. 228 may be used. They are self-registering maximum thermometers, *i. e.*, a portion of the mercury is separated from the mercurial column, to form the index, the top of which indicates the temperature. Before being used, the index must be well below the normal temperature. Various forms of surface thermometers have been used.]

Walferdin's **metastatic thermometer** (Fig. 229) is specially useful for comparative observation. The tube is very narrow in comparison with the bulb, and in order that the stem be not too long, it is constructed so that the amount of mercury can be varied. A quantity of mercury is taken, so that with the temperature expected the thread of mercury will

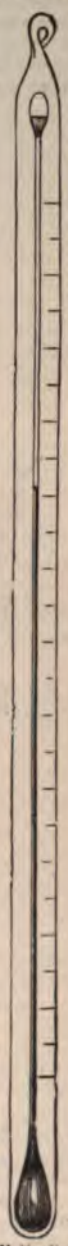
FIG. 228. FIG. 229.

A, Cassella's "infallible," B, "Ferris' perfect," and C, Evans' and Wormull's "standard" clinical thermometers.

stand about the middle of the stem. A small bulb at the upper part of the stem receives the excess of Hg. Suppose a temperature between 37°-40° C. is to be measured, the bulb is first heated a little over 40° C., it is then suddenly cooled, and shaken at the same time, so that the thread of mercury is thereby suddenly broken above 40°. The tube is so narrow that 1° C. is equal to about 10 centimetres of the length of the tube, so that $\frac{1}{100}$° C. is still 1 millimetre in length. The scale is divided empirically, but the value of the divisions must be compared with a normal thermometer.

Kronecker and Meyer used very small maximal "**outflow thermometers,**" and caused them to pass through the intestinal canal, or through large blood vessels. The mercury flows out of the short open tube, and of course more flows out, the higher the temperature. After these small bulbs have passed through the animal, a comparison is instituted with a normal thermometer, to determine at what temperature the mercury reaches the free margin of the tube.

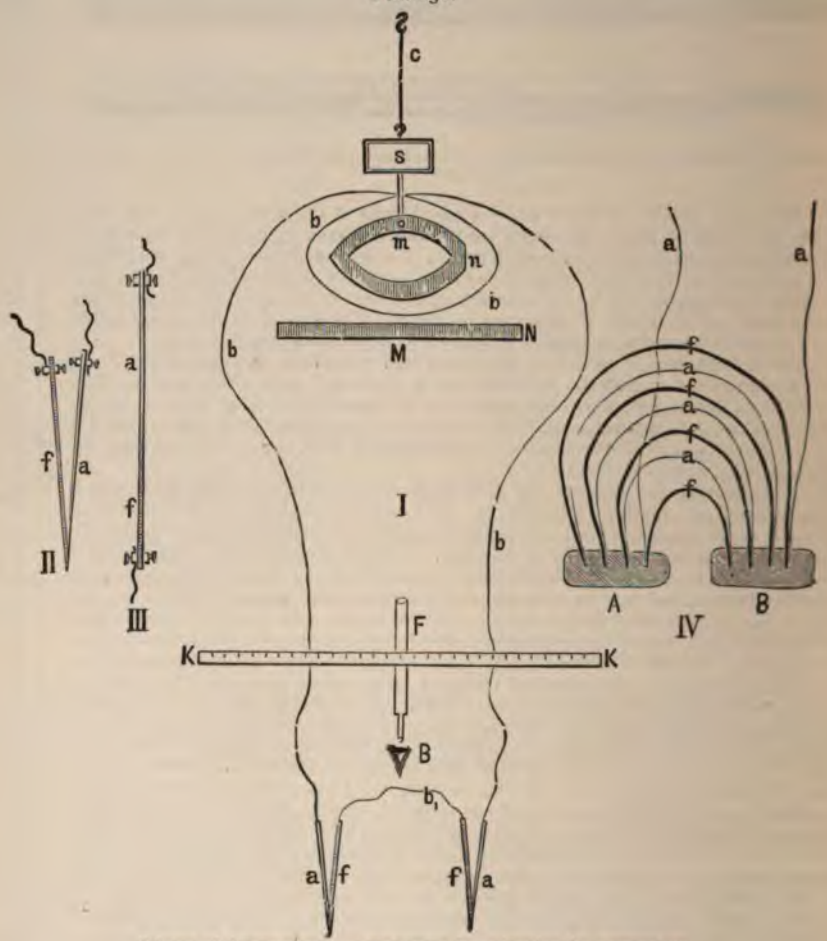
B. Thermo-electric Method.—This method enables us to determine the temperature accurately and rapidly (Fig. 230, I). The **thermo-electric galvanometer** of Meissner and Meyerstein consists of a circular magnet (*m*) suspended by a thread of silk (*c*), to which a small mirror (S) is attached. A large stationary bar magnet (M) is placed near the magnet (*m*), so that the north poles (*n* and N) of both magnets point in the same direction, and it is so arranged that the suspended magnet is caused to point to the north by a minimal action of M. A thick copper wire (*b*, *b*) is coiled several times round *m* (although in the figure it is represented as a single coil), and the ends of the wire are soldered to two thermo-elements, each composed of two different metals—iron and German silver, the two similar free elements being united by a wire (*b*), so that the two thermo-elements form part of a closed circuit. A horizontal scale (K, K) is placed at a distance of 3 metres from the mirror, so that the divisions of the scale are seen in the mirror. The scale itself rests upon a telescope (F) directed toward the mirror. The observer (B), who looks through the telescope, can see the divisions of the scale in the mirror. When the magnet, and with it the mirror, swing out of the magnetic meridian, the observer notices other divisions of the scale in the mirror. When one of the thermo-elements is heated, an electrical current is produced, which passes from the iron to the German silver in the heated couple, and causes a deviation of the suspended magnet. Suppose a person were swimming in the direction of the current in the conducting wire, then the north pole of the magnet goes to the north (*Ampère*). The tangent of the angle ϕ, through which the freely movable magnet is diverted by a galvanic current, from its position of rest or zero, in the magnetic meridian, is the same as the galvanic stream; G is proportional to the magnetic energy D, *i. e.*, tang. $\phi = \frac{G}{D}$. If G is to remain the same, and the tang, ϕ to be as large as possible, the magnetic energy must be diminished as much as possible. If the magnetism of the suspended magnet be indicated by *m*, and that of the earth by T, the magnetic directing energy $D = Tm$, so that D can be distinguished in two ways: (1) by diminishing the magnetic moment of the suspended magnet, as may be done by using a pair of astatic needles, such as are used in Nobili's galvanometer; (2) and also by weakening the magnetism of the earth, by placing an accessory stationary magnet (Hauy's rod) in the same direction, and near the suspended magnet. An important arrangement for rapidly getting the magnet to zero is the dead-



Walferdin's metastatic thermometer.

beat arrangement of Gauss (not figured in the scheme). It consists of a thick copper cylinder, on which the wire of the coil is wound. This mass of copper may be regarded as a closed multiplicator with a very large transverse section. The vibrating magnet induces in this closed circuit a current of electricity, whose intensity is greatest when the velocity of the excursion of the magnet is greatest, and which takes the opposite direction as soon as the magnet returns toward zero. These induced currents cause a diminution of the vibration of the magnet in this way, that the arc of vibration of the magnet diminishes very rapidly, almost in a geometrical progression. The induced damping current is stronger, the less the resistance in the closed circuit, and in the damper or dead-beat arrangement itself, the greater the section of the copper ring. This damping arrangement limits

FIG. 230.



Scheme of thermo-electric arrangements for estimating the temperature.

the oscillations of the magnet, and it comes to rest rapidly and promptly after 3 or 4 small vibrations so that much time is saved. The angle of deviation is so small that the angle itself may be taken instead of the tangent.

The **thermo-electric needles** of Dutrochet (II) may be placed in the circuit. They consist of iron and German silver soldered at their points; or the needles of Becquerel (III) may be used. They consist of the same metal soldered in a straight line, one behind the other. The needles must always be covered by a varnish, which will prevent the parenchymatous juices from acting upon them, and causing a current. Before the experiment we must determine what extent of excursion on the scale is obtained with a certain temperature. In order to determine this, a delicate thermometer is fixed

to each of the thermo-couples, and both are placed in oil baths, which differ in temperature—say by 1° C.—as can be determined by the thermometer. When the current is closed, the excursion on the scale will indicate 1° C. Suppose that the excursion was 150 mm., then each mm. of the scale would be equal to $\frac{1}{150}$° C. When this is determined, the two thermo-needles may be placed in the different tissues or organs of animals, and, of course, we obtain the difference of temperature in these places. Or one thermo-couple may be placed in a bath of constant temperature (nearly that of the body), in which is placed a delicate thermometer, while the other needle is introduced into the organ to be investigated. In this case, we obtain the difference of temperature between the tissue and the source of the constant heat. The electric current passes in the warmer needle from the iron to the German silver, and thus through the wires of the apparatus. For small differences of temperature, such as occur in the body, the thermo-electric energy is always proportional to the difference of temperature of the two needles or couples. In place of a single pair of needles several may be used, whereby the sensitiveness of the apparatus is greatly increased. Helmholtz found that by using sixteen antimony-bismuth couples, he could detect an increase of $\frac{1}{4000}$° C. Schiffer prepared a simple thermopile (IV) by soldering together alternately four pairs of wires of iron (f) and German silver (a). These are placed in the two organs (A and B) which are to be investigated, whereby a very high degree of exactness is obtained.

209. **TEMPERATURE TOPOGRAPHY.**—Although the blood, in virtue of its continual motion (completing, as it does, the circulation in twenty-three seconds), must exercise a very considerable influence on the equilibration of the temperature in different organs, nevertheless, a completely uniform temperature does not exist, and the temperature varies in different parts :—

1. **Skin** (*J. Davy*).

Middle of the sole of the foot,	32.26° C.	Middle of upper arm,	35.40° C.
Near tendo-Achillis,	33.85	Inguinal fold,	35.80
Anterior surface of leg,	33.05	Near cardiac impulse,	34.40
Middle of calf,	33.85	Face,	31.00
Bend of knee,	35.00	Nose and tip of ear,	22.24

In the closed axilla, 36.49 (mean, of 505 individuals);—36.5 to 37.25 (*Wunderlich*);—36.89° C. (*Liebermeister*). The skin over muscles is warmer than that over bone (*Kunkel*).

The temperature of the skin of the head is higher in the forehead and parietal region than in the occipital region; the skin on the left side of the head is warmer than on the right. Dyspnœa increases the temperature of the skin.

Method.—Liebermeister determines the temperature of **free cutaneous surfaces** thus: The bulb of the thermometer is heated slightly above the temperature expected; after the mercury begins to fall, the bulb is placed on the skin, and if the bulb has the same temperature as the skin, the mercury remains stationary. This experiment must be repeated several times.

2. **Cavities.**

Mouth under the tongue,	37.19° C.	Vagina,	38.30° C.
Rectum,	38.01	Urine,	37.03

Uterine cavity somewhat warmer; cervical canal of the uterus somewhat cooler.

The temperature falls in the **stomach** during digestion (§ 166, 1). Cold injections (11° C.) into the rectum rapidly lower the temperature in the stomach 1° C. (*Winternitz*).

3. **The temperature of the blood** is, as a mean, 39° C. The venous blood in internal viscera is warmer than the arterial, but it is cooler in peripheral parts :—

Blood of the right heart,	38.8°	Blood of the superior vena cava,	36.78°
" left heart,	38.6	" inferior vena cava,	38.11
" aorta,	38.7	" crural vein,	37.20
" hepatic vein,	39.7	" (*Cl. Bernard and v. Liebig.*)	

The lower temperature of the **blood in the left heart** may be explained by the blood becoming cooled in its passage through the lungs during respiration. According to Heidenhain and Körner, the right heart is slightly warmer because it lies in relation with the warm liver, while the left heart is surrounded by the lung, which contains air. This observation is disputed by others, who say that the left heart is slightly warmer because the combustion processes are more active in arterial blood, and heat is evolved during the formation of oxyhæmoglobin. The blood in the **veins** is usually cooler than in the corresponding arteries, owing to the superficial position of the former, whereby they give off heat during their long course; thus the blood of the *jugular vein* is ½ to 2° C. lower than the blood in the *carotid*; the *crural vein* ¾ to 1° cooler than in the *crural artery*. **Superficial veins**, more especially those of the skin, give off much heat, and their blood is, therefore, somewhat cooler.

The **warmest blood** is that of the **hepatic vein**, 39.7° C., partly owing to the great chemical changes which occur within the liver, from its secretory activity (§ 210, *a*), and partly to its protected situation.

4. The individual **tissues** are warmer: (1) The greater the transformation of kinetic energy into heat, *i.e.*, the greater the tissue metabolism; (2) the more blood they contain; (3) and the more protected their situation. According to Heidenhain and Körner, the cerebrum is the warmest organ in the body.

Subcutaneous tissue (sheep), . .	37.35° C.	Rectum, ...	40.67° C.
Brain, ...	40.25	Right heart, ...	41.60
Liver, ...	41.25	Left heart, ...	40.90
Lungs, ...	41.40		(*Berger.*)

Becquerel and Brechet found the temperature of the human subcutaneous tissue to be 2.1° C. lower than that of the neighboring muscles. The **horny tissues** do not produce heat, and their low temperature is due to the conduction of heat from the parts on which they grow. The temperature of the **cornea** partly depends on that of the **iris**, and the more contracted the pupil is, the more heat it receives from the blood vessels of the iris.

210. CONDITIONS AFFECTING THE TEMPERATURE OF ORGANS.—The temperature of the individual organs is by no means constant; it is influenced by many conditions; among these are the following:—

(1) *The more heat* **produced** *independently within a part, the higher is its temperature.* As the amount of heat produced within a part depends upon its metabolism, therefore, when the metabolism is increased, the amount of heat produced is similarly increased.

(*a*) **Glands** produce more heat during the act of **secretion**, as is proved by the higher temperature of their secretion, or by the higher temperature of the **venous blood** flowing out of their veins.

Ludwig found that when he stimulated the chorda tympani, the **saliva** of the sub-maxillary gland was 1.5° C. warmer than the blood in the carotid, which supplied the gland with blood (p. 258). The blood in the renal vein in a **kidney** which is secreting is warmer than the blood in the renal artery. The secreting **liver** produces much heat (§ 178). Cl. Bernard investigated the temperature of the blood of the **portal** and **hepatic veins** during hunger, at the beginning of digestion, and when digestion was most active, and he found:—

Temperature of portal vein, . .	37.8° C.	*After 4 days' starvation.*	Blood of right heart. 38.8° (Hunger period.)
" hepatic vein, .	38.4		
Temperature of portal vein, . .	39.9	*Beginning of digestion.*	
" hepatic vein, .	39.5		
Temperature of portal vein,. .	39.7	*Digestion most active.*	Blood of right heart, during digestion, 39.2°.
" hepatic vein, .	41.3		

In the dog a moderate diet, chemical or mechanical stimulation of the gastric mucous membrane, or even the sight of food, raises the temperature in the **stomach** and **intestine.**

(*b*) When the **muscles contract**, they evolve heat. Davy found that an active muscle became 0.7° C. warmer; while Becquerel, by means of a thermo-galvanometer, found that human muscles, when kept contracted for five minutes, became 1° C. warmer (§ 302).

This is one of the reasons why the temperature may rise above 40° during **rapid running.** A temperature obtained by energetic muscular action usually does not fall to the normal until after resting for 1½ hour. The low temperature of paralyzed limbs depends partly upon the absence of the muscular contractions.

(*c*) With regard to the effect of **sensory nerves** upon the temperature, some of the chief points to ascertain are—whether the *circulation* is accelerated or retarded by their stimulation, or whether the *respiration* is increased or diminished (§ 214, II, 3), and whether the *muscles of the skeleton* are relaxed or contracted reflexly (§ 214, I, 3). In the former case the temperature of the interior and rectum is increased; in the latter, diminished.

(*d*) The temperature of the body rises during **mental exertion.** Davy observed an increase of 0.3° C. after vigorous mental exertion.

(*e*) The parenchymatous fluids, serous fluids and lymph produce little heat, owing to their feeble metabolism, hence they have the same temperature as their surroundings; the epidermal and horny tissues do not produce heat, they merely conduct it from subjacent structures.

(2) *The temperature depends, to a large extent, upon the amount of blood in* an organ, and also upon the *rapidity* with which the *blood is renewed* by the circulation. This is best observed in the difference of the temperature between a cold, pale, bloodless hand, and a warm, red, congested one.

Becquerel and Brechet found that the temperature of the human biceps fell several tenths of a degree when the axillary artery was compressed. Ligature of the crural artery and vein in a dog causes a fall of several degrees. If the extremities be kept suspended in the air, they become bloodless and cold.

Liebermeister has pointed out a difference with regard to the external and internal parts of the body. The **external parts** give off more heat than they produce, so that they become cooler the more slowly new blood flows into them, and warmer the greater the rapidity of the blood stream through them. Acceleration of the blood stream, therefore, causes the temperature of peripheral parts to approximate more and more to the temperature of internal organs, while retardation of the blood stream causes them to approach the temperature of the surrounding medium. Exactly the reverse is the case with **internal parts,** where a large amount of heat is produced, and heat is given up almost alone to the blood which flows through them. Their temperature must fall when the blood stream through them is accelerated, and it is raised when the blood stream is retarded. Hence it follows, that the *greater the difference of the temperature between peripheral and internal parts, the slower must be the velocity of the circulation.*

(3) If the **position of an organ** be such, or if other conditions cause it to give off heat by **conduction** or **radiation,** then its temperature *falls.*

A good example of this is the **skin,** which varies greatly in temperature according to the temperature of the surrounding medium, whether it is covered or uncovered, whether it is dry or moist with sweat (which abstracts heat when it evaporates). When much cold food or drink is taken, the **stomach** is cooled, and when ice-cold air is breathed, the **respiratory passages** as far as the bronchi are cooled.

211. ESTIMATION OF HEAT.—Calorimetry is the method of determining the amount of heat possessed by any body, or what amount of heat it is capable of producing. The unit of measurement is the "**heat unit,**" *i. e.,* the amount of heat (or potential energy) required to raise the temperature of 1 gramme of water 1° C. (see *Introduction*).

Experiment has shown that *equal quantities of different substances require very unequal amounts of heat to raise them to the same temperature, e. g.,* 1 kilo. water requires nine times as much heat as 1 kilo. iron to raise it to the same temperature. In the human body, therefore, which is composed of very different substances, unequal amounts of heat will be required to raise them all to the same temperature. The same amount of heat transferred to two different substances will raise them to different temperatures. Hence, bodies of different temperatures may contain equal amounts of heat. The amount of heat required to raise a definite quantity (*e. g.,* 1 grm.) of a substance to a certain higher degree (*e. g.,* 1° C.) is called "**specific heat.**" The specific heat of water (which of all bodies has the highest specific heat) is taken as = 1. By "**heat capacity**" is meant that property of bodies in virtue of which they must absorb a given amount of heat in order to have a certain temperature.

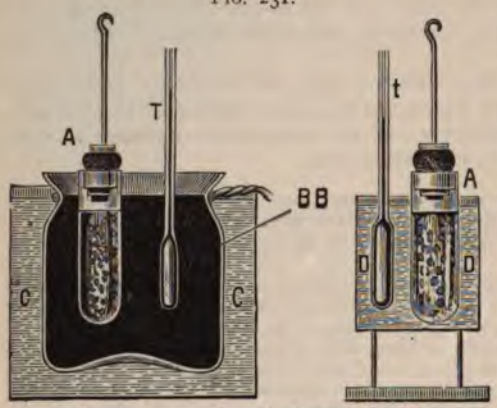
Calorimetry is employed:—*To determine the specific heat of the different organs of the body.*—Only a few observations have been made. The **mean specific heat** of the following animal parts (water = 1) is:—

Human blood = 1.02 (?)	Human muscle = 0.741	Fat tissue = 0.712
Arterial blood = 1.031 (?)	Ox muscle = 0.787	Striped muscle = 0.825
Venous blood = 0.892 (?)	Compact bone = 0.3	Defibrinated blood = 0.927
Cow's milk = 0.992	Spongy bone = 0.71	(*J. Rosenthal.*)

The specific heat of the *human body,* as a whole, is about that of an equal volume of water (?).

Kopp's Method.—The *solid* to be investigated is broken in pieces about the size of a pea, and placed in a test-tube, A, with thin walls, which is closed above with a cork, from which a copper wire with a hook on it projects (Fig. 231). The test-tube contains a certain quantity of fluid which does not dissolve the substance, but which lies between its pieces and covers it. It is weighed three times to ascertain the weight (1) of the empty glass, (2) after it is filled with the solid substance, (3) after the fluid is added, so that we obtain the weight of the solid substance, m, and that of the fluid, f. The test-tube and its contents are placed in a *mercury bath*, BB, and this again in an *oil bath*, CC, and the whole is raised to a high temperature. Into BB there is introduced a fine thermometer, T. When the tube, A, has reached the necessary temperature (say 40°), it is rapidly placed in the water of the accompanying calorimeter box, DD. The water in this box, which also contains a thermometer, D, is kept in motion until it has completely absorbed all the heat given off by A. Let T represent the temperature to which A and its contents were raised in the mercury bath, and T_1 the temperature to which it fell in the calorimeter; let s be the specific heat, and m the weight of the solid substance in the test-tube, while σ and μ represent the specific heat of the weight of the interstitial fluid in the test-tube; and lastly, let w equal the amount of water in contact with A, which absorbs and gives off heat; then W represents the amount of heat which the test-tube and its contents give off during cooling.

FIG. 231.



Kopp's apparatus for estimating specific heat.

$$W = (s \,.\, m + w + \sigma\,\mu)\,(T - T_1).$$

The amount of heat, W_1, absorbed by the calorimeter is

$$W_1 = M\,(t_1 - t),$$

where M represents the amount of water in the calorimeter, t the original temperature of the water in the calorimeter, and t_1 the temperature to which it is raised by placing A in it. If W and W_1 are equal, then

$$\textit{the specific heat, } s = \frac{M\,(t_1 - t) - (w + \sigma\,.\,\mu)\,(T - T_1)}{m\,(T - T_1)}.$$

If a fluid substance is placed in the test-tube, and its weight $= m$, and its specific heat $= s$, the formula for the specific heat of the fluid to be investigated is

$$s = \frac{M\,(t_1 - t) - w\,(T - T_1)}{m\,(T - T_1)}.$$

II. Calorimetry is more important for determining the amount of heat produced in a given time by the body as a whole, or by its *individual parts*.

Lavoisier and Laplace made the first calorimetric observations on animals in 1783, by means of an ice calorimeter; a guinea pig melted 13 oz. of ice in ten hours. Crawford, and afterward Dulong and Despretz, used Rumford's water calorimeter, which is similar to Favre and Silbermann's. Small animals are placed in the inner thin-walled copper chamber (K), which is placed in a water bath surrounded on all sides by some non-conducting material. We require to know the amount of water, and its original temperature. The number of calories is obtained from the increase of the temperature at the end of the experiment, which lasts several hours. The air is supplied to the animal through a special apparatus, resembling a gasometer. The amount of CO_2 in the gases evolved is estimated.

According to Despretz, a bitch forms 14,610 heat units per hour—*i.e.*, 393,000 in twenty-four hours. Other things being equal, a man seven times heavier than this would produce in twenty-four hours about 2,750,000 calories. Senator found that a dog weighing 6330 grms. produced 15,370 calories, and excreted at the same time 367 grms. CO_2. The first calorimetric experiments on man were made by Scharling (1849). Liebermeister estimated the amount of heat given off by a man placed in a cold bath, which was surrounded with a woolen covering. Leyden

placed a lower limb in the calorimeter, whereby 6000 grms. water were raised 1° C. in an hour. If we assume that the total superficial area of the body is fifteen times greater than that of the leg, the human body would produce 2,376,000 calories in twenty-four hours.

212. **THERMAL CONDUCTIVITY OF TISSUES.**—The thermal conductivity of animal tissues is of special interest in connection with the skin and subcutaneous fatty tissue. The fatty layer under the skin, more especially in the whale, walrus, and seal, forms a protective covering, whereby the conduction of heat from internal organs is rendered almost impossible. Investigations upon this subject, however, are few. Griess attempted to estimate the thermal conductivity by heating one part of the tissue, and determining when and in what direction pieces of wax placed on the tissue to be investigated began to melt. He investigated the stomach of the sheep, the bladder, skin, hoof, horn, and bones of an ox, deer's horn, ivory, mother-of-pearl, shell of haliotis. He found that fibrous tissues conducted heat more readily in the direction of their fibres than at right angles to the course of the fibres. Hence, the figures obtained from the melted wax were usually elliptical. Landois has made similar observations, and he finds that tissues conduct better in the direction of their fibres. After bones, blood clot was the best conductor, then followed spleen, liver, cartilage, tendon, muscle, elastic tissue, nail and hair, bloodless skin, gastric mucous membrane, washed fibrin. It is specially interesting to note how much better skin containing *blood* in its blood vessels conducts than does bloodless skin. Hence little heat is given off from a bloodless skin, while congested skin conducts and gives off much more heat.

Like all other substances, the human body is enlarged by heat. A man weighing 60 kilos., and whose temperature is raised from 37° C. to 40° C., is enlarged about 62 cubic centimetres. Connective tissue (tendon) is extended by heat, while elastic tissue and the skin, like caoutchouc, are contracted.

213. **VARIATIONS OF THE MEAN TEMPERATURE.**—(1) **General Climatic and Somatic Influences.**—In the **tropics** the mean temperature of the body is about ½° C. higher than in **temperate climates**, where again it is several tenths of a degree warmer than in **cold climates**; but this has recently been denied. The difference is comparatively trivial, when we remember that a man is subjected to a variation of over 40° C. in passing from the equator to the poles. Observations on more than 4000 persons show that when a person goes from a warm to a cold climate, his temperature is but slightly diminished, but when he goes from a cold to a warm climate his temperature rises relatively considerably more. In the *temperate* zone, the temperature of the body during a *cold winter* is usually 0.1° to 0.3° C. lower than it is on a warm summer day. The **elevation of a place** above sea level has no obvious effect on the temperature of the body. There seems to be no difference in different **races**, nor in the **sexes**, other conditions being the same. Persons of powerful physique and **constitution** are said to have generally a slightly higher temperature than feeble, weak, anæmic persons.

(2) **Influence of the General Metabolism.**—As the formation of heat depends upon the transformation of chemical compounds, whose chief final products in addition to H_2O, are CO_2 and urea, the amount of heat formed must go *pari passu* with the amount of these excreta. The more rapid metabolism which sets in after a full meal, causes a rise of temperature to several tenths of a degree ("Digestion fever"). As the metabolism is much diminished during **hunger**, this explains why the mean temperature in a fasting man is 36.6°, while it is 37.17° on ordinary days (§ 237).

Jürgensen also found that the temperature fell on the first day of inanition (although there was a temporary rise on the second day). In experiments made upon starving animals, the temperature at first fell rapidly, then remained constant for a considerable time, while during the last days it fell considerably. Schmidt starved a cat—on the 15th day the temperature was 38.6°; on the 16th, 38.3°; 17th, 37.64; 18th, 35.8; 19th (death) = 33.0°. Chossat found that starving mammals and birds had a temperature 16° C. below normal on the day of their death.

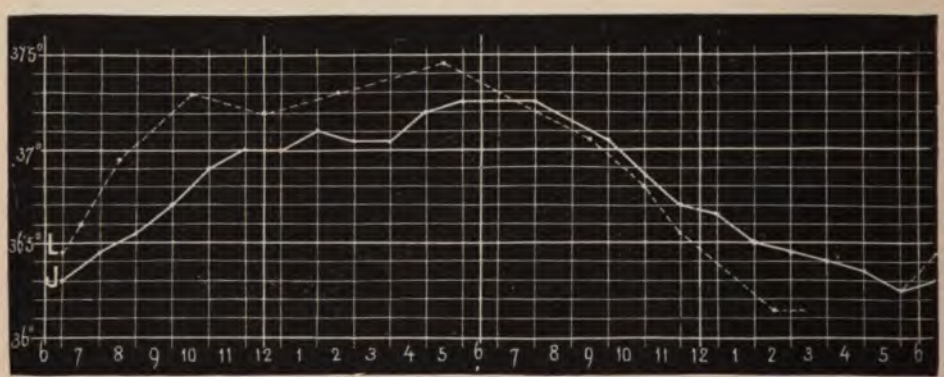
(3) **Age** has a decided effect upon the temperature of the body. The extent of the general metabolism is in part an index of the heat of the body at different ages, but it is possible that other, as yet unknown, influences are also active.

Age.	Mean Temperature at the Ordinary Temperature.	Normal Limits.	Where Measured.
Newly-born,	37.45° C.	37.35–37.55° C.	Rectum.
5–9 year,	37.72	36.87–37.62	Mouth and Rectum.
15–20 "	37.37	36.12–38.1	Axilla.
21–30 "	37.22	. .	"
25–30 "	36.91	. .	"
31–40 "	37.1	36.25–37.5	"
41–50 "	36.87	. .	"
51–60 "	36.83	. .	"
80 "	37.46	. .	Mouth.

Newly-born animals exhibit peculiarities owing to the sudden change in their conditions of existence. Immediately after birth, the infant is 0.3° warmer than the vagina of the mother, viz., 37.86°. A short time after birth, the temperature falls 0.9°, while twelve to twenty-four hours afterward it has risen to the normal temperature of an infant, which is 37.45°. Several irregular variations occur during the first weeks of life. During sleep, the temperature of an infant falls 0.34° to 0.56°, while continued crying may raise it several tenths of a degree. **Old people,** on account of their feeble metabolism, produce little heat; they become cold sooner, and hence ought to wear warm clothing to keep up their temperature.

(4) **Periodical Daily Variations.**—In the course of twenty-four hours there are regular periodic variations in the mean temperature, and these occur at all ages. As a general rule, the temperature *continues to rise during the day* (maximum at 5 to 8 P.M.), while it continues to *fall during the night* (minimum 2 to 6 A.M.). The mean temperature occurs at the third hour after breakfast.

FIG. 232.



Variations of the daily temperature in health during twenty-four hours. L——, after Liebermeister; J——, after Jürgensen.

The mean height of all the temperatures taken during a day in a patient is called the **"daily mean,"** and according to Jaeger it is 37.13° in the rectum in health. A daily mean of more than 37.8° is a "fever temperature," while a mean under 37.0° C. is regarded as a "collapse temperature."

As the variations occur when a person is **starved** for a day—although those that occur at the periods at which food ought to have been taken are less—it is obvious that the variations are not due entirely to the taking of food. [The * indicates taking of food.]

The daily variation in the **frequency of the pulse** often coincides with variation of the temperature. Bärensprung found that the mid-day temperature maximum slightly preceded the pulse maximum (§ 70, 3, C).

If we sleep during the day, and do all our daily duties during the night, the above described typical course of the temperature is reversed. With regard to the effect of activity or rest, it appears that the activity of the muscles during the day tends to increase the mean temperature slightly, while at night the mean temperature is less than in the case of a person at rest.

The **peripheral parts** of the body exhibit more or less regular variations of their temperature. In the **palm** of the hand, the progress of events is the following: After a relatively high night temperature there is a rapid fall at 6 A. M., which reaches its minimum at 9 to 10 A. M. This is followed by a slow rise, which reaches a high maximum after dinner; it falls between 1 to 3 P. M., and after two or three hours reaches a minimum. It rises from 6 to 8 P. M., and falls again toward morning. A rapid fall of the temperature in a peripheral part corresponds to a rise of temperature in internal parts.

(5) **Many operations** upon the body affect the temperature. After **hemorrhage** the temperature falls at first, but it rises again several tenths of a degree, and is usually accompanied by a shiver or slight rigor: several days thereafter it falls to normal, and may even fall somewhat below it. The sudden loss of a large amount of blood causes a fall of the temperature of ½ to 2° C. Very long-continued hemorrhage (dog) causes it to fall to 31° or 29° C.

This is obviously due to the diminution of the processes of oxidation in the anæmic body, and to the enfeebled circulation. Similar conditions causing diminished metabolism effect the same result. Continued stimulation of the peripheral end of the vagus, so that the heart's action is enormously slowed, diminishes the temperature several degrees in rabbits (*Landois and Ammon*).

The **transfusion** of a considerable quantity of blood raises the temperature about half an hour after the operation. This gradually passes into a febrile attack, which disappears within several hours. When blood is transfused from an artery to a vein of the same animal, a similar result occurs (§ 102).

(6) Many **poisons** diminish the temperature, *e. g.*, chloroform and the anæsthetics, **alcohol** (§ 235), digitalis, **quinine**, aconitin, muscarin. These appear to act partly by rendering *the tissues less liable to undergo molecular transformations* for the production of heat. In the case of the anæsthetics, this effect perhaps occurs, and is due possibly to a semi-coagulation of the nervous substance (?). They may also act partly by influencing the **giving off of heat** (§ 214, II). Other poisons increase the temperature for opposite reasons.

The temperature is **increased** by **strychnin**, nicotin, picrotoxin, veratrin, laudanin.

(7) Various **diseases diminish** the temperature, which may be due either to lessened production of heat (diminution of the metabolism), or to increased expenditure of heat. Loewenhardt found that in paralytics and in insane persons, several weeks before their death, the rectal temperature was 30° to 31° C., in diabetes 30° C., or less; the lowest temperature observed and life retained in a drunk person was 24° C.

The temperature is **increased** in *fever*, and the highest point reached just before death, and recorded by Wunderlich, was 44.65° C. (compare § 220).

214. REGULATION OF THE TEMPERATURE.—As the bodily temperature of man and similar animals is **nearly constant**, notwithstanding great variations in the temperature of their surroundings, it is clear that some mechanism must exist in the body, whereby the heat economy is **constantly regulated**. This may be brought about in **two ways**; either by controlling the transformation of potential energy into heat, or by affecting the amount of heat given off according to the amount produced, or to the action of external agencies.

[The constancy or thermostatic condition of the temperature is brought about by three co-operant factors, the **thermogenic** or heat producing, the **thermolytic** or heat discharging, and the **thermotaxic** or mechanism by which heat production and heat loss are balanced, and it is obvious that the last must be in relation with the other two. The thermotaxic mechanism is developed last, is least pronounced in the lower vertebrata, and is most *easily* liable to fail under injury or disease (*MacAlister*).]

I. Regulatory Arrangements governing the production of Heat.—Liebermeister estimated the amount of heat produced by a healthy man at 1.8 calorie per minute. It is highly probably that, within the body, there exist mechanisms which determine the molecular transformations upon which the evolution of heat depends. This is accomplished chiefly in a **reflex manner.** The peripheral ends of cutaneous nerves (by thermal stimulation), or the nerves of the intestine and the digestive glands (by mechanical or chemical stimulation during digestion or inanition), may be irritated, whereby impressions are conveyed to the **heat centre**, which sends out impulses through efferent fibres to the depôts of potential energy, either to increase or diminish the extent of the transformations occurring in them. The nerve channels herein concerned are entirely unknown. Many considerations, however, go to support such an hypothesis (§ 377).

[**Thermotaxic Mechanism, Thermal Nerves and Centres.**—Just as the respiration and the state of the blood vessels are regulated from a central focus, so the question arises, does the same obtain with regard to temperature? Studying this question, however, it must be borne in mind that thermometric observations alone are not sufficient; the true test must be calorimetric. Sir Benjamin Brodie observed that in a case of injury of the spinal cord in the neck the temperature in the thigh rose very high. In some cases the temperature falls. Wood has shown that section of the cord above the origin of the splanchnics leads to decided increase in the amount of heat dissipated, but to a decided diminution of heat production. The vasomotor paralysis has much to do in these cases with the loss of heat. In warm-blooded animals, exposed to a high temperature, the heat production is diminished, but when they are exposed to a low temperature it is increased. If a warm-blooded animal's medulla oblongata be divided, there is a fall of temperature, chiefly due to its vasomotor paralysis, and such an animal behaves, as regards the effect of heat and cold, exactly like a poikilothermal animal, *i.e.*, its metabolism and heat production are increased by cold and diminished by heat. If, however, the incision be made above the pons, so as to leave the vasomotor centre intact in the dog, there is a rise of the temperature and increased heat production for 24 hours afterward.

This suggests the idea that this region is traversed by inhibitory nerves, so that when they are cut off from their centres situate above, the augmentor nerves can act more vigorously. This suggests the existence of thermo-inhibitory centres situate higher up in the brain. If an animal be curarized, not only is there paralysis of voluntary motor acts, but on stimulating an ordinary motor nerve, not only is there no muscular contraction, but there is no rise of temperature of the muscles supplied by that nerve. In such an animal the temperature rises and falls with the temperature of the surrounding medium. Even although the respirations be kept constant and the vasomotor nerves intact, the thermogenic activity of muscles, therefore, seems to be dependent on their innervation.]

[**Cerebral Centres.**—Apart from the cortical heat centres (§ 377), Ott, Aronsohn, Sachs, Richet and others have shown that if a needle be thrust through the skull and brain, so as to injure certain deeper-seated parts, there is a rise of temperature and increased heat production for several hours. The experiment may be repeated several times in the same rabbit. Ott gives three areas which, when so injured, cause these effects: (1) a part of the brain in the median side of the corpus striatum, and near the nodus cursorius; (2) a part between the corpus striatum and the optic thalamus; and (3) the anterior end of the optic thalamus itself. From the effect of atropin, Ott suggests the existence of spinal centres as well.]

The following phenomena indicate the existence of mechanisms regulating the production of heat:—

(1) The temporary application of *moderate cold raises the bodily temperature*, while heat, similarly applied to the external surface, lowers it (§§ 222 and 224).

(2) Cooling of the surroundings increases the amount of CO_2 excreted, by increasing the production of heat, while the O consumed is also increased simultaneously; heating the surrounding medium diminishes the CO_2 (§ 127, 5).

D. Finkler found, from experiments upon guinea pigs, that the production of heat was more than doubled when the surrounding temperature was diminished 24° C. The metabolism of the guinea pig is increased in winter 23 per cent. as compared with summer, so that the same relation obtains as in the case of a diminution of the surrounding temperature of short duration.

C. Ludwig and Sanders-Ezn found that in a rabbit there was a rapid increase in the amount of CO_2 given off, when the surroundings were cooled from 38° to 6° or 7° C.; while the excretion was diminished when the surrounding temperature was raised from 4°–9° to 35°–37°, so that the thermal stimulation, due to the temperature of the surrounding medium, acted upon the combustion within the body. Pflüger found that a rabbit which was dipped in cold water used more O and excreted more CO_2.

If the cooling action was so great as to reduce the *bodily* temperature to 30°, the exchange of gases diminished, and where the temperature fell to 20°, the exchange of gases was diminished one-half. It is to be remembered, however, that the *excretion of* CO_2 does not go hand in hand with the formation of CO_2. If mammals be placed in a *warm* bath which is 2° to 3° higher than their own temperature, the excretion of CO_2 and the consumption of O are increased, owing to the stimulation of their metabolism, while the excretion of urea is also increased in animals and in man (§ 133, 5).

(3) **Cold** acting upon the skin causes **involuntary muscular movements** (shivering, rigors), and also **voluntary movements**, both of which produce heat.

The cold excites the action of the muscles, which is connected with processes of oxidation (*Pflüger*). After poisoning with **curara**, which paralyzes voluntary motion, this regulation of the heat falls to a minimum (*Röhrig* and *Zuntz*), [while the bodily temperature rises and falls with a rise or fall in the temperature of the surrounding medium].

(4) Variations in the **temperature of the surroundings** affect the **appetite for food**; in winter, and in cold regions, the sensation for hunger and the appetite for the fats, or such substances as yield much heat when they are oxidized, are increased; in summer and in hot climates, they are diminished. Thus the mean temperature of the surroundings, to a certain extent, determines the amount of the heat-producing substances to be taken in the food.

II. Regulatory Mechanisms governing the Excretion of Heat or Thermolysis.—The mean amount of heat given off by the human skin in twenty-four hours, by a man weighing 82 kilos., is 2092 to 2592 calories, *i.e.*, 1.36 to 1.60 per minute.

(1) **Heat** causes **dilatation of the cutaneous vessels**; the skin becomes red, congested, and soft; it contains more fluids, and becomes a better conductor of heat; the epithelium is moistened, and **sweat** appears on the surface. Thus

increased excretion of heat is provided for, while the evaporation of the sweat also abstracts heat.

The amount of heat necessary to convert into vapor 1 grm. of water at 100° C., is equal to that required to heat 10 grms. from 0° to 53.67° C. The sweat as secreted is at the temperature of the body; if it were completely changed into vapor, it would require the heat necessary to raise it to the boiling point, and also that necessary to convert it into vapor.

Cold causes contraction of the cutaneous vessels; the skin becomes pale, less soft, poorer in juices, and collapsed; the epithelium becomes dry, and does not permit fluids to pass through it to be evaporated, so that the excretion of heat is diminished. The *excretion of heat* from the periphery, and the transverse *thermal conduction* through the skin, are diminished by the contraction of the vessels and muscles of the skin, and by the expulsion of the well-conducting blood from the cutaneous and subcutaneous vessels. The cooling of the body is very much affected, owing to the diminution of the cutaneous blood stream, just as occurs when the current through a coil or worm of a distillation apparatus is greatly diminished. If the blood vessels dilate, the temperature of the surface of the body rises, the difference of temperature between it and the surrounding cooler medium is increased, and thus the excretion of heat is increased. Tomsa has shown that the fibres of the skin are so arranged anatomically, that the tension of the fibres produced by the erector pili muscles causes a diminution in the thickness of the skin, this result being brought about at the expense of the easily expelled blood.

By the systematic application of stimuli, *e.g.*, **cold baths**, and washing with cold water, the muscles of the skin and its blood vessels may be caused to contract, and become so vigorous and excitable, that when cold is suddenly applied to the body, or to a part of it, the excretion of heat is energetically prevented, so that cold baths and washing with cold water are, to a certain extent, "gymnastics of the cutaneous muscles," which, under the above circumstances, protect the body from cold.

(2) **Increased temperature causes increased heart beats**, while **diminished temperature diminishes** the **number** of contractions of the heart (§ 58, II, *a*). The relatively warm blood is pumped by the action of the heart from the internal organs of the body to the surface of the skin, where it readily gives off heat. The more frequently the same volume of blood passes through the skin—twenty-seven heart beats being necessary for the complete circuit of the blood—the greater will be the amount of heat given off, and conversely. Hence, the frequency of the heart beat is in direct relation to the rapidity of cooling. In very hot air (over 100° C.) the pulse rises to over 160 per minute. The same is true in fever (§ 70, 3 *c*.). Liebermeister gives the following numbers in an adult:—

Pulse beats, per min., . . .	78.6	91.2	99.8	108.5	110	137.5
Temperature in C°., . . .	37°	38°	39°	40°	41°	42°

(3) **Increased Temperature Increases the Number of Respirations.**—Under ordinary circumstances, a much larger volume of air passes through the lungs when it is warmed almost to the temperature of the body. Further, a certain amount of watery vapor is given off with each expiration, which must be evaporated, thus abstracting heat. Energetic respiration aids the circulation, so that respiration acts indirectly in the same way as (2). According to other observers, the increased consumption of O favors the combustion in the body, whereby the increased respiration must act in producing an amount of heat greater than normal (§ 127, 8). This excess is more than compensated for by the cooling factors above mentioned. Forced respiration produces cooling, even when the air breathed is heated to 54° C., and saturated with watery vapor.

(4) **Covering of the Body.**—Animals become clothed in winter with a winter fur or covering, while in summer their covering is lighter, so that the excretion of heat in surroundings of different temperatures is thereby rendered more constant.

Many animals which live in very cold air or water (whale) are protected from

too rapid excretion of heat by a *thick layer of fat* under the skin. Man provides for a similar result by adopting summer and winter clothing.

(5) The **position of the body** is also important; pulling the parts of the body together, approximation of the head and limbs, keep in the heat; spreading out the limbs, erection of the hairs, pluming the feathers, allow more heat to be evolved. If a rabbit be kept exposed to the air with its legs extended for three hours, the rectal temperature will fall from 39° C. to 37° C. Man may influence his temperature by remaining in a warm or a cold room—by taking hot or cold drinks—hot or cold baths—remaining in air at rest or air in motion, *e. g.*, by using a fan.

CLOTHING.—Warm Clothing is the Equivalent of Food.—As clothes are intended to keep in the heat of the body, and heat is produced by the combustion and oxidation of the food, we may say the body takes in heat directly in the food, while clothing prevents it from giving off too much heat. Summer clothes weigh 3 to 4 kilos., and winter ones 6 to 7 kilos.

In connection with clothes, the following considerations are of importance:—

(1) *Their capacity for conduction.*—Those substances which conduct heat badly keep us warmest. Hare skin, down, beaver skin, raw silk, taffeta, sheeps' wool, cotton wool, flax, spun silk, are given in order, from the worst to the best conductors. (2) The *capacity for radiation.*—Coarse materials radiate more heat than smooth, but color has no effect. (3) *Relation to the sun's rays.*—Dark materials absorb more heat than light-colored ones. (4) Their *hygroscopic properties* are important, whether they can absorb much moisture from the skin and gradually give it off by evaporation, or the reverse. The same weight of wool takes up twice as much as linen; hence the latter gives it off in evaporation more rapidly. Flannel next the skin is not so easily moistened, nor does it so rapidly become cold by evaporation; hence it protects against the action of cold. (5) The *permeability for air* is of importance, but does not stand in relation with the heat-conducting capacity, The following substances are arranged in order from the most to the least permeable—flannel, buckskin, linen, silk, leather, wax cloth.

215. HEAT BALANCE.—As the temperature of the body is maintained within narrow limits, the amount of heat taken in must balance the heat given off, *i. e.*, exactly the same amount of potential energy must be transformed in a given time into heat, as heat is given off from the body. An adult produces as much heat in half an hour as will raise the temperature of his body 1° C. If no heat were given off, the body would become very hot in a short time; it would reach the boiling point in thirty-six hours, supposing the production of heat continued uninterruptedly. The following are the most important calculations on the subject:—

A. Helmholtz was the first to estimate numerically the amount of heat produced by a man:—

(1) **Heat Income.**—(*a*) A healthy adult, weighing 82 kilos., expires in twenty-four hours 878.4 grms. CO_2 (*Scharling*). The combustion of the C therein into CO_2 produces . . . . . 1,730,760 cal.

(*b*) But he takes in more O than reappears in the CO_2; the excess is used in oxidation processes, *e. g.*, for the formation of H_2O, by union with H, so that 13,615 grms. H will be oxidized by the excess of O, which gives 318,000 "

2,049,360 "

(*c*) About 25 per cent. of the heat must be referred to sources other than combustion (*Dulong*), so that the total . . . . . = 2,732,000 "

2,732,000 calories are actually sufficient to raise the temperature of an adult, weighing 80 to 90 kilos., from 10° to 38° or 39° C., *i. e.*, to a normal temperature.

(2) **Heat Expenditure.**—(*a*) Heating the food and drink, which have a mean temperature of 12° C. . . . . 70,157 cal. = 2.6 per cent.

(*b*) Heating the air respired = 16,400 grms. with an initial temperature of 20° C. . . . . 70,032 " = 2.6 "

(*When the temperature of the air is* 0°, 140,064 *cal.* = 5.2 *per cent.*)

(*c*) Evaporation of 656 grms. water by the lungs, ... 397,536 " = 14.7 "

(*d*) The remainder given off by radiation and evaporation of water by the skin, ... (77.5 *per cent. to*) = 81.1 "

B. Dulong.—(1) **Heat Income.**—Dulong and others sought to estimate the amount of heat from the C and H contained in the food. As we know that the combustion of 1 grm. C = 8040 heat units, and 1 grm. H = 34,460 heat units, it would be easy to determine the amount of heat were the C simply converted into CO_2 and the H into H_2O. But Dulong omitted the H in the carbohydrates (*e. g.*, grape sugar = $C_6H_{12}O_6$) as producing heat, because the H is already combined with O, or at least is the proportion in which it exists in water. This assumption is hypothetical, for the atoms of C in a carbohydrate may be so firmly united to the other atoms, that before oxidation can take place their relations must be altered, so that potential energy is used up, *i. e.*, heat must be rendered latent; so that these considerations rendered the following example of Dulong's method given by Vierordt very problematical:—

An adult eats in twenty-four hours, 120 grms. proteids, 90 grms. fat, and 340 grms. starch (carbohydrates). These contain:—

Proteids,	120 grms.	contain	64.18	C. and	8.60	H.
Fat,	90 "	"	70.20	"	10.26	
Starch,	330 "	"	146.82		. .	
			281.20	and	18.86	
The urine and fæces contain still unconsumed,			29.8	"	6.3	
Remainder to be burned,			251.4	"	12.56	

As 1 grm. C. = 8040 heat units and 1 grm. H = 34,460 heat units, we have the following calculation:—

251.4 × 8,040 = 2,031,312 (from combustion of C).
12.56 × 34,460 = 432,818 (" " H),

2,464,130 heat units.

(2) **Heat Expenditure:**—

	Heat units.	Per cent. of the excreta.
1. 1900 grms. are excreted daily by the urine and fæces, and they are 25° warmer than the food,	47,500	1.9
2. 13,000 grms, air are heated (from 12° to 37° C.) (heat capacity of the air = 0.26),	184,500	3.38
3. 330 grms. water are evaporated by the respiration (1 grm. = 582 heat units),	192,060	7.68
4. 660 grms, water are evaporated from the skin,	384,120	15.37
Total,	708,180	
Remainder radiated and conducted from the skin,	1,791,820	71.67
Total amount of heat units given off,	2,500,000	100.00

C. Heat Income.—Frankland burned the food directly in a calorimeter, and found that 1 grm. of the following substances yielded:—

Albumin, 1 grm., ... 4998 heat units.
Grape sugar, 1 grm., ... 3217 "
Ox fat, 1 grm., ... 9069 "

The albumin, however, is only oxidized to the stage of urea, hence the heat units of urea must be deducted from 4998, which gives 4263 heat units obtainable from 1 grm. albumin. When we know the number of grammes consumed, a simple multiplication gives the number of heat units.

The heat units will vary, of course, with the nature of the food. J. Ranke gives the following:—

With **animal diet**, ... 2,779,524 heat units.
" **food free from N**, ... 2,059,506 "
" **mixed diet**, ... 2,200,000 "
" **during hunger**, ... 2,012,816 "

216. VARIATIONS IN HEAT PRODUCTION.—(1) **Influence of Bodily Surface.**—Rubner found that the production of heat depended more upon the size of the body and its superficial area than upon the body weight. Small or young animals have a relatively larger surface than large or older ones, and as the removal of the heat takes place chiefly from the external surface, animals with a larger surface must produce more heat. Small animals used relatively more O. Rubner's investigations on dogs of different size gave a heat production of 1,143,000 calories for every square metre of cutaneous surface. On comparing the body weight with the cutaneous surface in different animals, he found that for every 1 kilo. of body weight there was in the rat 1650, rabbit 946, man 287 square centimetres of surface.

(2) **Age and Sex.**—The heat production is less in infancy and in old age, and it is less in proportion in the female than in the male.

(3) **Daily Variation.**—The heat production shows variations in twenty-four hours corresponding with the temperature of the body (§ 213, 4).

(4) The heat production is greater in the **waking** condition, during physical and mental **exertion**, and during **digestion**, than in the opposite conditions.

217. RELATION OF HEAT PRODUCTION TO WORK.—The potential energy supplied to the body may be transformed into **heat** and **kinetic energy** (see *Introduction*). In the resting condition, almost all the potential energy is changed to heat; the workman, however, transforms potential energy into **work**—mechanical work—in addition to heat. These two may be compared by using an equivalent measurement, thus, 1 **heat unit** (energy required to raise 1 gramme of water 1° C.) = 425.5 gramme-metres.

Relation of Heat to Work.—The following example may serve to illustrate the relation between heat production and the production of work: Suppose a small steam engine to be placed within a capacious calorimeter, and a certain quantity of coal to be burned, then as long as the engine does not perform any mechanical work, heat alone is produced by the burning of the coal. Let this amount of heat be estimated, and a second experiment made by burning the same amount of coal, but allow the engine to do a certain amount of work—say, raise a weight—by a suitable arrangement. This work must, of course, be accomplished by the potential energy of the heating material. At the end of this experiment, the temperature of the water will be much less than in the first experiment, *i. e.*, fewer heat units have been transferred to the calorimeter when the engine was heated than when it did no work. Comparative experiments of this nature have shown that in the second experiment, the useful work is very nearly proportional to the decrease of the heat (*Hirn*).

Compare this with what happens within the body: A man in a **passive condition** forms from the potential energy of the food between 2½ to 2¾ million calories. The **work done** by a workman is reckoned at 300,000 kilogramme-metres (§ 300).

If the organism were precisely similar to a machine, a smaller amount of heat, corresponding to the work done, would be formed in the body. As a matter of fact, the organism produces less heat from the same amount of potential energy when mechanical work is done. There is one point of difference between a workman and a working machine. The workman consumes much more potential energy in the same time than a passive person; much more is transformed in his body; and hence the increased consumption is not only covered, but even overcompensated. Hence, the workman is warmer than the passive person, owing to the increased muscular activity (§ 210, 1, *b*). Take an example: Hirn remained *passive*, and absorbed 30 grms. O per hour in a calorimeter, and produced 155 calories. When in the calorimeter he did work equal to 27,450 kilogramme-metres, which was transferred beyond it; he absorbed 132 grms. O, and produced only 251 calories.

In estimating the work done, we must include only the heat equivalent of the work transferred beyond the body; lifting weights, pushing anything, throwing a weight, and lifting the body are examples. In ordinary walking we must take into account that we overcome the resistance of the air and the activity of the muscles.

The organism is superior to a machine in as far as it can, from the same amount of potential energy, produce more work in proportion to heat. While the very best steam engine gives ⅛ of the potential energy in the form of work, and ⅞ as heat, the body produces ⅕ as work and ⅘ as heat. *Chemical energy* can never do work alone, in a living or dead motor, without heat being formed at the same time.

218. ACCOMMODATION FOR VARYING TEMPERATURES.—All substances which possess high conductivity for heat, when brought into contact with the skin, appear to be very much colder or hotter than bad conductors of heat. The reason of this is that these bodies abstract far more heat, or conduct more heat than other bodies. Thus the water of a cool bath, being a better

conductor of heat, is always thought to be colder than air at the same temperature. In our climate it appears to us that—

Air, at 18° C. is moderately warm;	**Water**, at 18° C. is cold;
" at 25°–28° C., hot;	" from 18°–29° C., cool;
" above 28°, very hot.	" " 29°–30° C., warm;
	" " 37.5° and above, hot.

Warm Media.—As long as the temperature of the body is higher than that of the surrounding medium, heat is given off, and that the more rapidly the better the conducting power of the surrounding medium. As soon as the temperature of the surrounding medium rises higher than the temperature of the body, the latter absorbs heat, and it does so the more rapidly the better the conducting power of the medium. Hence, hot water appears to be warmer than air at the same temperature. A person may remain eight minutes in a **bath** at 45.5° C. (dangerous to life!); the hands may be plunged into water at 50.5° C., but not at 51.65° C., while at 60° violent pain is produced.

A person may remain for eight minutes in **hot air** at 127° C., and a temperature of 132° C. has been borne for ten minutes, and yet the body temperature rise only to 38.6° or 38.9°. This depends upon the air being a bad conductor, and thus it gives less heat to the body than water would do. Further, and what is more important, the skin becomes covered with sweat, which evaporates and abstracts heat, while the lungs also give off more watery vapor. The enormously increased heart-beats—over 160—and the *dilated blood vessels*, enable the skin to obtain an ample supply of blood for the formation and evaporation of sweat. In proportion as the secretion diminishes, the body becomes unable to endure a hot atmosphere; hence it is that in *air containing much watery vapor* a person cannot endure nearly so high a temperature as in dry air, so that heat must accumulate in the body. In a Turkish vapor bath of 53° to 60° C., the rectal temperature rises to 40.7° or 41.6° C. A person may work continuously in air at 31° C. which is almost saturated with moisture.

If a person be placed in **water** at the temperature of the body, the normal temperature rises 1° C. in one hour, and in 1½ hour about 2° C. A gradual increase of the temperature from 38.6° to 40.2° C. causes the axillary temperature to rise to 39.0° within fifteen minutes.

219. **STORAGE OF HEAT.**—As the uniform temperature of the body, under normal circumstances, is due to the reciprocal relation between the amount of heat produced and the amount given off, it is clear that heat must be stored up in the body when the evolution of heat is diminished. **The skin is the chief organ regulating the evolution of heat**; when it and its blood vessels contract, the heat evolved is diminished, when they dilate it is increased. **Heat may be stored up** when—

(*a*) The *skin* is extensively *stimulated*, whereby the cutaneous vessels are temporarily contracted. (*b*) Any other circumstances prevent heat from being given off by the skin. (*c*) When the *vaso-motor centre is excited*, causing all the blood vessels of the body—those of the skin included—to contract. This seems to be the cause of the rise of temperature after transfusion of blood, and the rise of temperature after the *sudden removal of water* from the body seems to admit of a similar explanation, as the inspissated blood occupies less space, and the contracted vessels of the skin admit less blood. (*d*) When the circulation in the cutaneous vessels of a large area is mechanically slowed, or when the smaller vessels are plugged by the injection of some sticky substance, or by the transfusion of foreign blood, the temperature rises (§ 102).

It is also obvious that when a normal amount of heat is given off, an increased production of heat must raise the temperature. The rise of the temperature after muscular or mental exertion, and during digestion, seems to be caused in this way. The rise which occurs several hours after a cold bath is probably due to the reflex excitement of the skin causing an increased production (*Jürgensen*).

When the temperature of the body, as a whole is raised 6° C., death takes

place, as in sunstroke. It seems as if there was a molecular decomposition of the tissues at this temperature; while, if a slightly lower temperature be kept up *continuously*, fatty degeneration of many tissues occurs (*Litten*). If animals, which have been exposed artificially to a temperature of over 42° to 44° C., be transferred to a cooler atmosphere, their temperature becomes sub-normal (36° C.), and may remain so for several days.

220. **FEVER.**—Fever consists in a "*disorder of the body heat*" and at the same time there is greatly *increased tissue metabolism* (especially in the muscles). Of course the mechanism regulating the balance of formation and expenditure of heat is disturbed. During fever the body is greatly incapacitated for performing mechanical work. It is evident, therefore, that the large amount of potential energy transformed is almost all converted into heat, so that the non-transformation of the energy into mechanical work is another important factor. We may take intermittent fever or **ague** as a type of fever, in which violent attacks of fever of several hours' duration alternate with periods free from fever. This enables us to analyze the symptoms. The **symptoms** of fever are:—

(1) The **increased temperature** of the body (38° to 39° C., slight; from 39° to 41° C. and upward, severe). The high temperature occurs not only in cases where the skin is red, and has a hot burning feeling (calor mordax), but even during the rigor or the shivering stage, the temperature is raised. The congested red skin is a good conductor of heat, while the pale, bloodless skin conducts badly; hence the former feels hot to the touch (§ 212).

[The following table in ° C. and ° F. indicates generally the degree of fever:—

35° C.	= 95° F.	. . . .	Collapse.	39° C.	= 102.2° F. } Moderate fever.
36	= 96.8	. . . .	Low.	39.5	= 103.1 }
36.5	= 97.7	. . . .	Sub-normal.	40	= 104 } High fever.
37	= 98.6	. . . .	**Normal.**	40.5	= 104.9 }
37.5	= 99.5 }			41	= 105.8 Hyperpyretic.
38	= 100.4 }	. . . .	Sub-febrile.		*Finlayson.*]
38.5	= 101.3 }				

(2) The **increased production of heat** is proved by calorimetic observations. This is, in small part, due to the increased activity of the circulation being changed into heat (§ 206, 2, *a*), but for the most part it is due to increased combustion within the body.

(3) The **increased metabolism** gives rise to the "consuming" or "wasting" character of fever, which was known to Hippocrates and Galen. In 1852 v. Bärensprung asserted that "all the so-called febrile symptoms show that the metabolism is increased." The increase of the metabolism is shown in the increased *excretion of* CO_2 = 70 to 80 per cent., while more O is consumed, although the respiratory quotient remains the same. According to D. Finkler, the CO_2 excreted shows greater variations than the O consumed. The *excretion of urea* is increased $\frac{1}{3}$ to $\frac{2}{3}$. In dogs suffering from septic fever, Naunyn observed that the urea began to increase before the temperature rose, "*prefebrile rise.*" Part of the urea, however, is sometimes retained during the fever, and appears after the fever is over, "*epicritical excretion of urea.*" The *uric acid* is also *increased;* the *urine pigment* (§ 19), derived from the hæmoglobin, may be increased twenty times, while the excretion of *potash* may be sevenfold. It is important to observe that the oxidation or combustion processes within the body of the fever patient are greatly increased when he is placed in a *warmer* atmosphere. The oxidation processes in fever, however, are also increased under the influence of *cooler* surroundings (§ 214, I, 2), but the increase of the oxidation in a warm medium is very much greater than in the cold (*D. Finkler*). The amount of CO_2 in the blood is diminished, but not at once after the onset even of a very severe fever (*Geppert*).

(4) The **diminished excretion of heat** varies in different stages of a fever. We distinguish several **stages in a fever**—(*a*) The **cold stage**, when the loss of heat is greatly diminished, owing to the pale, bloodless skin, but at the same time the heat production is increased $1\frac{1}{2}$ to $2\frac{1}{2}$ times. The sudden and considerable rise of the temperature during this stage shows that the diminished excretion of heat is not the only cause of the rise of the temperature. (*b*) During the **hot stage** the *heat given off* from the congested red skin is *greatly increased*, but at the same time more heat is produced. Liebermeister assumes that a rise of 1, 2, 3, 4° C. corresponds to an increased production of heat of 6, 12, 18, 24 per cent. (*c*) In the **sweating stage** the excretion of heat through the red moist skin and evaporation are greatest, more than two or three times the normal. The heat production is either increased, normal, or sub-normal, so that under these conditions the temperature may also be sub-normal (36° C.).

(5) The **heat-regulating mechanism is injured.**—A warm temperature of the surroundings raises the temperature of the fever patient more than it does that of a non-febrile person. The depression of the heat production, which enables normal animals to maintain their normal temperature in a warm medium (§ 214), is much less in fever (*D. Finkler*).

The **accessory phenomena** of fever are very important: Increase in the intensity and number of heart beats (§ 214, II, 2) and respirations (in adults 40, and children 60 per min.), both being

compensatory phenomena of the increased temperature; further, diminished digestive activity and intestinal movements (§ 186, D); disturbances of the cerebral activities; of secretion; of muscular activity; slower excretion, *e.g.*, of potassium iodide through the urine. In severe fever, molecular degenerations of the tissues are very common. For the condition of the blood corpuscles in fever, see § 10, the vascular tension, § 69, the saliva, § 146, digestion, § 186.

Quinine, the most important febrifuge, causes a decrease of the temperature by limiting the production of heat (§ 213, 6). Toxic doses of the metallic salts act in the same way, while there is at the same time diminished formation of CO_2. [**Antipyretics** or **Febrifuges.**—All methods which diminish abnormal temperature belong to this group. As the constant temperature of the body depends on (1) the amount of heat production, and (2) the loss of heat, we may lower the temperature either in the one way or the other. When cold water is applied to the body, it abstracts heat, *i. e.*, it affects the results of fever, so that Liebermeister calls such methods **antithermic.** But those remedies which diminish the actual heat production are true **antipyretic.** In practice, however, both methods are usually employed, and spoken of collectively as antipyretics.]

[Among the methods which are used to abstract heat from the body, are the application of colder fluids, such as the cold bath, affusion, douche, spray, ice, or cold mixtures, etc. A person suffering from high fever requires to be repeatedly placed in a cold bath to produce any permanent reduction of the temperature. Some remedies act by favoring the radiation of heat, by dilating the cutaneous vessels (alcohol), while others excite the sweat glands—*i. e.*, are *sudorifics*—so that the water by its evaporation removes some heat. Among the drugs which influence tissue changes and oxidation, and thereby lessen heat production, are quinine, salicylic acid, some of the salicylates, digitalis, and veratrin. Bloodletting was formerly used to diminish abnormal temperature. Among the newer antipyretic remedies are hydrochlorate of kairin and antipyrin, both of which belong to the aromatic group (derivatives of benzol), which includes also many of our best antiseptics.]

221. ARTIFICIAL INCREASE OF THE BODILY TEMPERATURE.—If **mammals** are kept *constantly* in air at 40° C., the excretion of heat from the body ceases, so that the heat produced is stored up. At first the temperature falls somewhat for a very short time, but soon a decided increase occurs. The respirations and pulse are increased, while the latter becomes irregular and weaker. The O absorbed and CO_2 given off are diminished after six to eight hours, and death occurs after great fatigue, feebleness, spasms, secretion of saliva, and loss of consciousness, when the bodily temperature has been increased 4° or at most 6° C. Death does not take place owing to rigidity of the muscles, for the coagulation of the myosin of mammals' muscles occurs at 49° to 50° C., in birds at 53° C., and in frogs at 40° C. If mammals are *suddenly* placed in air at 100° C., death occurs (in 15 to 20 min.) very rapidly, and with the same phenomena, while the bodily temperature rises 4° to 5° C. In rabbits the body weight diminishes 1 grm. per min. Birds bear a high temperature somewhat longer; they die when their blood reaches 48° to 50° C.

Even **man** may remain for some time in air at 100–110–132° C., but in ten to fifteen minutes there is danger to life. The skin is burning to the touch, and red; a copious secretion of sweat bursts forth, and the cutaneous veins are fuller and redder. The pulse and respirations are greatly accelerated. Violent headache, vertigo, feebleness, and stupefaction, indicate great danger to life. The rectal temperature is only 1° to 2° C. higher. The high temperature of fever may even be dangerous to human life. If the temperature remains for any length of time at 42.5° C., death is almost certain to occur. Coagulation of the blood in the arteries is said to occur at 42.6° C. If the artificial heating *does not produce death*, fatty infiltration and degeneration of the liver, heart, kidneys, and muscles begin after thirty-six to forty-eight hours.

Cold-blooded animals, if placed in hot air or warm water, soon have their temperature raised 6 to 10° C. The highest temperature compatible with life in a frog must be below 40° C., as the frog's heart and muscles begin to coagulate at this temperature. Death is preceded by a stage resembling death, during which life may be saved.

Most of the **juicy plants** die in half an hour in air at 52° C., or in water at 46° C. (*Sachs*). Dried seeds of corn may still germinate after long exposure to air at 120° C. Lowly organized plants, such as algæ, may live in water at 60° C. (*Hoppe-Seyler*). Several bacteria withstand a boiling temperature (*Tyndall*).

222. EMPLOYMENT OF HEAT.—Action of Heat.—The short, but not intense, action of heat on the surface causes, in the first place, a transient slight decrease of the bodily temperature,

partly because it retards reflexly the production of heat, and partly because, owing to the dilatation of the cutaneous vessels and the stretching of the skin, more heat is given off. A warm bath above the temperature of the blood at once increases the bodily temperature.

Therapeutic Uses.—The application of heat to the entire body is used where the bodily temperature has fallen, or is likely to fall, very low, as in the algid stage of cholera, and in infants born prematurely. The *general* application of heat is obtained by use of warm baths, packing, vapor baths, and the copious use of hot drinks. The *local* application of heat is obtained by the use of warm wrappings, partial baths, plunging the parts in warm earth or sand, or placing wounded parts in chambers filled with heated air. After removal of the heating agent, care must be taken to prevent the great escape of heat due to the dilatation of the blood vessels.

223. **INCREASE OF TEMPERATURE POST-MORTEM.—Phenomena.**— Heidenhain found that in a dead dog, before the body cooled, there was a constant temporary rise of the temperature, which slightly exceeded the normal. The same observation had been occasionally made on human bodies immediately after death, especially when death was preceded by muscular spasms [also in yellow fever]. Thus, Wunderlich measured the temperature fifty-seven minutes after death in a case of tetanus, and found it to be 45.375° C.

Causes.—(1) *A temporary increased production of heat after death*, due chiefly to the change of the semi-solid myosin of the muscles into a solid form (rigor mortis). As the muscle coagulates, heat is produced. All conditions which cause rapid and intense coagulation of the muscles—*e. g.*, spasms, favor a *post-mortem* rise of temperature (see § 295); a rapid coagulation of the blood has a similar result (§ 28, 5).

(2) Immediately after death a series of *chemical processes* occur within the body, whereby heat is produced. Valentin placed a dead rabbit in a chamber, so that no heat could be given off from the body, and he found that the internal temperature of the animal's body was increased. The processes which cause a rise of temperature *post-mortem* are more active during the first than the second hour; and the higher the temperature at the moment of death, the greater is the amount of heat evolved after death.

(3) Another cause is the *diminished excretion of heat post-mortem*. After the circulation is abolished, within a few minutes little heat is given off from the surface of the body, as rapid excretion implies that the cutaneous vessels must be continually filled with warm blood.

224. **ACTION OF COLD ON THE BODY.—Phenomena.**—A short, temporary, slight cooling of the skin (removing one's clothes in a cool room, a cool bath for a short time, or a cool douche) causes either no change or a slight rise in the bodily temperature. The slight rise, when it occurs, is due to the stimulation of the skin causing reflexly a more rapid molecular transformation, and therefore a greater production of heat, while the amount of heat given off is diminished owing to contraction of the small cutaneous vessels and the skin itself (*Liebermeister*). The continuous and intense application of cold causes a decrease of the temperature, chiefly by conduction, notwithstanding that at the same time there is a greater production of heat. After a cold bath the temperature may be 34°, 32°, and even 30° C.

As an **after-effect** of the great abstraction of heat, the temperature of the body after a time remains lower than it was before (*"primary after-effect"*—*Liebermeister*); thus after an hour it was 0.22° C. in the rectum. There is a *"secondary after-effect"* which occurs after the first after-effect is over, when the temperature rises (*Jürgensen*). This effect begins five to eight hours after a cold bath, and is equal to + 0.2° C. in the rectum. Hoppe-Seyler found that some time after the application of heat there was a corresponding lowering of the temperature.

Taking Cold.—If a rabbit be taken from a surrounding temperature of 35° C., and suddenly cooled, it shivers, and there may be diarrhœa. After two days the temperature rises 1.5° C., and albuminuria occurs. There are microscopic traces of interstitial inflammation in the kidneys, liver, lungs, heart, and nerve sheaths, the dilated arteries of the liver and lung contain thrombi, and in the neighborhood of the veins are accumulations of leucocytes. In pregnant animals the fœtus shows the same conditions. Perhaps the greatly cooled blood acts as an irritant causing inflammation.

Action of Frost.— The continued application of a high degree of cold causes at first contraction of the blood vessels of the skin and its muscles, so that it becomes pale. If continued paralysis of the cutaneous vessels occurs, the skin becomes red, owing to congestion of its vessels. As the passage of fluids through the capillaries is rendered more difficult by the cold, the blood stagnates, and the skin assumes a *livid appearance*, as the O is almost completely used up. Thus the peripheral circu-

lation is slowed. If the action of the cold be still more intense, the peripheral circulation stops completely, especially in the thinnest and most exposed organs—ears, nose, toes, and fingers. The sensory nerves are paralyzed, so that there is numbness with loss of sensibility, and the parts may even be frozen through and through. As the slowing of the circulation in the superficial vessels gradually affects other areas of the circulation, the pulmonary circulation is enfeebled, and diminished oxidation of the blood occurs, notwithstanding the greater amount of O in the cold air, so that the *nerve centres* are affected. Hence arise great dislike to making movements or any muscular effort, a painful sensation of fatigue, a peculiar and almost irresistible desire to sleep, cerebral inactivity, blunting of the sense organs, and lastly, coma. The blood freezes at —3.9° C., while the juices of the superficial parts freeze sooner. Too rapid movements of the frost bitten parts ought to be avoided. Rubbing with snow, and the very gradual application of heat, produce the best results. Partial death of a part is not unfrequently produced by the prolonged action of cold.

225. ARTIFICIAL LOWERING OF THE TEMPERATURE.—Phenomena.—The artificial cooling of **warm-blooded animals**, by placing them in cold air or in a freezing mixture, gives rise to a series of characteristic phenomena. If the animals (rabbits) are cooled so that the temperature (rectum) falls to 18°, they suffer great depression, without, however, the voluntary or reflex movements being abolished. The *pulse* falls from 100 or 150 to 20 beats per minute, and the blood pressure falls to several millimetres of Hg. The *respirations* are few and shallow. Suffocation does not cause spasms, the secretion of urine stops, and the liver is congested. The animal may remain for twelve hours in this condition, and when the muscles and nerves show signs of paralysis, coagulation of the blood occurs after numerous blood corpuscles have been destroyed. The retina becomes pale, and death occurs with spasms and the signs of asphyxia. If the bodily temperature be reduced to 17° and under, the voluntary movements cease before the reflex acts. An animal cooled to 18° C., and left to itself, at the same temperature as the surrounding, does not recover of itself, but if artificial respiration be employed, the temperature rises 10° C. If this be combined with the application of external warmth, the animals may recover completely, even when they have been apparently dead for forty minutes. Walther cooled adult animals to 9° C., and recovered them by artificial respiration and external warmth; while Horvath cooled *young* animals to 5° C. Mammals, which are born blind, and birds which come out of the egg devoid of feathers, cool more rapidly than others. Morphia, and more so, **alcohol**, accelerate the cooling of mammals, at the same time the exchange of gases falls considerably; hence, drunken men are more liable to die when exposed to cold.

Artificial Cold-blooded Condition.—Cl. Bernard made the important observation, that the muscles of animals that had been cooled remained irritable for a long time, to direct stimuli as well as to stimuli applied to their nerves; and the same is the case when the animals are asphyxiated for want of O. An "*artificial cold-blooded condition*," *i. e.*, a condition in which warm-blooded animals have a lower temperature, and retain muscular and nervous excitability, may also be caused in warm-blooded animals, by dividing the cervical spinal cord and keeping up artificial respiration; further, by moistening the peritoneum with a cool solution of common salt.

Hibernation presents a series of similar phenomena. Valentin found that hibernating animals become half awake when their bodily temperature is 28° C.; at 18° C. they are in a somnolent condition, at 6° they are in a gentle sleep, and at 1.6° C. in a deep sleep. The heart beats and the blood pressure fall, the former to 8 to 10 per minute. The respiratory, urinary, and intestinal movements cease completely, and the cardio-pneumatic movement alone sustains the slight exchange of gases in the lungs (§ 59). They cannot endure cooling to 0° C.; and awake before the temperature falls so low. Hibernating animals may be cooled to a greater degree than other mammals; they give off heat rapidly, and they become warm again rapidly, and even spontaneously. Newborn mammals resemble hibernating animals more closely in this respect than do

Cold-blooded animals may be cooled to 0°. F
formed in the lymph of the peritoneal cavity, from
dead, but when placed in a warm medium they
again. The germs and ova of lower animals,

cold be moderate, it merely retards development. Bacteria, *e. g.*, Bacillus anthracis, survive a temperature of — 130° C.; yeast, even — 100° C.

Varnishing the skin causes a series of similar phenomena. The varnished skin gives off a large amount of heat by radiation, and sometimes the cutaneous vessels are greatly dilated. Hence the animals cool rapidly and die, although the consumption of O is not diminished. If cooling be prevented by warming them and keeping them in warm wool, the animals live for a longer time. The blood *post-mortem* does not contain any poisonous substances, nor even are any materials retained in the blood which can cause death, for if the blood be injected into other animals, these remain healthy.

226. EMPLOYMENT OF COLD.—**Cold** may be applied to the whole or part of the surface of the body in the following conditions:—

(*a*) By placing the body for a time in a **cold bath**, to abstract as much heat as possible, when the bodily temperature in fever rises so high as to be dangerous to life. This result is best accomplished and lasts longest when the bath is gradually cooled from a moderate temperature. If the body be placed at once in cold water, the cutaneous vessels contract, the skin becomes bloodless, and thus obstacles are placed in the way of the excretion of heat. A bath gradually cooled in this way is borne longer. The addition of stimulating substances, *e. g.*, salts, which cause dilatation of the cutaneous vessels, facilitates the excretion of heat; even salt water conducts heat better. If alcohol be given internally at the same time, it lowers the temperature.

(*b*) Cold may be applied **locally** by means of ice in a bag, which causes contraction of the cutaneous vessels and contraction of the tissues (as in inflammation), while at the same time heat is abstracted locally.

(*c*) Heat may be abstracted locally by the **rapid evaporation** of volatile substances (ether, carbon disulphide), which causes numbness of the sensory nerves. The introduction of media of low temperature into the body, respiring cool air, taking cold drinks, and the injection of cold fluids into the intestine act locally, and also produce a more general action. In applying cold it is important to notice that the initial contraction of the vessels and the contraction of the tissues are followed by a greater dilatation and turgescence, *i. e.*, by a healthy reaction.

227. HEAT OF INFLAMED PARTS.—**"Calor," or heat,** is reckoned one of the fundamental phenomena of inflammation, in addition to rubor (**redness**), tumor (**swelling**), and dolor (**pain**). But the apparent increase in the heat of the inflamed parts is not above the temperature of the blood. Simon, in 1860, asserted that the arterial blood flowing to an inflamed part was cooler than the part itself, but this has been contradicted. The outer parts of the skin in an inflamed part are warmer than usual, owing to the dilatation of the vessels (rubor) and the consequent acceleration of the blood stream in the inflamed part, and owing to the swelling (tumor) from the presence of good heat-conducting fluids; but the heat is not greater than the heat of the blood. It is not proved that an increased amount of heat is produced owing to increased molecular decompositions within an inflamed part.

228. HISTORICAL AND COMPARATIVE.—According to Aristotle, the heart prepares the heat within itself, and sends it along with the blood to all parts of the body. This doctrine prevailed in the time of Hippocrates and Galen, and occurs even in Cartesius and Bartholinus (1667, "flammula cordis"). The **iatro-mechanical school** (*Boerhave, van Swieten*) ascribed the heat to the friction of the blood on the walls of the vessels. The **iatro-chemical school,** on the other hand, sought the source of heat in the fermentations that arose from the passage of the absorbed substances into the blood (*van Helmont, Sylvius, Ettmüller*). Lavoisier (1777) was the first to ascribe the heat to the combustion of carbon in the lungs. After the construction of the **thermometer** by Galileo, Sanctorius (1626) made the first thermometric observations on sick persons, while the first *calorimetric* observations were made by Lavoisier and Laplace. **Comparative** observations are given at § 207, and also under *Hibernation* (§ 225).

PHYSIOLOGY OF METABOLIC PHENOMENA.

By the term **metabolism** we mean those phenomena whereby all—even the most lowly—living organisms are capable of incorporating the substances obtained from their food into their tissues, and making them an integral part of their own bodies. This part of the process is known as **assimilation.** Further, the organism in virtue of its metabolism forms a store of potential energy, which it can transform into *kinetic energy*, and which, in the higher animals at least, appears most obvious in the form of muscular work and heat. The **changes of the constituents of the tissues,** by which these transformations of the potential energy are accompanied, result in the formation of **excretory products,** which is another part of the process of metabolism. The normal metabolism requires the supply of food quantitatively and qualitatively of the proper kind, the laying up of this food within the body, a regular chemical transformation of the tissues, and the formation of the effete products which have to be given out through the excretory organs. [Synthetic or constructive metabolism is spoken of as **anabolic,** and destructive or analytical metabolism as **katabolic,** metabolism.]

229. THE MOST IMPORTANT SUBSTANCES USED AS FOOD.—Water.—When we remember that 58.5 per cent. of the body consists of water, that water is being continually given off by the urine and fæces, as well as through the skin and lungs, that the processes of digestion and absorption require water for the solution of most of the substances used as food, and that numerous substances excreted from the body require water for their solution, especially in the urine, the great importance of water and its continual renewal within the organism are at once apparent. As put by Hoppe-Seyler, all organisms live in water, and even in running water, a saying which ranks with the old saying—"Corpora non agunt nisi fluida."

Water—as far as it is not a constituent of all fluid foods—occurs in different forms as drink: (1) **Rain water,** which most closely resembles distilled or chemically pure water, always contains minute quantities of CO_2, NH_3, nitrous and nitric acids. (2) **Spring water** usually contains much mineral substance. It is formed from the deposition of watery vapor or rain from the air, which permeates the soil, containing much CO_2; the CO_2 is dissolved by the water, and aids in dissolving the alkalies, alkaline earths, and metals, which appear in solution as bicarbonates, *e. g.*, of lime or iron oxide. The water is removed from the spring by proper mechanical appliances, or it bubbles up on the surface in the form of a "spring." (3) **River water** usually contains much less mineral matter than spring water. Spring water floating on the surface rapidly gives off its CO_2, whereby many substances—*e. g.*, lime—are thrown out of solution, and deposited as insoluble precipitates.

Gases.—Spring water contains little O, but much CO_2, the latter giving to it its fresh taste. Hence, vegetable organisms flourish in spring water, while animals requiring, as they do, much O, are but poorly represented in such water. Water flowing freely gives up CO_2, and absorbs O from the air, and thus affords the necessary conditions for the existence of fishes and other marine animals. River water contains $\frac{1}{30}$ to $\frac{1}{20}$ of its volume of absorbed gases, which may be expelled by boiling or freezing.

Drinking water is chiefly obtained from springs. River water, if used for this purpose, must be filtered to get rid of mechanically suspended impurities. For household purposes a charcoal filter may be used, as the charcoal acts as a disinfectant. **Alum** has a remarkable action. When added to give a dilution containing 0.0001 per cent., it makes turbid water clear

Investigation of Drinking Water.—Drinking water, even in a thick layer, ought to be completely *colorless, not turbid, and without odor.* Any odor is best recognized by heating it to 50° C., and adding a little caustic soda. It ought not to be *too hard, i. e.*, it ought not to contain too much lime (and magnesia) salts.

By the term "**degree of hardness**" of a water is meant the unit amount of lime (and magnesia) in 100,000 parts of water; a water of 20 degrees of hardness contains 20 parts of lime (calcium oxide) combined with CO_2, sulphuric, or hydrochloric acids (the small amount of magnesia may be neglected). *A good drinking water ought not to exceed 20 degrees of hardness.* The hardness is determined by titrating the water with a standard soap solution, the result being the formation of a scum of lime soap on the surface. The hardness of *unboiled* water is called its *total hardness*, while that of *boiled water* is called **permanent hardness.** Boiling drives off the CO_2, and precipitates the calcium carbonate, so that the water at the same time becomes softer.

The presence of **sulphuric acid,** or sulphates, is determined by the water becoming turbid on adding a solution of barium chloride and hydrochloric acid.

Chlorine occurs in small amount in pure spring water, but when it occurs there in large amount—apart from its being derived from saline springs, near the sea or manufactories—we may conclude that the water is contaminated from water closets or dunghills, so that the estimation of chlorine is of importance. For this purpose use a solution, A, of 17 grms. of crystallized silver nitrate in 1 litre of distilled water; 1 cubic centimetre of this solution precipitates 3.55 milligrammes of chlorine as silver chloride. Use also B, a cold saturated solution of neutral potassium chromate. Take 50 cubic centimetres of the water to be investigated, and place it in a beaker, add to it 2 to 3 drops of B, and allow the fluid A to run into it from a burette until the white precipitate first formed *remains* red, even after the fluid has been stirred. Multiply the number of cubic centimetres of A used by 7.1, and this will give the amount of chlorine in 100,000 parts of the water. **Example**—50 c. cmtr. requires 2.9 c. cmtr. of the silver solution, so that 100,000 parts of the water contain $2.9 \times 7.1 = 20.59$ parts chlorine (*Kubel Tiemann*). Good water ought not to contain more than 15 milligrammes of chlorine per litre.

The presence of **lime** may be ascertained by acidulating 50 cubic centimetres of the water with HCl, adding ammonia in excess, and afterward adding ammonia oxalate; the white precipitate is lime oxalate. According to the degree of turbidity, we judge whether the water is "soft" (poor in lime), or "hard" (rich in lime).

Magnesia is determined by taking the clear fluid of the above operation, after removing the precipitate of lime, and adding to it a solution of sodium phosphate and some ammonia; the crystalline precipitate which occurs is magnesia.

The more feeble all these reactions which indicate the presence of sulphuric acid, chlorine, lime, and magnesia, are, the better is the water. In addition, good water ought not to contain more than traces of nitrates, nitrites, or compounds of ammonia, as their presence indicates the decomposition of nitrogenous organic substances.

For **nitric acid,** take 100 cubic centimetres of water acidulated with two or three drops of concentrated sulphuric acid, add several pieces of zinc together with a solution of potassium iodide, and starch solution—a blue color indicates nitric acid. The following test is very delicate: Add to half a drop of water in a capsule two drops of a watery solution of Brucinum sulphuricum, and afterward several drops of concentrated sulphuric acid; a rose-red coloration indicates the presence of nitric acid.

The presence of **nitrous acid** is ascertained by the blue coloration which results from the addition of a solution of potassium iodide, and solution of starch, after the water has been acidulated with sulphuric acid.

Compounds of ammonia are detected by Nessler's reagent, which gives a yellow or reddish coloration when a trace of ammonia is present in water; while a large amount of these compounds gives a brown precipitate of the iodide of mercury and ammonia.

The **contamination of water** by decomposing animal substance is determined by the amount of N it contains. In most cases it is sufficient to determine the amount of *nitric acid* present. For this purpose we require (A) a solution of 1.871 grms. potassium nitrate in 1 litre distilled water—1 cubic centimetre contains 1 milligramme nitric acid; (B) a dilute solution of indigo, which is prepared by rubbing together one part of pulverized indigotin with six parts H_2SO_4, and allowing the deposit to subside, when the blue fluid is poured into forty times its volume of distilled water and filtered. This fluid is diluted with distilled water until a layer, 12 to 15 mm. in thickness, begins to be transparent.

To test the activity of B, place 1 cubic centimetre of A in 24 cubic centimetres water, add some common salt and 50 cubic centimetres concentrated sulphuric acid, and allow B to flow from a burette into this mixture until a faint green color is obtained. The number of cubic centimetres of B used correspond to 1 milligramme of nitric acid.

Twenty-five cubic centimetres of the water to be investigated are mixed with 50 cubic centimetres ...rated H_2SO_4, and titrated with B until a green color is obtained. This process must be

repeated, and on the second occasion the solution B must be allowed to flow in at once, when usually somewhat more indigo solution is required to obtain the green solution. The number of cubic centimetres of B (corresponding to the strength of B, as determined above) indicates the amount of nitric acid present in 25 c.cmtr. of the water investigated. As much as 10 milligrammes nitric acid have been found in spring water (*Marx, Trommsdorff*).

Sulphuretted Hydrogen is recognized by its *odor*; also by a piece of blotting paper moistened with alkaline solution of lead becoming brown when it is held over the boiling water. If it occurs as a *compound* in the water, sodium nitro-prusside gives a reddish-violet color

It is of the greatest importance that drinking water should be *free from the presence of* **organic matter** in a state of decomposition. Organic matter in a state of decomposition, and the organisms therewith associated, when introduced into the body, may give rise to fatal maladies, *e. g.*, cholera and typhoid fever. This is the case when the water supply has been contaminated from water which has percolated from water closets, privies and dung pits. *The presence of organic matter may be detected thus* (1) A considerable amount of the water is evaporated to dryness in a porcelain vessel, if the residue be heated again a brown or black color indicates the presence of a considerable amount of organic matter; and if it contain N, there is an odor of ammonia. Good water treated in this way gives only a light brown stain. The presence of **micro-organisms** may be determined microscopically after evaporating a small quantity of the water on a glass slide. (2) The addition of *potassio-gold chloride* to the water gives a black frothy precipitate after long standing. (3) A solution of *potassium permanganate*, added to the water in a covered jar, gradually becomes decolorized, and a brownish precipitate is formed.

Water containing much organic matter should *never* be used as drinking water, and this is especially the case when there is an epidemic of typhoid fever, cholera or diarrhœa. In all such circumstances, the water ought to be boiled for a long time, whereby the organic germs are killed. The insipid taste of the water after boiling may be corrected by adding a little sugar or lime juice.

230. **THE MAMMARY GLANDS AND MILK.—Milk Duct.**—About 20 galactoferous ducts open singly upon the surface of the nipple. Each of these, just before it opens on the surface, is provided with an oval dilatation—the **sinus lacteus.** When traced into the gland, the galactoferous ducts divide like the branches of a tree, and a large branch of the duct passes to each **lobe** of the gland, all the lobes being held together by loose connective tissue. Only during lactation do all the fine terminations of the ducts communicate with the globular glandular acini. Every gland **acinus** consists of a membrana propria, surrounded externally with a network of branched connective-tissue corpuscles, and lined internally with a somewhat flattened polyhedral layer of nucleated **secretory cells** (Fig. 233). The size of the lumen of the acini depends upon the secretory activity of the glands; when it is large, it is filled with milk containing numerous refractive fatty granules. The walls of the milk ducts consist of fibrillar connective tissue, some fibres are arranged longitudinally, but the chief mass are disposed circularly, and are permeated externally with elastic fibres, while in the finer ducts there is a membrana propria continuous with that of the gland acini. The ducts are lined by cylindrical epithelium.

FIG. 233.

Acini of the mammary gland of a sheep during lactation. *a*, membrana propria; *b*, secretory epithelium.

During the *first few days after delivery*, the breasts secrete a small amount of milk of greater consistence, and of a yellow color—the **colostrum**—in which large cells filled with fatty granules occur—the colostrum corpuscles (Fig. 235). Sometimes a nucleus is observable within them, and rarely they exhibit amœboid movements (Fig. 234, *c*, *d*, *e*). The regular secretion of milk begins after three to four days. It was formerly supposed that the cells of the acini underwent a fatty degeneration, and thus produced the fatty granules of the milk. It is more probable, from recent observations, that the cells of the acini manufacture the fatty granules, and their protoplasm eliminates them, at the same time forming the clear fluid part of the milk.

Changes during Secretion.—Pratsch and Heidenhain found that the secretory cells in the **non-secreting gland** (Fig. 234, I) were flat, polyhedral and uni-nucleated, while the **secreting cells** (Fig. 234, II) often contained several nuclei, were more albuminous, higher, and cylindrical in form. The edge of the cell directed toward the lumen of the acinus undergoes characteristic changes during secretion. Fatty granules are formed in this part of the cell, and are afterward extruded. The decomposed portion of the cell is dissolved in the milk, and the fatty granules become free as milk globules (Fig. 234, II, *a*). If nuclei are present in that part of the cell which is broken up, they also pass into the milk and give rise to the presence of nuclein in the secretion.

Besides the milk globules and colostrum corpuscles, Rauber has found leucocytes undergoing fatty

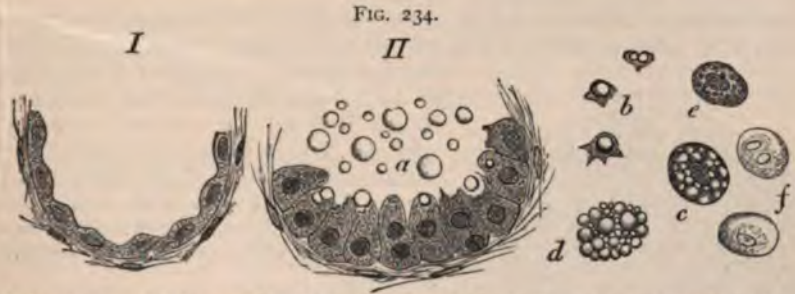
degeneration and single pale cells (*f*). Occasionally milk globules are found with traces of the cell substance adhering to their surface (*b*).

Formation of Milk.—Concerning the formation of the **individual constituents** of milk, H. Thierfelder, who digested fresh mammary glands directly after death, found that during the digestion of the glands, at the temperature of the body, a reducing substance, probably **lactose**, was formed by a process of fermentation. The mother substance (saccharogen) is soluble in water, but not in alcohol or ether, is not destroyed by boiling, and is not identical with glycogen. The ferment which forms the lactose is connected with the gland cells—it does not pass into the milk, nor into a watery extract of the gland. During the digestion of the mammary glands at the temperature of the body, **casein** is formed, probably from serum albumin, by a process of fermentation. This ferment occurs in the milk.

The **nipple** and its **areola** are characterized by the presence of pigment—more abundant during pregnancy—in the rete Malpighii of the skin, and by large papillæ in the cutis vera. Some of the papillæ contain touch corpuscles. Numerous non-striped muscular fibres surround the milk ducts in the deep layers of the skin and in the subcutaneous tissue, which contains no fat. These muscular fibres can be traced, following a longitudinal course, to the termination of the ducts on the surface. The small *glands of Montgomery*, which occur on the areola during lactation, are just small milk glands, each with a special duct opening on the surface of the elevation.

Arteries proceed from several sources to supply the mamma, but their branches do not accompany the milk ducts; each gland acinus is surrounded by a network of *capillaries*, which communicate with those of adjoining acini by small arteries and veins. The veins of the areola are arranged in a circle (circulus Halleri). The **nerves** are derived from the supraclavicular, and the II–IV–VI intercostals; they proceed to the skin over the gland, to the very sensitive nipple, to the blood vessels and non-striped muscle of the nipple, and to the gland acini, where their mode of termination is still

FIG. 234.



I. Inactive acinus of the mamma. II. During the secretion of milk—*a*, *b*, milk globules; *c*, *d*, *e*, colostrum corpuscles; *f*, pale cells (bitch).

unknown. **Lymphatics** surround the alveoli, and they are often full. The milk appears to be prepared from the lymph contained in the lymphatics surrounding the acini.

The **comparative anatomy** of the mamma.—The rodents, insectivora, and carnivora have 10 to 12 teats, while some of them have only 4. The pachydermata and ruminantia have 2 to 4 abdominal teats, the whale has 2 near the vulva. The apes, bats, vegetable-feeding whales, elephants, and sloths have 2, like man. In the marsupials the tubes are arranged in groups, which open on a patch of skin devoid of hair without any nipple. The young animals remain within the mother's pouch, and the milk is expelled into their mouths by the action of a muscle—the compressor mammæ.

The **development** of the human mamma begins in both sexes during the third month; at the fourth and fifth months a few simple tubular gland ducts are arranged radially around the position of the future nipple, which is devoid of hair. In the new-born child the ducts are branched twice or thrice, and are provided with dilated extremities, the future acini. Up to the twelfth year, in both sexes, the ducts continue to divide dendritically, but without any proper acini being formed. In the girl at **puberty**, the ducts branch rapidly; but the acini are formed *only at the periphery* of the gland; during **pregnancy**, acini are also formed in the centre of the gland, while the connective tissue at the same time becomes somewhat more opened out. At the **climacteric period**, or menopause, all the acini and numerous fine milk ducts degenerate. In the *adult male*, the gland remains in the non developed infantile condition. Accessory or supernumerary glands upon the breast and abdomen are not uncommon; sometimes the mamma occurs in the axilla, on the back, over the acromion process, or on the leg. A slight secretion of milk in a newly-born infant is normal.

During the **evacuation of the milk** (500–1500 cubic centimetres daily), there is not only the mechanical action of **sucking**, but also the activity of the gland itself (§ 152). This consists in the erection of the nipple, whereby its non-striped muscular fibres compress the sinuses on the milk ducts, and empty them, so that the milk may flow out in streams. The gland acini are also excited to

secretion reflexly by the stimulation of the **sensory nerves** of the nipple. The vessels of the gland are dilated, and there is a copious transudation into the gland—the transuded fluid being manufactured into milk under the influence of the secretory protoplasm. The amount of secretion depends upon the blood pressure (*Röhrig*). During sucking, not only is the milk in the gland extracted, but new milk is formed, owing to the accelerated secretion. Emotional di-turbances—anger, fear, etc.—arrest the secretion. Laffont found that stimulation of the mammary nerve (bitch) caused erection of the teat, dilatation of the vessels, and secretion of milk. After section of the cerebro-spinal nerves going to the mamma, Eckhard observed that erection of the teat ceased, although the secretion of milk in a goat was not interrupted. The rarely observed **galactorrhœa** is perhaps to be regarded as a paralytic secretion analogous to the paralytic secretion of saliva. Heidenhain and Pratsch found that the secretion (bitch) was increased by injecting strychnine or curara after section of the nerves of the gland. The **"milk fever,"** which accompanies the first secretion of milk, probably depends on stimulation of the vasomotor nerves, but this condition must be studied in relation with the other changes which occur within the pelvic cavity after birth. [Some substances, such as atropin, arrest the secretion of milk.]

231. **MILK AND ITS PREPARATIONS.—Milk** represents a **complete** or **typical food** in which are present all the constituents necessary for maintaining the life and growth of the body of an infant (§ 236). [If an adult were to live on milk alone, to get the 23 oz. of dry solids necessary, he would have to take 9 pints of milk daily, which would give far too much water, fat, and proteids.] To every 10 parts of proteids there are 10 parts fat and 20 parts sugar. Relatively more of the fat than the albumin of the milk is absorbed (*Rubner*); while a part of both is excreted in the fæces.

Characters.—Milk is an opaque, bluish-white fluid with a sweetish taste and a characteristic odor, probably due to the peculiar volatile substances derived from the cutaneous secretions of the glands, and it has a specific gravity of 1026 to 1035. When it stands for a time, numerous milk globules, butter globules, or **cream**, collect on its surface, under which there is a bluish watery fluid. Human milk is always *alkaline*, cow's milk may be alkaline, acid, or amphoteric; while the milk of carnivora is always acid.

FIG. 235.

Microscopic appearance of milk, (M) upper half, and colostrum (C) lower half.

Milk Globules.—When milk is examined *microscopically*, it is seen to contain numerous small, highly refractive **oil globules**, floating in a clear fluid—the **milk plasma** (Figs. 234, *a*, *b*, 235); while colostrum corpuscles and epithelium from the milk ducts are not so numerous. The white color and opacity of the milk are due to the presence of the milk globules, which reflect the light; the globules consist of a fat, or butter, and are said by some to be surrounded with a very thin envelope of *casein* or haptogen membrane.

If acetic acid be added to a microscopic preparation of milk, the fatty granules run together to form irregular masses. If cow's milk be shaken with caustic potash, the casein envelopes are dissolved, and if ether be added, the milk becomes clear and transparent, as the ether dissolves out all the fatty particles in the solution. Ether cannot extract the fat from cow's milk until acetic acid or caustic potash is added to liberate the fats from their envelopes; but shaking with ether is sufficient to extract the fats from human milk. Some observers deny that an envelope of casein exists, and according to them milk is a simple emulsion, kept emulsionized owing to the colloid swollen-up casein in the milk plasma. The treatment of milk with potash and ether makes the casein unable any longer to preserve the emulsion (*Soxhlet*).

The **fats of the milk globules** are the triglycerides of stearic, palmitic, oleic (very little), myristic, arachinic (butinic), capric, caprylic, caproic, and butyric acids, with traces of acetic and formic acids and cholesterin.

Butter.—When milk is beaten or stirred for a long time (*i.e.*, churned), the fat of the milk globules is ultimately obtained in the form of *butter*, owing to the rupture of the envelopes of casein. Butter is soluble in alcohol and ether, and it is clarified by heat (60° C.), or by washing in water at 40° C. When allowed to stand exposed to the air, it first becomes **sour**, owing to the formation of lactic acid, and afterward **rancid**, owing to the glycerine of the neutral fats being decomposed by fungi into acrolein, and formic acid, while the volatile fatty acids give it its rancid odor.

The **milk plasma**, obtained by filtration through a clay filter or membranes, is a clear, slightly opalescent fluid, and contains **casein** (§ 249, III, 3), some **serum albumin** (§ 32), **peptone** (0.13 per cent.), **nuclein**, and a trace of diastatic ferment (in human milk).

The presence of other peculiar chemical bodies, *e.g.*, lactoprotein, globulin, albumose, galactin, etc., is disputed by some chemists.

When milk is **boiled** the albumin coagulates, while the surface also becomes covered with a thin scum or layer of casein, which has become insoluble [the rest of the milk remaining fluid].

Casein.—When milk is filtered through fresh animal membranes or through a clay filter, the *casein* does not pass through. **Precipitation.**—It is precipitated by adding crystals of $MgSO_4$ to saturation. [If to milk twice its volume of a saturated solution of NaCl and crystals of NaCl be added, and the whole shaken thoroughly, casein is precipitated, and carries down with it fat, so that the clear filtrate contains the lactose, salts, and coagulable proteids.]

The plasma contains **milk sugar** (§ 252); a carbohydrate resembling dextrin, (? lactic acid), lecithin, urea, extractives, kreatin, sarkin (potassic sulphocyanide in cow's milk), sodic and potassic chlorides, alkaline phosphates, calcium and magnesium sulphates, alkaline carbonates, traces of iron, fluorine, and silica, CO_2, N, and O.

The **coagulation of milk** *depends upon the coagulation of its casein.* In milk, casein is combined with calcium phosphate, which keeps it in solution; acids which act on the calcium phosphate cause coagulation of the casein (acetic and tartaric acids in excess redissolve it). All acids do not coagulate human milk. It is coagulated by two or more drops of hydrochloric acid (0.1 per cent.) or acetic acid (0.2 per cent.). The *spontaneous* coagulation of milk after it has stood for a time, especially in a warm place, is due to the production of **lactic acid**, which is formed from the milk sugar in the milk by the action of **bacillus acidi lactici** [which is introduced from without] (§ 184, I). It changes the neutral alkaline phosphate into the acid phosphate, takes the casein from the calcium phosphate, and precipitates the casein. The sugar is decomposed into lactic acid and CO_2.

Rennet (§ 250, 9, *d*, § 166, II) coagulates milk with an *alkaline* reaction (sweet whey). This ferment *decomposes the casein* into the precipitated cheese and also into the slightly soluble whey albumin, so that the coagulation by rennet is a process quite distinct from the coagulation of milk by the gastric and pancreatic juices, [and also from the precipitation produced by acids. The presence of calcium phosphate seems to be necessary for the complete action of the rennet (*Hammarsten*)].

[**Experiments.**—Warm a little milk to 40° C., and add a few drops of commercial rennet, setting aside the mixture in a warm place; a solid coagulum is then formed, and by and by the whey separates from it. If the milk be previously diluted with water, no coagulum is formed; and if the rennet be boiled before, it, like other ferments, is destroyed. A solution of rennet may be prepared by extracting the fourth stomach of the calf with glycerine. [When the milk is coagulated we obtain the **curd**, consisting of casein with some milk globules entangled in it; the **whey** contains some soluble albumin and fat, and the great proportion of the salts and milk sugar, together with lactic acid.]

[A **milk-coagulating ferment** is found in certain plants (artichokes, figs, Carica papaya), and causes milk to coagulate in neutral or alkaline solutions. It is also found in the small intestine of the calf, while a 5 per cent. NaCl solution of the seeds of *Withania coagulans* coagulates milk in an alkaline medium.]

Boiling (by killing all the lower organisms), sodium bicarbonate ($\frac{1}{1000}$), ammonia, salicylic acid ($\frac{1}{2000}$), glycerine, and ethereal oil of mustard prevent the spontaneous coagulation. Fresh milk makes tincture of guaiacum blue, but boiled milk does not do so. When milk is exposed to the air for a long time, it gives off CO_2 and absorbs O; the fats are increased (? owing to the development of fungi in the milk), and so are the alcoholic and ethereal extracts, from the decomposition of the casein. According to Schmidt-Mülheim, some of the casein becomes converted into peptone, but this occurs only in unboiled milk.

Composition.—100 parts of milk contain—

	Human.		Cow.	Goat.	Ass.
Water,	87.24 to 90.58		86.23	86.85	89.01
Solids,	9.42 " 12.39		13.77	13.52	10.99
Casein,	2.91 " 3.92	1.90 to 2.36	3.23	2.53	3.57
Albumin,	... ...		0.50	1.26	
Butter,	2.67 " 4.30		4.50	4.34	1.85
Milk sugar,	3.15 " 6.09		4.93	3.78	5.05
Salts,	0.14 " 0.28		0.61	0.65	

Human milk contains less albumin, which is more soluble than the albumin in the milk of animals.

Colostrum contains much serum-albumin, and very little casein, while all the other substances, and especially the fats, are more abundant.

Gases.—Pflüger and Setschenow found in 100 vols. of milk 5.01 to 7.60 CO_2; 0.09 to 0.32 O; 0.70 to 1.41 N, according to volume. Only part of the CO_2 is expelled by phosphoric acid.

Salts.—The *potash salts* (as in blood and muscle) are more abundant than the soda compounds, while there is a considerable amount of calcium phosphate, which is necessary for *forming the bones* of the infant. Wildenstein found in 100 parts of the **ash** of human milk—sodium chloride, 10.73; potassium chloride, 26.33; potash, 21.44; lime, 18.78; magnesia, 0.87; phosphoric acid, 19; ferric phosphate, 0.21; sulphuric acid, 2.64; silica, traces. The amount of salts present is affected by the salts of the food.

Conditions Influencing the Composition.—The oftener the breasts are *emptied*, the richer the milk becomes in casein. The last milk obtained at any time is always richer in butter, as it comes from the most distant part of the gland—viz., the acini. Some substances are diminished and others increased in amount, according to the *time after delivery*. The following are *increased:* Until the second month after delivery, casein and fat; until the 5th month, the salts (which diminish progressively from this time onward); from the 8th to the 10th month, the sugar. The following are *diminished:* From 10th to 24th month, casein; from 5th to 6th and 10th to 11th month, fat; during 1st month, the sugar; from the 5th month, the salts.

The greater the amount of milk that is secreted (woman), the more casein and sugar, and the less butter it contains. The milk of a primipara is less watery. Rich feeding, especially proteids (small amount of vegetable food), increases the amount of milk and the casein, sugar and fat in it; a large amount of carbohydrates (not fats) increases the amount of sugar.

[**Modifying Conditions.**—That cow's milk is influenced by the pasture and food is well known. Turnip as food gives a peculiar odor, taste, and flavor to the milk, and so do the fragrant grasses. The mental state of the nurse influences the quantity and quality of the milk. Jaborandi is the nearest approach to a galactagogue, but its action is temporary. Atropin is a true anti-galactagogue. The composition of the milk may be affected by using fatty food, by the use of salts, and above all by the diet (*Dolan*).]

[Milk may be a **vehicle for communicating disease**—by direct contamination, from the water used for adulterating it or cleansing the vessels in which it is kept; by the milk absorbing deleterious gases; by the secretion being altered in diseased animals.] Milk ought not to be kept in zinc vessels, owing to the formation of zinc lactate.

Substitutes.—If other than human milk has to be used, ass's milk most closely resembles human milk. Cow's milk is best when it contains plenty of fatty matters—it must be diluted with its own volume of water at first, and a little milk sugar added. The casein of cow's milk differs qualitatively from that of human milk; its coagulated flocculi or curd are much coarser than the fine curd of human milk, and they are only ¾ dissolved by the digestive juices, while human milk is completely dissolved. Cow's milk when boiled is less digestible than unboiled.

Tests for Milk.—The **amount of cream** is estimated by placing the milk for twenty-four hours in a tall cylindrical glass graduated into a hundred parts, or **creamometer**; the cream collects on the surface, and ought to form from 10 to 24 vols. per cent. [The cream is generally about $\frac{8}{100}$.] The specific gravity (fresh cow's milk, 1029 to 1034; when creamed, 1032 to 1040) is estimated with the **lactometer** at 15° C. The **sugar** is estimated by titration with Fehling's solution (§ 150, II), but in this case 1 cubic centimetre of the solution corresponds to 0.0067 grm. of milk sugar; or its amount may be estimated with the *polariscopic apparatus* (§ 150). The **proteids** are precipitated and the fats extracted with ether. The fats in fresh milk form about 3 per cent., and in skimmed milk 1½ per cent. The amount of **water** in relation to the milk globules is estimated by the **lactoscope** or the **diaphanometer** of Donné (modified by Vogel and Hoppe-Seyler), which consists of a glass vessel with plane parallel sides placed 1 centimetre apart. A measured quantity of milk is taken, and water is added to it from a burette until the outline of a candle flame placed at a distance of 1 metre can be distinctly seen through the diluted milk. This is done in a dark room For 1 cubic centimetre of good cow's milk, 70 to 85 centimetres water are required. [Other forms of lactoscope are used, all depending on the same principle of an optical test, viz., that the opacity of milk varies with and is proportional to the amount of butter-fats present, *i.e.*, the oil globules. Bond uses a shallow cylindrical vessel with the bottom covered by black lines on a white surface. A measured

quantity of water is placed in this vessel, and milk is added, drop by drop, until the parallel lines on the pattern at the bottom of the dish cease to be visible. On counting the number of drops, a table accompanying the appliance gives the percentage of fats. This method gives approximate results. In all cases it is well to use fresh milk.]

Various substances pass into the milk *when they are administered to the mother*—many odoriferous vegetable bodies, *e.g.*, anise, vermuth, garlic, etc.; chloral, rhubarb, opium, indigo, salicylic acid, iodine, iron, zinc, mercury, lead, bismuth, antimony. In osteomalacia the amount of lime in the milk is increased (*Gusserow*). Potassium iodide diminishes the secretion of milk by affecting the secretory function. Among **abnormal constituents** are—hæmoglobin, bile pigments, mucin, blood corpuscles, pus, fibrin. Numerous fungi and other low organisms develop in evacuated milk, and the rare *blue* milk is due to the development of bacillus cyanogenēum. The milk serum is blue, not the fungus. Blue milk is unhealthy, and causes diarrhœa. There are fungi which make milk *bluish-black* or *green*. *Red* and *yellow* milk are produced by a similar action of chromogenic fungi (§ 184). The former is produced by Micrococcus prodigiosus, which is colorless. The color seems to be due to fuchsin. The yellow color is produced by bacillus synxanthus. Some of the pigments seem to be related to the aniline and others to the phenol coloring matters (*Hüppe*).

The **rennet-like action of bacteria** is a widely diffused property of these organisms; they coagulate and peptonize casein and may ultimately produce further decompositions. The butyric acid bacillus (§ 184) first coagulates casein, then peptonizes it, and finally splits it up, with the evolution of ammonia (*Hüppe*)

Milk becomes *stringy* owing to the action of cocci which form a stringy substance [= *dextran*, $C_{12}H_{10}O_{10}$ (*Scheibler*)], just as beer or wine undergoes a similar or ropy change. [The milk of diseased animals may contain or transmit directly infectious matter.]

Preparations of Milk.—(1) **Condensed milk**—80 grms. cane sugar are added to 1 litre of milk; the whole is evaporated to $\frac{1}{3}$; and while hot sealed up in tin cans. For children one teaspoonful is dissolved in a pint of cold water, and then boiled.

(2) **Koumiss** is prepared by the Tartars from mare's milk. After the addition of koumiss and sour milk, the whole is violently stirred, and it undergoes the alcoholic fermentation, whereby the milk sugar is first changed into galactose, and then into alcohol; so that koumiss contains 2 to 3 per cent. of alcohol; while the casein is at first precipitated, but is afterwards partly re-dissolved and changed into acid albumin and peptone. Tartar koumiss seems to be produced by the action of a special bacterium (Diaspora caucasia).

(3) **Cheese** is prepared by coagulating milk with rennet, allowing the whey to separate, and adding salt to the curd. When kept for a long time cheese "**ripens**," the casein again becomes soluble in water, probably from the formation of soda albuminate; in many cases it becomes semi-fluid, when it takes the characters of peptones. When further decomposition occurs, leucin and tyrosin are formed. The fats increase at the expense of the casein, and they again undergo further change, the volatile fatty acids giving the characteristic odor. The formation of peptone, leucin, tyrosin, and the decomposition of fat recall the digestive processes. [Cheese is coagulated casein entangling more or less fat, so that the richness of the cheese will depend upon the kind of milk from which it is made. There are, in this sense, three kinds of cheese, *whole milk*, *skimmed milk*, and *cream* cheese, the last being represented by Stilton, Roquefort, Cheshire, etc. The composition is shown in the following table, after Bauer:—

	Water.	Nitrogenous Matter.	Fat.	Extractives.	Ash.
Cream cheese, . .	35.75	7.16	30.43	2.53	4.13
Whole milk, . . .	46.82	27.62	20.54	2.97	3.05
Skim milk, ...	48.02	32.65	8.41	6.80	4.12

Cream cheese, especially if it be made from goat's milk, acquires a very high odor and strong flavor when it is kept and "**ripens**"; the casein is partly decomposed to yield ammonia and ammonium sulphide, while the fats yield butyric, caproic, and other acids]

232. EGGS must be regarded as a complete food, as the organism of the young chick is developed from them. The **yolk** contains a characteristic proteid body—*vitellin* (§ 249), and an *albuminate* in the envelopes of the yellow yolk spheres—*nuclein*, from the white yolk; *fats* in the yellow yolk (palmitin, olein), cholesterin, much *lecithin*; and as its decomposition product, glycerin-phosphoric acid—*grape sugar*, *pigments* (lutein), and a body containing iron and related to hæmoglobin;

lastly, *salts* qualitatively the same as in blood—quantitatively as in the *blood corpuscles*—and *gases*. The chief constituent of the **white of egg** is *egg albumin* (§ 249), together with a small amount of palmitin and olein partly saponified with soda; grape sugar, extractives; lastly salts, qualitatively resembling those of blood, but quantitatively like those of *serum*, and a trace of fluorine. Relatively more of the nitrogenous constituents than of the fatty constituents of eggs are absorbed (*Rubner*).

[The **shell** is composed chiefly of mineral matter (91 per cent. of calcic carbonate, 6 per cent. of calcic phosphate, and 3 per cent. of organic matter.) A hen's egg weighs about 1¾ oz., of which the shell forms about $\frac{1}{10}$. Note the amount of **fats** in the yolk.]

Composition :—

	White of Egg.	Yolk.
Water,	84.8	51.5
Proteids,	12.0	15.0
Fats, etc.,	2.0	30.0
Mineral matter,	1.2	1.4
Pigment extractives,	...	2.1

233. **FLESH AND ITS PREPARATIONS.—Flesh**, in the form in which it is eaten, contains in addition to the muscle substance proper, more or less of the elements of fat, connective and elastic tissue mixed with it (§ 293). The following results refer to flesh freed as much as possible from those constituents. The chief proteid constituent of the contractile muscular substance is **myosin**; *serum albumin* occurs in the fluid of the fibres, in the lymph and blood of muscle. The *fats* are for the most part derived from the interfascicular fat cells, while *lecithin* and *cholesterin* come from the nerves of the muscles; the *gelatin* is derived from the connective tissue of the perimysium, perineurium, and the walls of blood vessels and tendons. The *red color* of the flesh is due to the hæmoglobin present in the sarcous substance, but in some muscles, *e. g.*, the heart, there is a special pigment, myohæmatin (*MacMunn*). *Elastin* occurs in the sarcolemma, neurilemma, and in the elastic fibres of the perimysium and walls of the vessels; the small amount of *keratin* is derived from the endothelium of the vessels. The chief muscular substance, the result of the retrogressive metabolism of the sarcous substance, is *kreatin* (—0.05 per cent.); *kreatinin*, the inconstant *inosinic acid*, then lactic, or rather *sarcolactic acid* (§ 293). Further, *taurin*, *sarkin*, *xanthin*, *uric acid*, *carnin*, *inosit* (most abundant in the muscles of drunkards), *urea* (0.1 per cent.) *dextrin* (in horse or rabbit, not constant); *grape sugar*, but this is very probably derived *post-mortem* from glycogen (0.43 per cent.), which occurs in considerable amount in fœtal muscles; lastly *fatty acids*. Among the **salts**, potash and phosphoric acid compounds are most abundant; magnesium phosphate exceeds calcium phosphate in amount. [The composition varies somewhat even in different muscles of the same animal.]

In 100 parts **Flesh** there are, according to Schlossberger and v. Bibra—

	Ox.	Calf.	Deer.	Pig.	Man.	Fowl.	Carp.	Frog.
Water	77 50	78.20	74.63	78 30	74.45	77.30	79.78	80.43

Carbonic "	...	8.02	...	...
Ammonia,	...	0.15	...	...

The **amount of fat** in flesh varies very much according to the condition of the animal. After removal of the visible fat, human flesh contains 7.15; ox, 11.12; calf, 10.4; sheep, 3.9; wild goose, 8.8; fowl, 2.5 per cent.

The amount of **extractives** is most abundant in those animals which exhibit energetic muscular action; hence it is largest in wild animals. The extract is increased after vigorous muscular action, whereby sarcolactic acid is developed, and the flesh becomes more tender and is more palatable. Some of the extractives excite the nervous system, *e. g.*, kreatin and kreatinin; and others give to flesh its characteristic agreeable flavor ["osmasome,"] but this is also partly due to the different fats of the flesh, and is best developed when the flesh is cooked. The extractives in 100 parts of flesh are, in man and pigeon, 3; deer and duck, 4; swallow, 7 per cent.

Cooking of Flesh.—As a general rule, the flesh of *young* animals, owing to the sarcolemma, connective tissue, and elastic constituents being less tough, is more tender and more easily digested than the flesh of old animals; after flesh has been kept for a time it is more friable and tender, as the inosit becomes changed into sarcolactic acid and the glycogen into sugar, and this again into lactic acid, whereby the elements of flesh undergo a kind of maceration. Finely divided flesh is more digestible than when it is eaten in large pieces. In cooking meat, the heat ought not to be too intense, and ought not to be continued too long, as the muscular fibres thereby become hard and shrink very much. Those parts are most digestible which are obtained from the centre of a roast where they have been heated to 60° to 70° C., as this temperature is sufficient, with the aid of the acids of the flesh, to change the connective tissue into gelatin, whereby the fibres are loosened, so that the gastric juice readily attacks them. In roasting beef, apply heat suddenly at first, to coagulate a layer on the surface, which prevents the escape of the juice.

Meat Soup is best prepared by cutting the flesh into pieces and placing them for several hours in cold water, and afterward boiling. Liebig found that 6 parts per 100 of ox flesh were dissolved by cold water. When this cold extract was boiled, 2.95 parts were precipitated as coagulated albumin, which is chiefly removed by "skimming," so that only 3.05 parts remain in solution. From 100 parts of flesh of fowl, 8 parts were extracted, and of these 4.7 was coagulated and 3.3 remained dissolved in the soup. By boiling for a very long time, part of the albumin may be redissolved. The dissolved substances are: (1) Inorganic salts of the meat, of which 82.27 per cent. pass into the soup; the earthy phosphates chiefly remain in the cooked meat. (2) Kreatin, kreatinin, the inosinates and lactates which give to broth or beef tea their stimulating qualities, and a small amount of aromatic extractives. (3) Gelatin, more abundantly extracted from the flesh of young animals. According to these facts, therefore, flesh broth or beef-tea is a powerful stimulant, supplying muscle with re-toratives, but is not a food in the ordinary sense of the term, as kreatin in general leaves the body unchanged (*v. Voit*). The flesh, especially if it be cooked in a large mass, after the extraction of the broth is still available as a food.

Liebig's Extract of Meat is an extract of flesh evaporated to a thick syrupy consistence. It contains no fat or gelatin, and is chiefly a solution of the extractives and salts of flesh.

[**Extract of Fish.**—A similar extract is now prepared from fish, and such extract has no fishy flavor, but presents much the same appearance, odor, and properties as extract of flesh.]

234. **VEGETABLE FOODS.**—The nitrogenous constituents of plants are not so easily absorbed as animal food (*Rubner*). Carbohydrates, starch, and sugar are very completely absorbed, and even a not inconsiderable proportion of cellulose may be digested. The more fats that are contained in the vegetable food, the less are the carbohydrates digested and absorbed.

1. The **cereals** are most important vegetable foods; they contain proteids, starch, salts, and water about 14 per cent. The nitrogenous body **glutin** is most abundant under the husk (Fig. 236, *c*). The use of whole meal containing the outer layers of the grain is highly nutritive, but bread containing much bran is somewhat indigestible (*Rubner*). Their composition is the following:—

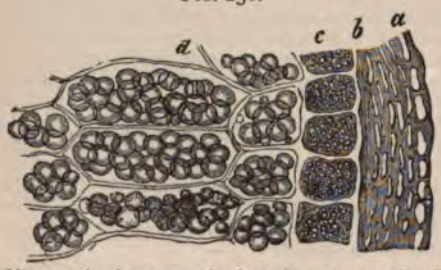
100 Parts of the Dry Meal contain			100 Parts of Ash contain		
Of	Albumin.	Starch.	Red Wheat.		White Wheat.
Wheat, ...	16.52%	56.25%	27.87	**Potash,**	33.84
Rye, ...	11.92	60.91	15.75	Soda, ...	...
Barley, ...	17.70	38.31	1.93	Lime, ...	3.09
Maize, ...	13.65	77.74	9.60	Magnesia	13.54
Rice, ...	7.40	86.21	1.36	Iron oxide	0.31
Buckwheat, . . .	6.8–10.5	65.05	49.36	**Phosphoric Acid,**	59.21
			0.13	Silica, ...	...

It is curious to observe that soda is absent from white wheat, its place being taken by other alkalies. Rye contains more cellulose and dextrin than wheat, but less sugar; rye bread is usually less porous.

[**Oatmeal** contains more nitrogenous substances (gliadin and glutin-casein) than wheaten flour, but owing to the want of adhesive properties it cannot be made into bread. The amount of fat and salts is large.]

In the preparation of bread the meal is kneaded with water until dough is formed, and to it is added salt and *yeast* (Saccharomycetes cerevisiæ). When placed in a warm oven, the proteids of the meal begin to decompose and act as a ferment upon the swollen-up starch, which becomes in part changed into sugar. The sugar is further decomposed into CO_2 and alcohol, the CO_2 forms bubbles, which cause the bread to "rise" and thus become spongy and porous. The alcohol is driven off by the baking (200°), while much soluble dextrin is formed in the crust of the bread. [But CO_2 may be set free within the dough by chemical means, without yeast or leaven, thus forming **unfermented bread.** This is done by mixing with the dough an alkaline carbonate and then adding an acid. Baking powders consist of carbonate of soda and tartaric acid. In Daughlish's process for **aerated** bread, the CO_2 is forced into water, and a dough is made with this water under pressure, and when the dough is heated, the CO_2 expands and forms the spongy bread. Bread as an article of food is deficient in N, while it is poor in fats and some salts. Hence the necessity for using some form of fat with it (butter or bacon).]

FIG. 236.



Microscopic characters of wheat (+ 200). *a*, cells of the bran; *b*, cells of thin cuticle; *c*, glutin cells; *d*, starch cells.

2. The **pulses** contain **much albumin**, *especially* **legumin**; together with starch, lecithin, cholesterin, and 9 to 19 per cent. water. Peas contain 18.02 proteids, and 34.81 starch; beans 28.54, and 37.50; lentils, 29.31, and 40, and more cellulose. Owing to the absence of glutin they do not form dough, and bread cannot be prepared from them. On account of the large amount of proteids which they contain, they are admirably adapted as food for the poorer classes.

[3. The whole group of **farinaceous** substances used as "pudding stuffs," such as corn-flour, arrow-root, rice, hominy, are really very largely composed of starchy substances.]

4. **Potatoes** contain 70 to 81 per cent. water. In the fresh juicy cellular tissue, which has an acid reaction, from the presence of phosphoric, malic, and hydrochloric acids, there is 16 to 23 per cent. of starch, 2.5 soluble albumin, globulin, and a trace of asparagin. The envelopes of the cells swell up by boiling, and are changed into sugar and gums by dilute acids. The poisonous solanin

occurs in the sprouts. In 100 parts of *potato ash*, May found 49.96 potash, 2.41 sodium chloride, 8.11 potassium chloride, 6.50 sulphuric acid derived from burned proteids, 7.17 silica.

5. In **fruits** the chief nutrient ingredients are sugar and salts; the organic acids give them their characteristic taste; the gelatinizing substance is the soluble so-called **pectin** ($C_{32}H_{48}O_{32}$), which can be prepared artificially by boiling the very insoluble pectose of unripe fruits and mulberries.

6. **Green Vegetables** are especially rich in salts, which resemble the salts of the blood; thus, dry salad contains 23 per cent. of salts, which closely resemble the salts of the blood. Of much less importance are the starch, cell substance, dextrin, sugar, and the small amount of albumin which they contain.

[Vegetables are chiefly useful for the salts they contain, while many of them are **antiscorbutic.** Their value is attested by the serious defects of nutrition, such as scurvy, which result when they are not supplied in the food. In Arctic expeditions and in the navy, lime juice is served out as an anti-scorbutic.]

[**Preserved Vegetables.**—The dried and compressed vegetables of Messrs. Chollet & Company are an excellent substitute for fresh vegetables, and are used largely in naval and military expeditions.]

[**Utilization of Food.**—As regards what percentage of the food swallowed is actually absorbed, we know that, stated broadly, vegetable food is assimilated to a much less extent than animal food in man. Fr. Hofmann gives the following table as showing this:—

Weight of Food.	Vegetable.		Animal.	
	Digested.	Undigested.	Digested.	Undigested.
Of 100 parts of solids, ...	75 5	24.5	89 9	11.1
" 100 " albumin, ...	46.6	53.4	81.2	18.8
" 100 " fats or carbohydrates, . .	90 3	9.7	96.9	3.1]

[The following table, abridged from Parkes, shows the composition of the chief articles of diet, and is also used for calculating diet tables:—

Articles.	Water.	Proteids.	Fats.	Carbo-hydrates.	Salts.
Beef steak, ...	74.4	20.5	3.5	...	1.6

Sugar, ...	3.0	...	...	96.5	0.5]

235. **CONDIMENTS, COFFEE, TEA, ALCOHOL.**—Some substances are used along with food, not so much on account of their nutritive properties as on account of their stimulating effects and agreeable qualities, which are exerted partly upon the organ of taste and partly upon the nervous system. These are called **condiments.**

Coffee, Tea, and **Chocolate** are prepared as infusions of certain vegetables [the first of the roasted berry, the second of the leaves, and the third of the seeds.] Their chief active ingredients are respectively **caffein, thein** ($C_8H_{10}N_4O_2 + H_2O$), and **theobromin** ($C_7H_8N_4O_2$), which are regarded as alkaloids of the vegetable bases, and which have recently been prepared artificially from xanthin (*E. Fischer*). [**Guarana,** or Brazilian cocoa, is made of the seeds ground into a paste in the form of a sausage. **Maté** or Paraguay tea (the leaves of a species of holly) is used in South America, and so also is the **coca** of the Andes (Erythroxylon Coca).] These "alkaloids" occur as such in the plants containing them; they behave like ammonia; they have an alkaline reaction, and form crystalline salts with acids. All these vegetable bases act upon the nervous system; some more feebly (as the above), others more powerfully (quinine); some stimulate powerfully, or completely paralyze (morphia, atropin, strychnin, curarin, nicotin).

Effects.—All these substances act on the nervous system; they quicken thought, accelerate movement, and stir one to greater activity. In these respects they resemble the stimulating extractives of beef tea. Coffee contains about ⅓ per cent. of caffein, part of which only is liberated by the act of roasting. Tea has 6 per cent. of thein; while green tea contains 1 per cent. ethereal oil, and black tea ½ per cent.; in green tea there is 18 per cent., in black 15 per cent. tannin; green tea yields about 46 per cent., and the black scarcely 30 per cent. of extract. The **inorganic salts** present are also of importance; tea contains 3.03 per cent. of salts, and among these are soluble compounds of iron, manganese, and soda salts. In coffee, which yields 3.41 per cent. of ash, potash salts are most abundant; in all three substances the other salts which occur in the blood are also present.

Alcoholic drinks owe their action chiefly to the **alcohol** which they contain. Alcohol, when taken into the body, undergoes certain changes and produces certain effects: (1) About 95 per cent. of it is oxidized chiefly into CO_2 and H_2O, so that it is so far a source of heat. As it undergoes this change very readily when taken to a certain extent, it may act as a substitute for the consumption of the tissues of the body, especially when the amount of food is insufficient. [Hammond found that when he lived on an insufficient amount of food, alcohol, if given in a certain quantity, supplied the place of the deficiency of food, and he even gained in weight. If, however sufficient food was taken, alcohol was unnecessary. As it interferes with oxidation, and where there is a sufficient amount of other food, in health, it is unnecessary, for dietetic reasons.] Small doses diminish the decomposition of the proteids to the extent of 6 to 7 per cent. Only a very small part of the alcohol is excreted in the urine; the odor of the breath is not due to alcohol, but to other volatile substances mixed with it, *e. g.*, fusel oil, etc. (2) In small doses it excites, while in large doses it paralyzes the nervous system. By its stimulating qualities it excites to greater action, which, however, is followed by depression. (3) It diminishes the sensation of hunger. (4) It excites the vascular system, accelerates the circulation, so that the muscles and nerves are more active, owing to the greater supply of blood. It also gives rise to a subjective feeling of warmth. In large doses, however, it paralyzes the vessels, so that they dilate, and thus much heat is given off (§ 213, 7; § 227). The action of the heart also becomes affected, the pulse becomes smaller, feebler, and more rapid. In high altitudes the action of alcohol is greatly diminished, owing to the diminished atmospheric pressure, whereby it is rapidly given off from the blood.

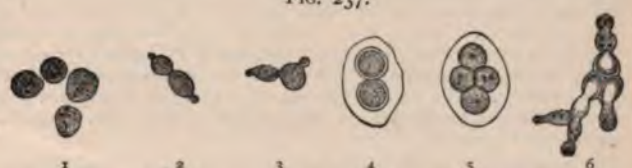
Alcohol in small doses is of great use in conditions of **temporary want,** and where the food taken is insufficient in quantity. When alcohol is taken regularly, more especially in large doses, it affects the nervous system, and undermines the physical and corporeal faculties, partly from the action of the impurities which it may contain, such as fusel oil, which has a poisonous effect upon the nervous

system, partly by the direct effects, such as catarrh and inflammation of the digestive organs, which it produces, and lastly, by its effect upon the normal metabolism.

[The action of alcohol in **lowering the temperature**, even in moderate doses, is most important. By dilating the cutaneous vessels, it thus permits of the radiating of much heat from the blood. When the action of alcohol is pushed too far, and especially when this is combined with the action of great cold, its use is to be condemned. Brunton has pointed out that, as regards its action on the **nervous system**, it seems to induce progressive paralysis, affecting the nervous tissues "in the inverse order of their development, the highest centres being affected first and the lowest last." The *judgment* is affected first, although the imagination and "emotions may be more than usually active." The *motor centres* and *speech* are affected, then the cerebellum is influenced, and afterward the cord, while by and by the centres essential to life are paralyzed, provided the dose be sufficiently large.]

Preparation.—Alcoholic drinks are prepared by the **fermentation** of various carbohydrates, such as sugar derived from starch. The alcoholic fermentation, such as occurs in the manufacture of beer, is caused by the development of the yeast plant, **Saccharomycetes cerevisiæ**; while in the fermentation of the grape (wine), S. Ellipsoideus is the species present (Fig. 237). The yeast takes the substances necessary for the maintenance of its organic processes directly from the mixture of the sugar, viz., carbohydrates, proteids and salts, especially calcium and potassium phosphates and magnesium sulphate. These substances undergo decomposition within the cells of the yeast plant, which multiply during the process, and there are produced alcohol and CO_2 (⅔ 150), together with glycerine (3.2 to 3.6 per cent.) and succinic acid 0.6 to 0.7 per cent.). Yeast is either added intentionally or it reaches the mixture from the air, which always contains its spores. When yeast is completely excluded, or if it be killed by boiling [or if its action be prevented by the presence of some germicide], the fermentation does not occur. The alcoholic fermentation is due to the activity of a low organism.

FIG. 237.



1, Isolated yeast cells; 2, 3, yeast cells budding; 4, 5, so-called endogenous formation of cells; 6, sprouting and formation of buds.

In the preparation of **brandy**, the starch of the grain or potatoes is first changed into sugar by the action of diastase or maltin. Yeast is added, and fermentation thereby produced; the mixture is distilled at 78.3°C. The fusel oil is prevented from mixing with the alcohol by passing the vapor through heated charcoal. The distillate contains 50 to 55 per cent. of alcohol.

In the preparation of **wine**, the saccharine juice of the grape — the **must** — after being expressed from the grapes, is exposed to the air at 10° to 15° C., and the yeast cells, which are floating about, drop into it and excite fermentation, which lasts 10 to 14 days, when the yeast sinks to the bottom. The clear wine is drawn off into casks, where it becomes turbid by undergoing an after-fermentation, until the sugar is converted into alcohol and CO_2, which is accompanied by the deposition of some yeast and tartar. If all the sugar is not decomposed—which occurs when there is not sufficient nitrogenous matter present to nourish the yeast—a *sweet wine* is obtained. Wine contains 89 to 90 per cent. water, 7 to 8 per cent. alcohol, together with æthylic, propylic, and butylic alcohol. The red color of some wines is due to the coloring matter of the skin of the grapes, but if the skins be removed before fermentation, red grapes yield white wine. When wine is stored, it develops a fine flavor or bouquet, The characteristic vinous odor is due to **œnanthic ether**. The *salts* of wine closely resemble the salts of the blood.

In the preparation of **beer** the grain is moistened, and allowed to germinate, when the temperature rises, and the starch (68 per cent. in barley) is changed into sugar. Thus "**malt**" is formed, which is dried, and afterward pulverized, and extracted with water at 70° to 75°, the watery extract being the "**wort.**" Hops are added to wort, and the whole is evaporated, when the proteids are coagulated. Hops give beer its bitter taste, and make it keep, while their tannic acid precipitates any starch that may be present, and clarifies the wort. After being boiled, it is cooled rapidly (12° C.); yeast is added, and fermentation goes on rapidly and with considerable effervescence at 10° to 14°. Beer contains 75 to 95 per cent. water; alcohol, 2 to 5 per cent. (porter and ale, to 8 per cent.); CO_2, 0.1 to 0.8 per cent.; sugar 2 to 8 per cent.; gum, dextrin, 2 to 10 per cent.; the hops yield traces of protein, fat, lactic acid, ammonia compounds, the salts of the grain and of the hops. In the **ash** there is a great preponderance of phosphoric acid and potash, both of which are of great importance for the formation of blood. In 100 parts of ash there are 40.8 potash, 20.0 phosphorus, magnesium phosphate 20, calcium phosphate 2.6, silica 16.6 per cent. The formation of blood, muscle, and other tissues from the consumption of beer is due to the phosphoric acid and potash, while if too much be taken, the potash produces fatigue.

Condiments are taken with food, partly on account of their taste, and partly because they excite secretion. Common salt, in a certain sense, is a condiment. We may also include many substances of unknown constitution which act upon the gustatory organs, *e. g.*, dextrin, and substances in the crust of bread and in meat which has been roasted.

236. EQUILIBRIUM OF THE METABOLISM.—By this term is meant that, under normal physiological conditions, just as much material is absorbed and assimilated from the food as is removed from the body by the excretory organs in the form of effete or end products, the result of the retrogressive tissue changes. The income must always balance the expenditure; wherever a tissue is used up, it must be replaced by the formation of new tissue. During the period of **growth**, the increase of the body corresponds to a certain increase of formation, whereby the metabolism of the growing parts of the body is 2.5 to 6.3 times greater than that of the parts already formed. Conversely, during senile **decay**, there is an excess of expenditure from the body.

Methods.—The normal equilibrium of the metabolism of the body is investigated (1) By determining chemically that the sum of all the substances passing into the body is equal to the sum of all the substances given off from it. Thus the C, N, H, O, salts and water of the food, and the O inspired, must be equal to the C, N. H, O, salts and water given off in the excreta (urine, fæces, air expired, water excreted). (2) The **physiological equilibrium** is determined empirically by observing that the body retains its normal weight with a given diet; so that, by simply weighing a person, a physician is enabled to determine exactly the state of convalescence of his patient. The tedious process of making an **elementary analysis** of the metallic substances was first undertaken in the Munich School by v. Bischoff, v. Voit, v. Pettenkofer, and others.

Circulation of C.—In the circulation of materials the total amount of C taken in the food, if the metabolism be in a condition of physiological equilibrium, must be equaled by the C in the CO_2 given off by the lungs and skin (90 per cent.), together with the relatively small amount of C in the organic excreta of the urine and fæces (10 per cent.).

Circulation of N.—*Nearly all the N* taken in with the food is excreted within twenty-four hours in the form of urea. A very small amount of nitrogenous matter is excreted in the fæces, while the other nitrogenous urinary constituents (uric acid, kreatinin, etc.) represent about 2 per cent. of N. A trace of the N is given off by the breath (§ 124), and a minute proportion in combination, in the epidermal scales (50 milligrammes daily in the hair and nails), and in the sweat.

Deficit of N.—That nearly all the N taken in the food reappears in the urine and fæces, as was stated by v. Voit to be the case in the carnivora and in the herbivora, and by v. Ranke in man, is contradicted partly by old and partly by new observations, which go to show that the whole of the N cannot be recovered from these excretions, but that on the contrary there is a considerable *deficit*.

According to Leo, only 0.55 per cent. of the albumin transformed within the body (assuming 15 per cent. N in albumin) gives off its N in the form of gaseous N (according to Seegen and Nowak, 12 times more). In every exact analysis of the metabolism of N this gaseous excretion of N must be taken into account.

The **excretion of N** after food does not take place regularly from hour to hour, but it increases at once and distinctly, reaches its maximum in five to six hours, and then gradually falls. The same is true of the excretion of **S** and **P**; but in these cases the maximum of excretion is reached at the fourth hour. When fat is added to a diet of flesh, the excretion of N and S is uniformly distributed over the individual hours of the day (*v. Voit and Feder*).

The nitrogenous constituents in the body during metabolism become poorer in C, and richer in N and O. Thus in **albumin** to 1 atom of N there are 4 atoms C; in **gelatin**, 3½ C; in **glycocoll**, 2 C; in **kreatin**, 1⅓ C; in **uric acid**, 1¼ C; in **allantoin**, 1 C; in **urea**, only ½ atom of C.

The **H** leaves the body chiefly in the form of **water**—a part, however, is in combination in other excreta; the **O** is chiefly excreted as CO_2 and water; a

little is given off in combination in other excreta; **water** is given off by evaporation from the lungs and skin, and also in the urine and fæces. As H is oxidized to H_2O, more water is excreted than is taken in. Most of the readily soluble **salts** are given off by the urine; the less soluble salts, especially those of potash, and the insoluble salts, in the fæces; while others are given off in the sweat. Of the **sulphur** of albumin, about one-half is excreted in the sulphur compounds in the urine, and the other half in the fæces (taurin) and in the epidermal tissues.

Every organism has a **minimum** and a **maximum limit** of **metabolism**, according to the amount of work done by the body, and its weight. If less food be given than is necessary to maintain the former, the body loses weight; while, if more be given after the maximum limit is reached, the food so given is not absorbed, but remains as a floating balance, and is given off with the fæces. When food is liberally supplied and the weight increases, of course the minimum limit rises; hence, during the process of "feeding" or "fattening," the amount of food necessary is very much greater than in poorly fed animals, for the same increase of the body weight. By continuing the process, a condition is at last reached in which the digestive organs are just sufficient to maintain the existing condition, but cannot act so as to admit of new additions being made to the body weight (*v. Bischoff, v. Voit, v. Pettenkofer*).

By the term "**luxus consumption**" is meant the direct combustion or oxidation of the superfluous food stuffs absorbed in the blood. This, however, does not exist; on the contrary, the material in the juices is always being used for building up the tissues. The albumin found in the fluids which everywhere permeate the tissues, has been called "**circulating albumin**," and according to v. Voit it undergoes decomposition sooner than the organized or "**organic albumin**" which forms an integral part of the tissue. According to v. Voit, in 24 hours 1 per cent. of the organic and 70 per cent. of the circulating albumin is used up.

[Liebig taught that the nitrogenous metabolism of the body depended on a corresponding decomposition of the proteids of the organs, so that the proteids in the food supplied the place of the proteids of the organs thus used up. He called the proteids "**plastic foods**" or "**tissue formers**," while he regarded the fats and carbohydrates as "**respiratory foods**," as he supposed that they alone were concerned in the evolution of heat. As a matter of fact, experiment proved that the N metabolism is to a large extent independent of the proteids of the food. The luxus-consumption theory was invented to explain this. It simply means, that proteids taken with the food not only replace the amount of proteids which have been decomposed during the activity of organs and tissues, but that any excess is immediately consumed without being converted into tissue, and thus this surplus amount giving rise to heat, by being oxidized, to a certain extent replaces the fats and carbohydrates. But Voit showed that the nitrogenous metabolism is not influenced by the activity of the organism, and he proved that in ordinary conditions only a small amount of the organic albumin, *i. e.*, that composing tissues and organs, undergoes decomposition, while, owing to the action of the cellular elements of the tissue, a large amount of the circulating albumin is split up, so that under ordinary conditions the organic albumin is comparatively stable. This he demonstrated from a comparison of the urea excreted, for the urea may be taken as an index of the N metabolism in well fed, fasting, and starving animals. But in certain **pathological conditions** the organic albumin may undergo rapid change, having become less stable, as in fevers, and poisoning with phosphorus.]

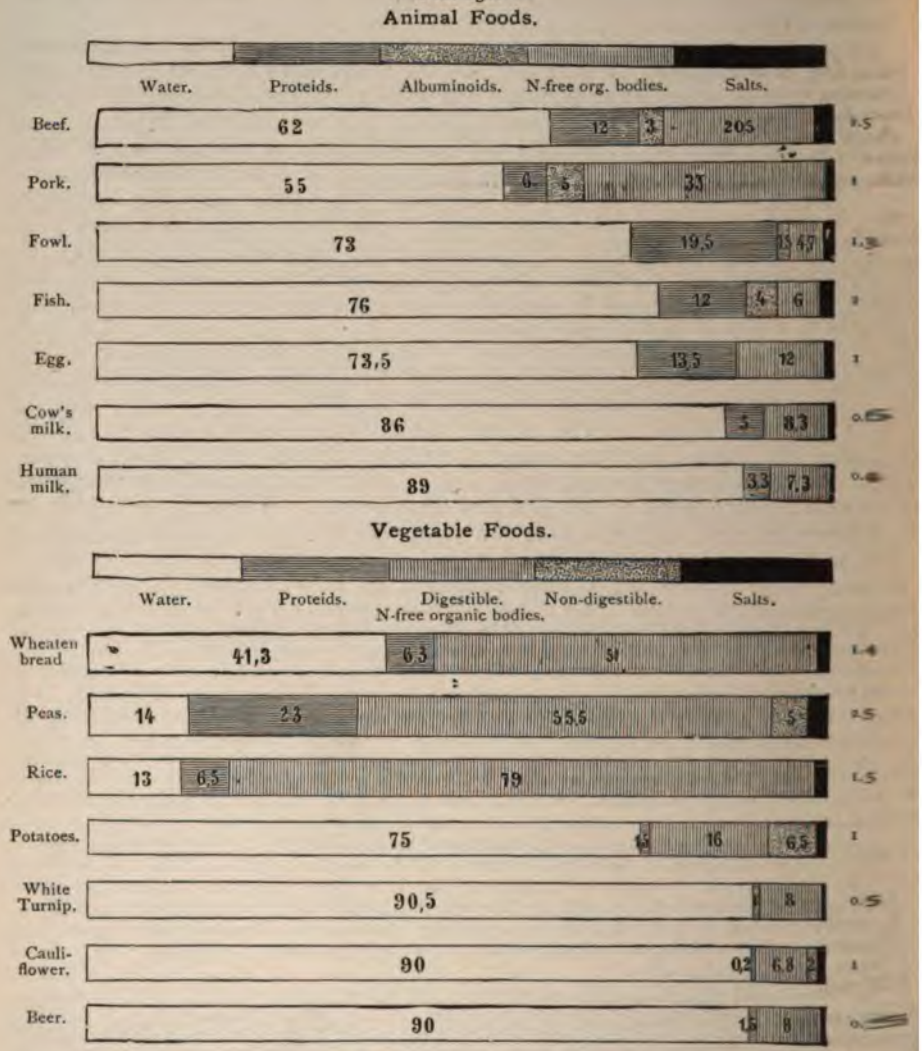
Quality and Quantity of the Diet.—As far as his organization is concerned, man belongs to the **omnivorous** animals, *i. e.*, those that can live upon a mixed diet. For an **adequate diet** man requires for his existence and to maintain health a mixture of the following **four** chief groups of food stuffs along with the necessary relishes; none of them must be absent from the food for any length of time. They are:—

1. **Water**—for an adult in his food and drink, 2700 to 2800 grms. [70 to 90 oz.] daily (§ 229 and § 247, 1).

[**Thirst.**—The needs of the economy for water are expressed by the sensation of thirst. The sensation of heat and dryness may be confined to the tongue, mouth and fauces, and indeed may be

excited by inhaling dry air. This **local** thirst may be allayed by swallowing water or by eating substances which excite the secretion of saliva. More frequently, however, the sensation is the expression of a **general** condition indicating the diminution of water in the tissues; or it may be due to excess of saline matters in the blood. In some diseases this sensation is very intense, *e.g.*, diabetes. If water be injected into the blood vessels, or stomach, both the general and local thirst are abolished, even although no water enters the mouth.]

FIG. 238.



2. **Inorganic substances** or **Salts** are an integral part of all tissues, without them the tissues cannot be formed. They occur in ordinary food. addition of too much salt increases the consumption of water, and this in t increases the transformation of N in the body. If an animal be deprived of s nutrition is interfered with; food deprived of its lime affects the formation of bones; deprival of common salt causes albuminuria (247, A, III). The alka salts serve to neutralize the sulphuric acid formed by the oxidation of the sulp

of the proteids. **Iron**, which is so essential for the formation of blood, exists in animals and plants in combination with complex organic bodies.

Only in times of famine is man driven to eat large quantities of inorganic substances, to extract the organic matter mixed therewith. A. v. Humboldt states, in regard to the inhabitants of the Orinoco, that they eat a kind of earth which contains innumerable infusoria.

3. At least **one** animal or vegetable albuminous body or **proteid** (§§ 248, 250). The proteids are required to replace the used-up nitrogenous tissues, *e. g.*, for muscles. They contain 15.4 to 16.5 per cent. N.

The **proteids** are in blood = 20.56 per cent.; muscles, 19.9 per cent.; liver, 11.74 per cent.; brain, 8.63 per cent.; blood plasma, 7.5 per cent.; milk, 3.94 per cent.; lymph, 2.46 per cent. According to Pflüger and Bohland, a youth of full stature, and 62 kilos. [136 lbs.] weight, decomposes 89.9 grms. of albumin daily.

Asparagin, in combination with gelatin, can replace albumin in the food (*Weiske*), while asparagin alone limits the decomposition of albumin in herbivora but not in carnivora (*J. Munk*). Ammoniacal salts, glycocoll, sarkosin, and benzamid increase with the amount of albumin in the body.

4. At least **one fat** (§ 251), **or** a digestible **carbohydrate** (§ 252). These chiefly serve to replace the transformed fats and non-nitrogenous constituents. Owing to the large amount of C which they contain, when they undergo oxidation, they form the chief source of the heat of the body (§ 206). Fats and carbohydrates may replace each other in the food, and in inverse proportion too, corresponding to the amount of C which each contains. As far as the mere evolution of heat is concerned, 100 parts of fat = 256 of grape sugar = 234 of cane sugar = 221 of dry starch (*Rubner*). A man consumes 210 grms. fat daily.

[5. Every proper diet ought to have a certain degree of **sapidity** or **flavor.** The substances which give this are not useful in the evolution of energy or building up the tissues, but they stimulate the nervous system and excite secretion. They are called "Genussmittel" (means of enjoying food) by the Germans, but we have no exact equivalent for this word in English, though the articles themselves are included under our expression "condiments." These substances are the aromatic matter in roast meat (osmasome), tea, vinegar, salt, mustard, pepper, etc.]

[**Condition of Diet for Health.**—In an adequate diet, not only (1) should the total quantity be sufficient and not more than sufficient, but (2) the constituents should exist in proper proportions, (3) be digestible, and (4) the whole should be in good condition, wholesome, and not adulterated with any substance prejudicial to health.]

With regard to the **relative proportions** of the various kinds of food which ought to be taken, experience has shown that the diet best suited for the body must contain 1 *part of nitrogenous foods to* 3½ *or, at most,* 4½ *of the non-nitrogenous.* Looking at ordinary foods from this point of view, we see how far they correspond to this requirement, and how several substances may be combined to produce a satisfactory diet.

	Nit.	Non-Nit.
1. Veal,	10	1
2. Hare's flesh,	10	2
3. Beef,	10	17
4. Lentils,	10	21
5. Beans,	10	22
6. Peas,	10	23
7. Mutton,	10	27
8. Pork,	10	30
9. Cow's milk,	10	30
10. Human milk,	10	37
11. Wheaten flour,	10	46
12. Oat meal,	10	50
13. Rye meal,	10	57
14. Barley meal,	10	57
15. White potatoes,	10	86
16. Blue "	10	115
17. Rice,	10	123
18. Buckwheat meal,	10	130

An examination of this table shows that, in addition to human milk, wheat flour has the right proportion of nitrogenous to non-nitrogenous substances. A man who tries to nourish himself on beef alone, commits as great a mistake as the one who would feed himself on potatoes alone. Experience has taught people that man may live upon milk and eggs, but that in addition to flesh we must eat bread or potatoes, while pulses require fat or bacon.

The diet varies with the **climate** and with the **season of the year.** As the organism must produce more heat in cold latitudes, the inhabitants of northern climates must eat more non-nitrogenous foods, such as fats and sugars or starches, which, on account of the large amount of C they contain, are admirably adapted for producing heat (§ 214, I, 4).

The graphic representation of the composition of foods (Fig. 238) shows the

relative proportions of the most important food stuffs, and how they vary from the standard of 1 nitrogenous to 3½ or 4½ non-nitrogenous.

The **absolute amount** of food stuffs required by an adult in twenty-four hours depends upon a variety of conditions. As the food represents the chemical reservoir of potential energy, from which the kinetic energy (in its various forms) and the heat of the body are obtained, the absolute amount of food must be increased when the body loses more heat, as in winter, and when more muscular activity (work) is accomplished. As a general rule *an adult requires daily* **130 grammes proteids, 84 grammes fats, 404 grammes carbohydrates, and 30 grammes salts.**

A HEALTHY ADULT **requires** IN 24 HOURS, OF **water-free** solids—

Food in Grammes.	At Rest. (*Playfair.*)	Moderate Work. (*Moleschott.*)	Laborious Work.	
			(*Playfair.*)	(*v. Pettenkofer and v. Voit.*)
Proteids,	70.87	130	155.92	137
Fats,	28.35	84	70.87	117
Carbohydrates (Sugar, Starch, etc.),	310.20	404	567.50	352
Salts,	14.00	30	40.00	40

[When we record these numbers in **ounces** we get the following results as **water-free solids** required by an average man (*Parkes*):—

	At Rest.	Ordinary Work.	Laborious Work.
Proteids,	2.5	4.6	6 to 7
Fats,	1.0	3.0	3.5 to 4.5
Carbohydrates,	12.0	14.4	16 to 18
Salts,	0.5	1.0	1.2 to 1.5
Total water-free food,	16.0	23.0	26.7 to 31

During ordinary work the proportion is about:—

Proteids 1: fats 0.6: carbohydrates 3.0,

i. e., 1 nitrogenous to 3.6 non-nitrogenous.]

[In a diet for ordinary work (23 oz. of *dry* solids) a man takes about $\frac{1}{100}$ part of his own weight daily; *ordinary food*, however, as it is consumed, contains between 50 and 60 per cent of water; if we add this proportion of water to the actually dry food, we get 48 to 60 oz. of ordinary food (exclusive of liquids). But we consume 50 to 80 oz. of water in some liquid form, making the total amount of water 70 to 90 oz. (*Parkes*).]

The following tables show the elementary composition of the income and expenditure:—

AN ADULT DOING A MODERATE AMOUNT OF WORK **takes in**:—

	C.	H.	N.	O.
120 grammes albumin, containing	64.18	8.60	18.88	28.34
90 " fats, "	70.20	10.26	. .	9.54
330 " starch, "	146.82	20.33	. .	162.85
	281.20	39.19	18.88	200.73

Add 744.11 grm. O from the air by respiration.
" 2818 " H_2O.
" 32 " Inorganic compounds (salts).

The whole is equal to $3\frac{1}{2}$ kilos. [7 lbs.], *i. e.*, about $\frac{1}{20}$ of the body weight; so that about 6 per cent. of the water, about 6 per cent. of the fat, about 1 per cent. albumin, and about 0.4 per cent. of the salts of the body are daily transformed within the organism.

AN ADULT DOING A MODERATE AMOUNT OF WORK **gives off**, in grammes:—

	Water.	C.	H.	N.	O
By respiration,	330	248.8	. .	?	651.15
Perspiration,	660	2.6	. .	. .	7.2
Urine,	1700	9.8	3.3	15.8	11.1
Fæces,	128	20.0	3 0	3.0	12.0
	2818	281.2	6.3	18.8	681.45

Add to this (besides 2818 grammes water as drink) 296 grammes water formed in the body by the oxidation of H. These 296 grammes of water contain 34.89 grms. H, and 263.41 grms. O; 26 grms. of salts are given off in the urine, and 6 by the fæces. 96.5 grms. of proteid (= 1.46 grm. per kilo.) are used up by a resting adult in 24 hours; but while working 107.6 grms. are used. Nominally 2.3 times as much fat as albumin are used up.

The investigations of the Munich School have shown that the following numbers represent the **minimum amount** of food necessary for different ages:—

Age.	Nitrogenous.	Fat.	Carbohydrates.
Child until 1½ years,	20–36 grms.	30–45 grms.	60–90 grms.
" from 6 to 15 years,	70–80 "	37–50 "	250–400 "
Man (moderate work),	118 "	56 "	500 "
Woman, "	92 "	44 "	400 "
Old man,	100 "	68 "	350 "
Old woman,	80 "	50 "	260 "

Small animals have a more lively metabolism than large ones. In small animals the decomposition of albumin per unit weight of body is greater than in large animals (*v. Voit*). Small animals as a rule consume more proteid than larger ones, because they generally have less bodily fat (*Rubner*).

Relation of N to C.—In most of the ordinary articles of diet, nitrogenous and non-nitrogenous substances are present, but in very varying proportion, in the different foods. Man requires that these shall be in the proportion of 1 : $3\frac{1}{2}$ to 1 : $4\frac{1}{2}$. If food be taken in which this proportion is not observed, in order to obtain the necessary amount of that substance which is contained in too small proportion in his food, he must consume far too much food. In order to obtain the **130 grammes of proteids** necessary a person must use

Cheese, ... 388 grms.	Beef, ... 614 grms.	Rice, ... 2562 grms.
Lentils, ... 491 "	Eggs, ... 968 "	Rye bread, . . 2875 "
Peas, ... 582 "	Wheat bread, . . . 1444 "	Potatoes, . . . 10,000 "

provided he were to take only one of these substances as food; so that if a workman were to live on potatoes alone, in order to get the necessary amount of N he would have to consume an altogether excessive amount of this kind of food.

To obtain the **448 grammes of carbohydrates**, or the equivalent amount of fat necessary to support him, a man must eat

Rice, ... 572 grms.	Peas, ... 819 grms.	Cheese, ... 2011 grms.
Wheat bread, . . . 625 "	Eggs, ... 902 "	Potatoes, ... 2039 "
Lentils, ... 806 "	Rye bread, ... 930 "	Beef, ... 2261 "

so that if he were to live upon cheese or flesh alone, he would require to eat an enormous amount of these substances.

In the case of **herbivora**, the proportion of nitrogenous to non-nitrogenous food necessary is 1 of the former to 8 or 9 parts of the latter.

237. HUNGER AND STARVATION.—If a warm-blooded animal be **deprived of all food**, it must, in order to maintain the temperature of its body and to produce the necessary amount of mechanical work, transform and utilize the potential energy of the constituents of its own body. The result is that its body weight diminishes from day to day, until death occurs from starvation.

The following table, from Bidder and Schmidt, shows the amounts of the different excreta in the case of a starved cat:—

Day.	Body weight.	Water taken.	Urine.	Urea.	Inorganic Substances in Urine.	Dry Fæces.	Expired C.	Water in Urine and Fæces.
1.	2464	...	98	7.9	1.3	1.2	13.9	91.4
2.	2297	11.5	54	5.3	0.8	1.2	12.9	50.5
3.	2210	...	45	4.2	0.7	1.1	13	42.9
4.	2172	68.2	45	3.8	0.7	1.1	12.3	43
5.	2129	...	55	4.7	0.7	1.7	11.9	54.1
6.	2024	...	44	4.3	0.6	0.6	11.6	41.1
7.	1946	...	40	3.8	0.5	0.7	11	37.5
8.	1873	...	42	3.9	0.6	1.1	10.6	40

18.†	1267	...	13	0.7	0.1	0.3	6.1	12.9
	−1197	131.5	733	65.8	9.8	15.7	190.7	734.4

The cat lost 1197 grms. in weight before it died, and this amount is apportioned in the following way: 204.43 grams. (= 17.01 per cent.) loss of albumin; 132.75 grms. (= 11.05 per cent.) loss of fat; 863.82 grms. loss of water (= 71.91 per cent. of the total body weight).

Methods.—In order to investigate the condition of **inanition** it is necessary (1) to weigh the animal daily; (2) to estimate daily all the C and N given off from the body in the fæces, urine, and expired air. The N and C, of course, can only be obtained from the decomposition of tissues containing them.

Among the **general phenomena of inanition**, it is found that strong, well-nourished dogs die after 4 weeks, man after 21 to 24 days—(6 melancholics who took water died after 51 days); small mammals and birds 9 days, and frogs 9 months. Vigorous adults die when they lose $\frac{1}{2}$ of their body weight, but young individuals die much sooner than adults. **The symptoms** are obvious. The mouth is dry, the walls of the alimentary canal become thin, and the digestive secretions cease to be formed; pulse beats and respirations are fewer; urine very acid, from the presence of an increased amount of sulphuric and phosphoric acids, while the chlorine compounds rapidly diminish and almost disappear. The blood contains less water and the plasma less albumin, the gall bladder is distended, which indicates a continuous decomposition of blood corpuscles within the liver. The liver is small and very dark colored, the muscles are very brittle and dry, so that there is great muscular weakness, and death occurs with the signs of great depression and coma.

The relations of the metabolism are given in the foregoing table, the diminution in the excretion of urea is much greater than that of CO_2, which is due to

a larger amount of fats than proteids being decomposed. According to the calculation, there is daily a tolerably constant amount of fat used up, while, as starvation continues, the proteids are decomposed in much smaller amounts from day to day, although the drinking of water accelerates their decomposition.

Loss of Weight of Organs.—It is of importance to determine to what extent the individual organs and tissues lose weight; some undergo simple loss of weight, *e. g.*, the bones, the fat undergoes very considerable and rapid decomposition, while other organs, as the heart, undergo little change, because they seem to be able to nourish themselves from the transformation products of other tissues.

A **starving cat**, according to v. Voit, lost—

	Per cent. originally present.	Per cent. of the total loss of body weight.
1. Fat,	97	26.2
2. Spleen,	66.7	0.6
3. Liver,	53.7	4.8
4. Testicles,	40.0	0.1
5. Muscles,	30.5	42.2
6. Blood,	27.0	3.7
7. Kidneys,	25.9	0.6
8. Skin,	20.6	8.8
9. Intestine,	18.0	2.0
10. Lungs,	17.7	0.3
11. Pancreas,	17.0	0.1
12. Bones,	13.9	5.4
13. Central Nervous System,	3.2	0.1
14. Heart,	2.6	0.02
15. Total loss of the rest of the body,	36.8	5.0

There is a very important difference according as the animals before inanition have been fed freely on flesh and fat [*i. e.*, if they have a surplus store of food within themselves], or as they have merely had a subsistence diet. Well-fed animals lose weight much more rapidly during the first few days than on the later days. V. Voit thinks that the albumin derived from the excess of food occurs in a state of loose combination in the body as "**circulating**" or "*storage albumin*," so that during hunger it must decompose more rapidly and to a greater extent than the "**organic albumin**," which forms an integral part of the tissues (§ 236). Further, in fat individuals, the decomposition of fat is much greater than in slender persons.

238. METABOLISM ON A PURELY FLESH DIET.—A man is not able to maintain his metabolism in equilibrium on a purely flesh diet; if he were compelled to live on such a diet, he would succumb. The reason is obvious. In beef the proportion of nitrogenous to non-nitrogenous elementary constituents of food is 1 : 1.7 (p. 405). A healthy person excretes 280 grammes [8 to 9 oz.] of carbon in the form of CO_2, in the expired air, and in the urine and fæces. If a man is to obtain 280 grammes C. from a flesh diet he must consume—digest and assimilate—more than 2 kilos. [4.4 lbs.] of beef in twenty-four hours. But our digestive organs are unequal to this task for any length of time. The person is soon obliged to take less beef, which would necessitate the using of his own tissues, at first the fatty parts and afterward the proteid substances.

A carnivorous animal (**dog**), whose digestive apparatus, being specially adapted for the digestion of flesh, has a short intestine and powerfully active digestive fluids, can only maintain its metabolism in a state of equilibrium when fed on a flesh diet free from fat, provided its body is already well supplied with fat, and is muscular. It consumes $\frac{1}{25}$ to $\frac{1}{20}$ part of the weight of its body in flesh, so that the excretion of urea increases enormously. If it eats a larger amount, it may "put on flesh," when, of course, it requires to eat more to maintain itself in this condition, until the limit of its digestive capacity is reached. If a well-nourished dog is fed on less than $\frac{1}{25}$ to $\frac{1}{20}$ of its body weight of flesh, it uses part of its own fat and muscle, gradually diminishes in weight, and ultimately succumbs. Poorly fed, non-muscular dogs are unable from the very beginning to maintain their metabolism in equilibrium for any length of time on a purely flesh diet, as they must eat so large a quantity of flesh that their digestive organs cannot digest it. The **herbivora** cannot live upon flesh food, as their digestive apparatus is adapted solely for the digestion of vegetable food.

[The **proteid metabolism** depends (1) on the amount of proteids ingested,

for the great mass of these becomes changed into circulating albumin; (2) upon the previous condition of nutrition of the organism, for we know that a certain amount of proteid may produce very different results in the same individual when he is in good health, and when he has suffered from some exhausting disease. (3) The use of other foods, *e. g.*, fats and carbohydrates. If a certain amount of fat be added to a diet of flesh, much less flesh is required, so that the N metabolism is reduced by fat. This is spoken of as the "**albumin-sparing action**" of fats.]

Exactly the same result occurs with **other forms of proteids**, as with flesh. It has been proved that **gelatin** may to a certain extent replace proteids in the food, in the proportion of 2 of gelatin to 1 of albumin. The carnivora, which can maintain their metabolism in equilibrium by eating a large amount of flesh, can do so with less flesh when gelatin is added to their food. A diet of gelatin alone, which produces much urea, is not sufficient for this purpose, and animals soon lose their appetite for this kind of food.

[**Gelatin.**—Voit has shown that gelatin readily undergoes metabolism in the body and forms urea, and if a small quantity be taken, it is completely and rapidly metabolized. When administered it acts just like fats and carbohydrates, as an "albumin-sparing" substance. It seems that gelatin is not available directly for the growth and repair of tissues.] Owing to the great solubility of gelatin, its value as a food used to be greatly discussed. The addition of gelatin in the form of calf's-foot jelly is recommended to invalids. [When a large amount of gelatin is given as food, owing to the large and rapid excretion of urea, the latter excites diuresis.] When chondrin is given along with flesh for a time, grape sugar is found in the urine.

[The **Metabolism of Peptones.**—Most of the proteids absorbed into the blood are previously converted into peptones by the digestive juices. It has been asserted, more especially by Brücke, that some albumin is absorbed unchanged (§ 192, 4), and that only this is capable of forming organic albumin, while the peptones, after undergoing a reconversion into albumin, undergo decomposition as such. This view is opposed by many observers, who maintain that peptones perform all the functions of proteids, so that peptones, with the other necessary constituents of an adequate diet, suffice to maintain a proper standard of health.]

239. **A DIET OF FAT OR OF CARBOHYDRATES.**—If **fat alone** be given as a food, the animal lives but a short time. The animal so fed excretes even less urea than when it is starving; so that the consumption of fat limits the decomposition of the animal's own proteids. As fat is an easily oxidized body, it yields heat chiefly, and becomes sooner oxidized than the nitrogenous proteids which are oxidized with more difficulty. If the amount of fat taken be very large, all the C of the fat does not reappear, *e. g.*, in the CO_2 of the expired air; so that the body must acquire fat, while at the same time it decomposes proteids. The animal thus becomes poorer in proteids and richer in fats at the same time.

[The **metabolism of fats** is not dependent on the amount of fats taken with the food. 1. It is largely influenced by **work**, *i. e.*, by the activity of the tissues, and in fact with muscular work CO_2 is excreted in greatly increased amount (§ 127, 6). 2. By the **temperature** of the surroundings, as more CO_2 is produced in the cold (§ 214, 2), and far more fatty foods are required in high latitudes. In their action on the organism, proteids and fats so far oppose each other, as the former increase the waste, and therefore oxidation, while the latter diminish it, probably by affecting the metabolic activity of the cells themselves (*Bauer*). As a matter of fact, fat animals or persons bear starvation better than spare individuals. In the latter, the small store of fat is soon used up, and then the albumin is rapidly decomposed. For the same reason corpulent persons are very apt to become still more so, even on a very moderate diet.]

When **carbohydrates alone** are given, they must first be converted by digestion into sugar. The result of such feeding coincides pretty nearly with feeding

with fat alone. But the sugar is more easily burned or oxidized within the body than the fat, and 17 parts of carbohydrate are equal to 10 parts of fat. Thus the diet of carbohydrates limits the excretion of urea more readily than a purely fat diet. The animals lose flesh, and appear even to use up part of their own fat.

[The **metabolism of carbohydrates** also serves to diminish the proteid metabolism, as they are rapidly burned up, and thus "spare" the circulating albumin. But Pettenkofer and Voit assert that they are rapidly destroyed in the body, even when given in large amount, so that they differ from fats in this respect. They are more easily oxidized than fats, so that they are always consumed first in a diet of carbohydrates and fats. By being consumed they protect the proteids and fats from consumption.]

The direct introduction of grape and cane sugar into the blood does not increase the amount of O used, but the amount of CO_2 is increased. [The doctrine of Liebig, that the oxygen taken in is a measure of the metabolic processes, is refuted by these and other experiments. It would seem that fat is not directly oxidized by O, but that it is split up into other simpler compounds which are slowly and gradually oxidized; in fact, fat may lessen the amount of O taken in, as it diminishes waste.]

240. FLESH AND FAT, OR FLESH AND CARBOHYDRATES.—An amount of flesh equal to $\frac{1}{25}$ to $\frac{1}{20}$ of the weight of the body is required to nourish a dog, which is fed on a purely flesh diet; if the necessary amount of fat or carbohydrates be added to the diet, a smaller quantity of flesh is required (*v. Voit*). For 100 parts of fat added to the flesh diet, 245 parts of dry flesh or 227 of syntonin can be dispensed with. If instead of fats carbohydrates are added, then 100 parts of fat = 230 to 250 of the latter (*Rubner*). When the amount of flesh is insufficient, the addition of fat or carbohydrates to the food always limits the decomposition of the animal's own substance. Lastly, when too much flesh is given along with these substances, the weight of the body increases more with them than without them. Under these circumstances, the animal's body puts on more fat than flesh. The **consumption of O** in the body is regulated by the mixture of flesh and non-nitrogenous substances, rising and falling with the amount of flesh consumed. It is remarkable that more O is consumed when a given amount of flesh is taken, than when the same amount of flesh is taken with the addition of fat.

It seems that, instead of fat, the corresponding amount of **fatty acids** has the same effect on the metabolism. [If a dog be fed with fatty acids and a sufficient amount of proteid, no fatty acids are found in the chyle, while fat is formed synthetically, the glycerin for the latter probably being produced in the body.] They are absorbed as an emulsion just like the fats. When so absorbed, they seem to be reconverted into fats in their passage from the intestine to the thoracic duct probably by the action of the leucocytes (*J. Munk, Will*). [**Glycerin** in small doses has no effect on the metabolism of proteid, but in large doses it increases it. It is consumed in the body, as shown by experiments on the respiratory products, and it prevents a certain amount of fat from being used up. About 20 per cent. is excreted in the urine (*Arnschink*).]

241. ORIGIN OF FAT IN THE BODY.—I. *Part* of the fat of the body is derived directly from the fat of the **food**, *i. e.*, it is absorbed and **deposited** in the tissues. This is shown by the fact that, with a diet containing a small amount of albumin, the addition of more fat causes a deposition of a larger amount of fat in the body (*v. Voit, Hofmann*).

[Hofmann starved a fat dog for 30 days until all its fat was used up. He fed it on lard and a little albumin for 5 days and then killed it. In 5 days it absorbed 1854 grms. of fat and 254 grms. of albumin. It added to its body 1353 grms. of fat; but this amount could not be formed from the proteids of the food, and therefore the fat must have come from the fat of the food. Pettenkofer and Voit arrived at the same result in another way. They fed dogs on fish and much fat, and by their respiration apparatus estimated the gaseous income and expenditure (§ 122). *All the N taken in reappeared in the excreta, but not all the C.* The amount of C retained was very large, therefore a non-nitrogenous residue must have been laid up in the body, and it could only be fat, as this was the only substance found in large amount in the body. They estimated the possible amount of

fat that could be formed from the proteids, and found that the amount stored up was far greater than this; so that the fat of the food must have been stored up in the tissues.]

Lebedeff found that dogs, which were starved for a month, so as to get rid of all their own fat, on being fed with linseed oil, or mutton suet and flesh, had these fats restored to their tissues. These fats, therefore, must have been absorbed and deposited. J. Munk found the same on feeding animals with rape-seed oil. Fatty acids may also contribute to the formation of fats, as glycerin when formed in the body must be stored up during metabolism (*J. Munk*).

Fatty acids may contribute to the formation of fats by union with the glycerin of the body during the metabolism.

II. A second source of the fats is albuminous bodies. In the case of the formation of fats from **proteids**, which may yield 11 per cent. of fat (according to Henneberg 100 parts of dry albumin can form 51.5 parts of fat), these proteids split up into a non-nitrogenous and a nitrogenous atomic compound. The former, during a diet containing much albumin, when it is not completely oxidized into CO_2, and H_2O, is the substance from which the fat is formed—the latter leaves the body oxidized chiefly to the stage of urea.

Examples.—That *fats are formed from proteids* is shown by the following: 1. A cow which produces 1 lb. of butter daily does not take nearly this amount of fatty matter in its food, so that the fat would appear to be formed from vegetable proteids. 2. Carnivora giving suck, when fed on plenty of flesh and *some* fat, yield milk rich in fat. 3. Dogs fed with plenty of flesh and some fat, add more fat to their bodies than the fat contained in the food. 4. Fatty degeneration, *e.g.*, of nerve and muscle, is due to a decomposition of proteids. 5. The transformation of entire bodies, *e.g.*, such as have lain for a long time surrounded with water, into a mass consisting almost entirely of palmitic acid or **adipocere** is also a proof of the transformation of part of the proteids into fats. 6. Fungi are also able to form fat from albumin during their growth. [7. In starving dogs, Bauer estimated the N and CO_2 given off, and O taken in, and then slowly poisoned them with phosphorus, and he found that the excretion of N was increased twofold, while the excretion of CO_2 and the absorption of O were diminished one-half. Therefore from a large amount of nitrogenous tissue, a nitrogenous body and a small amount of a carbonaceous compound were excreted, while a large amount of a non-nitrogenous residue was retained unconsumed. There was fatty degeneration of all the organs, the fat being derived from the non-nitrogenous part of the proteid. The same obtains with arsenic and antimony.]

Fats not merely absorbed.—Experiments which go to show that the fat of animals, during the fattening process, is not absorbed as such, from the food, are: 1. Fattening occurs with flesh and soaps; it is most improbable that the soaps are transformed into neutral fats by taking up glycerin and giving up alkali. 2. If a lean dog be fed with flesh and palmitin- and stearin-soda soap, the fat of its body contains, in addition to palmitin and stearin, *olein* fat, so that the last must be formed by the organism from the proteids of the flesh. Further, Ssubotin found that, when a lean dog was fed on lean meat and spermaceti frt, a very small amount of the latter was found in the fat of the animal. Although these experiments show that the fat of the body must be formed from the decomposition of proteids, they do not prove that *all* the fat arises in this way, and that none of it is absorbed and redeposited (§ 241, I).

III. According to v. Voit, no fat is formed in the body directly from **carbohydrates**, *e.g.*, by reduction. As fattening occurs on a diet of pure flesh with the addition of carbohydrates, it is assumed that the carbohydrates are consumed or oxidized in the body, and that thereby a non-nitrogenous body derived from the proteids is prevented from being burned up, and that it is changed into fat, and stored up as such. No doubt fat is formed *indirectly* in the blood in this way (§ 240).

From experiments upon fattening animals, however, Lawes and Gilbert, Lehmann, Heiden, v. Wolff, and others, think they are entitled to conclude that the carbohydrates absorbed are *directly* concerned in the formation of fats, a view which is supported by Henneberg, B. Schulze, and Soxhlet. According to Pasteur, glycerin (the basis of neutral fats) may be formed from carbohydrates.

[Tscherwinsky fed two similar pigs from the same litter; No. I weighed 7300 grms.; No. II 7290 grms. No. I was killed and its fat and proteids estimated. No. II was fed for four months on grain and then killed, the grain and excreta and the undigested fat and proteids were analyzed, so that the amount of fat and proteid absorbed in four months was estimated. The pig then weighed 24 kilos., it was killed and its fat and proteids estimated.

No. II contained	2.50	kilos.	albumin and	9.25	kilos.	fat.
No. I "	0.96	"	"	0.69	"	"
Assimilated,	1.56	"	"	8.56	"	"
Taken in in food,	7.49	"	"	0.66	"	"
Difference,	—5.93	"	"	+7.90	"	"

There were therefore 7.90 kilos of fat in the body which could not be accounted for in the fat of the food. The 5.93 kilos. of albumin of the food which were not assimilated as albumin could yield only a small part of the 7.90 kilos of fat, so that at least 5 kilos. of fat must have been formed from carbohydrates. Lawes and Gilbert calculated that 40 per cent. of the fat in pigs was derived from carbohydrates. How the carbohydrates are changed into fat in the body is entirely unknown.]

Formerly it was believed that bees could prepare wax from honey alone; this is a mistake—an equivalent of albumin is required in addition—the necessary amount is found in the raw honey itself.

242. CORPULENCE —The addition of too much fat to the body is a pathological phenomenon which is attended with disagreeable consequences. With regard to the **causes** of obesity, without doubt there is an **inherited tendency** (in 33 to 56 per cent. of the cases) in many families —and in some breeds of cattle, to lay up fat in the body, while other families may be richly supplied with fat, and yet remain lean. The chief cause, however, is taking **too much food**, *i. e.*, more than the amount required for the normal metabolism; corpulent people, in order to maintain their bodies, must eat absolutely and relatively more than persons of spare habit, under analogous conditions of nutrition (§ 236).

Conditions favoring Corpulence.—(1) A diet rich in *proteids*, with a corresponding addition of *fat* or *carbohydrates*. As flesh or muscle is formed from proteids, and part of the fat of the body is also formed from albumin; the assumption that fats and carbohydrates fatten, or, when taken alone, act as fattening agents, is completely without foundation. (2) *Diminished disintegration* of materials within the body, *e. g.*, (*a*) *diminished muscular activity* (much sleep and little exercise); (*b*) *abrogation of the sexual functions* (as is shown by the rapid fattening of castrated animals, as well as by the fact that some women, after cessation of the menses, readily become corpulent); (*c*) *diminished mental activity* (the obesity of dementia), phlegmatic temperament. On the contrary, vigorous mental work, excitable temperament, care and sorrow, counteract the deposit of fat; (*d*) *diminished extent of the respiratory activity*, as occurs when there is a great deposition of fat in the abdomen, limiting the action of the diaphragm (breathlessness of corpulent people), whereby the combustion of the fatty matters which become deposited in the body is limited; (*e*) a corpulent person requires to use relatively *less heat-giving substances* in his body, partly because he gives off *relatively* less heat from his compact body, than is done by a slender, long-bodied individual, and partly because the thick layer of fat retards the conduction of heat (§ 214, 4). Thus, corresponding to the relatively diminished production of heat, more fat may be stored up; (*f*) a *diminution of the red blood corpuscles*, which are the great exciters of oxidation in the body, is generally followed by an increase of fat—fat people, as a rule, are fat because they have relatively less blood (§ 41)—women with fewer red blood corpuscles are usually fatter than men; (*g*) the *consumption of alcohol* favors the conservation of fat in the body, the alcohol is easily oxidized, and thus prevents the fat from being burned up (§ 235).

Disadvantages.—Besides the inconvenience of the great size and weight of the body, corpulent people suffer from breathlessness—they are easily fatigued, are liable to intertrigo between the folds of the skin, the heart becomes loaded with fat, and they not unfrequently are subject to apoplexy.

In order to **counteract corpulence** we ought to (1) *Reduce uniformly all articles of diet.* The diet and body ought to be weighed from week to week, and as long as there is no diminution in the body weight the amount of food ought to be gradually and uniformly reduced (notwithstanding the appetite). This must be done very gradually and not suddenly. A *moderate* reduction of fat and carbohydrates in a normal diet, at the same time leads to a diminution of the fat of the body itself. Let a person who is capable of muscular exertion take 156 grms. proteid, 43 grms. fat, and 114 grms. carbohydrates; but in those where congestions, hydræmia, breathlessness have taken place, take 170 grms. proteid, 25 grms. fat, and 70 grms. carbohydrates (*Oertel*). It is not advisable to limit the amount of fat and carbohydrates alone, as is done in the **Banting cure** or Bantingism. Apart altogether from the fact that fat is formed from proteids, if too little non-nitrogenous food be taken, severe disturbance of the bodily metabolism is apt to occur. (2) It is advisable during the chief meal to limit the consumption of fluids of all sorts (even until three-quarters of an hour thereafter), and thus render the absorption and digestive activity of the intestine less active (*Oertel*). (3) The *muscular activity* ought to be greatly developed by doing plenty of muscular work, or taking plenty of exercise, both physical and mental. (4) *Favor the evolution of heat* by taking baths of considerable duration, and afterward rubbing the skin strongly so as to cause it to red; further, dress lightly, and at night use light bed-clothing; tea and coffee are useful, as the circulation. (5) Use gentle laxatives; acid fruits, cider; alkaline carbonates (of

Marienbad, Carlsbad, Vichy, Neuenahr, Ems, etc.) act by increasing the intestinal evacuations and diminishing absorption. (6) If from accumulation of fat there is danger of failure of the heart's action, Oertel recommends hill climbing, whereby the cardiac muscle is exercised and strengthened. At the same time the circulation becomes more lively and the metabolism is increased.

[**Oertel's Method** goes on the idea of strengthening the cardiac musculature, which is sought to be accomplished by (1) limiting the amount of fluids consumed, and (2) carefully regulated muscular exertion. The amount of food is first reduced one-half, and the water to a still lower amount, while the nitrogenous elements in food are increased, the non nitrogenous are decreased. The person is then instructed to take exercise under certain medical precautions, first on level ground, and then on gradually increasing gradients.]

Fatty Degeneration.—The process of fattening consists in the deposition of drops of fat within the fat cells of the panniculus and around the viscera, as well as in the marrow of bone (but they are never deposited in the subcutaneous tissue of the eyelids, of the penis, of the red part of the lips, in the ears and nose). This is quite different from the fatty atrophy or **fatty degeneration** which occurs in the form of fatty globules or granules in albuminous tissues, *e. g.*, in muscular fibres (heart), gland cells (liver, kidney), cartilage cells, lymph and pus corpuscles, as well as in nerve fibres separated from their nerve centres. The fat in these cases is derived from albumin, much in the same way as fat is formed in the gland cells of the mammary and sebaceous glands. Marked fatty degeneration not unfrequently occurs after severe fevers, and after artificial heating of the tissues; when a too small amount of O is supplied to the tissues, as occurs in cases of phosphorus poisoning (*Bauer*); in drunkards; after poisoning with arsenic and other substances, and after some disturbances of the circulation and innervation. Some organs are especially prone to undergo fatty degeneration during the course of certain diseases.

243. METABOLISM OF THE TISSUES.—The **blood stream** is the chief medium whereby new material is supplied to the tissues and the effete products removed from them. The **lymph** which passes through the thin capillaries comes into actual contact with the tissue elements. Those tissues which are devoid of blood vessels in their own substance, such as the cornea and cartilage, receive nutrient fluid or lymph from the adjacent capillaries, by means of their cellular elements, which act as juice-conducting media. Hence, when the normal circulation is interfered with, by atheroma or calcification of the walls of the blood vessels, these tissues are secondarily affected [this, for example, is the case in arcus senilis of the cornea, due to a fatty degeneration of the corneal tissue, owing to some affection of the blood vessels on which the cornea depends for its nutrition]. Total compression or ligature of *all* the blood vessels results in necrosis of the parts supplied by the ligatured blood vessels.

Atrophies caused by diminution of the normal supply of blood, gradually, in the course of time become less and less (*Samuel*).

Hence, there must be a *double current* of the tissue juices; the **afferent** or **supply current,** which supplies the new material, and the **efferent stream,** which *removes* the effete products. The former brings *to* the tissues the proteids, fats, carbohydrates, and salts from which the tissues are formed. It is evident that any interruption of the arterial supply to the tissues will diminish this supply.

That such a current exists is proved by injecting an indifferent, easily recognizable substance into the blood, *e.g.*, potassium ferrocyanide, when its presence may be detected in the tissnes, to which it has been carried by the outgoing current.

The **efferent stream** carries away the decomposition products *from* the various tissues, more especially urea, CO_2 H_2O, and salts, and these are transferred as quickly as possible to the organs through which they are excreted.

That such a current exists is proved by injecting such a substance as potassium ferrocyanide into the tissues, *e. g.*, subcutaneously, when its presence may be detected in the urine within two to five minutes.

If the current from the tissues to the blood is so active that the excretory organs cannot eliminate all the effete products from the blood, then these products are found in the tissues. When certain poisons are injected subcutaneously, they pass rapidly into the blood and are carried in great quantity to other tissues, *e. g.*, to the nervous system, on which they act with fatal effect, before they are eliminated

to any great extent from the blood by the action of the excretory organs. The effete materials are carried away from the tissues by *two* channels, viz., by the **veins** and by the **lymphatics**, so that if these be interfered with, the metabolism of the tissues must also suffer. When a limb is ligatured so as to compress the veins and the lymphatics, the efferent stream stagnates to such an extent that considerable swelling of the tissues or œdema may occur (§ 203). The action of the muscles and fasciæ are very important in removing these effete matters.

H. Nasse found that the blood of the jugular vein is 0.225 per 1000 specifically heavier than the blood of the carotid, and contains 0.9 parts per 1000 more solids; 1000 cubic centimetres of blood circulating through the head yield about 5 cubic centimetres of transudation into the tissues.

The **extent and intensity of the metabolism** of the tissues depend upon a variety of factors.

1. Upon their **activity.**—The increased activity of an organ is indicated by the increased amount of blood going to it, and by the more active circulation through it (§ 100). When an organ is completely inactive, such as a paralyzed muscle, or the peripheral end of a divided nerve, the amount of blood and the nutritive exchange of fluid diminish within these parts. The parts thus thrown out of activity become pale, relaxed, and ultimately undergo fatty degeneration. The increased metabolism of an organ during its activity has been proved experimentally in the case of **muscle**, and [(§ 263) also in the brain (*Speck*)]. Langley and Sewell have recently observed directly the metabolic changes within sufficiently thin lobules of **glands** during life. The cells of serous glands (§ 143), and those of mucous, and pepsin-forming glands (§ 164), during quiescence, become filled with coarse granules, which are dark in transmitted light and white in reflected light, which granules are consumed or disappear during granular activity. During **sleep**, when most organs are at rest, the metabolism is limited, darkness also diminishes it; while **light** excites it, obviously owing to nervous influences. The variations in the total metabolism of the body are reflected in the excretion of CO_2 (§ 127, 9) and urea (§ 257), which may be expressed graphically in the form of a curve corresponding with the activity of the organism; this curve corresponds very closely with the daily variations in the respirations, pulse, and temperature (p. 374).

2. The **composition of the blood** has a marked effect upon the current on which the metabolism of the tissues depends. Very **concentrated** blood, which contains a small amount of water, as after profuse sweating, severe diarrhœa, cholera, makes the tissues dry, while if much water be absorbed into the blood, the tissues become more succulent and even œdema occur. When much common salt is present in the blood, and when the red blood corpuscles contain a diminished amount of O, and especially if the latter condition be accompanied by muscular exertion causing dyspnœa, a large amount of albumin is decomposed, and there is a great formation of urea. Hence, exposure to a rarefied atmosphere is accompanied by increased excretion of urea. Certain abnormal conditions of the blood produce remarkable results; blood charged with *carbonic oxide* cannot absorb O from the air, and does not remove CO_2 from the tissues (§ 16). The presence of *hydrocyanic acid* in the blood (§ 16) is said to interrupt at once the chemical oxidation processes in the blood, so that rapid asphyxia, owing to cessation of the *internal* respiration, occurs. Fermentation is interrupted by the same substance in a similar way. A *diminution of the total amount* of the blood causes more fluid to pass from the tissues into the blood, but the absorption of substances—such as poisons or pathological effusions—from the tissues or intestines is delayed. If the substances which pass from the tissues into the blood be rapidly eliminated from it, absorption takes place more rapidly.

3. The **blood pressure**, when it is greatly increased, causes the tissues to contain more fluid, while the blood itself becomes more concentrated, to the extent of 3 to 5 per 1000. We may convince ourselves that blood plasma easily passes

through the capillary wall, by pressing upon the efferent vessel coming from the chorium deprived of its epidermis, *e. g.*, by a burn or a blister, when the surface of the wound becomes rapidly suffused with plasma. Diminution of the blood pressure produces the opposite result. The oxidation processes in the body are diminished after the use of P, Cu, ether, chloroform, and chloral.

4. **Increased temperature of the tissues** (several hours daily) does not increase the breaking up of albumin and fats. (See §§ 220, 221, 225.)

5. The **influence of the nervous system** on the metabolism is twofold. On the one hand, it acts indirectly through its effect upon the blood vessels, by causing them to contract or dilate through the agency of **vasomotor nerves**, whereby it influences the amount of blood supplied, and also affects the blood pressure. But quite independently of the blood vessels, it is probable that certain special nerves—the so-called **trophic nerves**—influence the metabolism or nutrition of the tissues (§ 342, *c*). That nerves do influence directly the transformation of matter within the tissues is shown by the secretion of saliva resulting from the stimulation of certain nerves, after cessation of the circulation (§ 145), and by the metabolism during the contraction of bloodless muscles. Increased respiration and apnœa are not followed by increased oxidation (*Pflüger*) (§ 127, 8).

[Gaskell has raised the question as to the existence of **katabolic** and **anabolic nerves** controlling respectively the analytic and synthetic metabolism of the tissues.]

244. **REGENERATION.**—The extent to which lost parts are replaced varies greatly in different organs. Among the *lower animals*, the parts of organs are replaced to a far greater extent than among warm-blooded animals. When a hydra is divided into two parts, each part forms a new individual—nay, if the body of the animal be divided into several parts in a particular way, then each part gives rise to a new individual (*Spallanzani*). The Planarians also show a great capability of reproducing lost parts (*Dugès*). Spiders and crabs can reproduce lost feelers, limbs, and claws; snails, part of the head, feelers, and eyes, provided the central nervous system is not injured. Many fishes reproduce fins, even the tail fin. Salamanders and lizards can produce an entire tail, including bones, muscles, and even the posterior part of the spinal cord; while the triton reproduces an amputated limb, the lower jaw, and the eye. This reproduction necessitates that a small stump be left, while total extirpation of the parts prevents reproduction. In amphibians and reptiles the regeneration of organs and tissues, as a whole, takes place after the type of the embryonic development, and the same is true as regards the histological processes which occur in the regenerated tail and other parts of the body of the earth-worm.

The extent to which regeneration can take place in mammals and in man is very slight, and even in these cases it is chiefly confined to young individuals. A true regeneration occurs in—

1. The **blood**, including the plasma, the colorless and colored corpuscles. (§ 7 and § 41.)

2. The **epidermal appendages** (§ 283) and the **epithelium** of the mucous membranes are reproduced by a proliferation of the cells of the deeper layers of the epithelium, with simultaneous division of their nuclei. Epithelial cells are reproduced as long as the matrix on which they rest and the lowest layer of cells are intact. When these are destroyed cell regeneration from below ceases, and the cells at the margins are concerned in filling up the deficiency. Regeneration, therefore, either takes place from below or from the margins of the wound in the epithelial covering; leucocytes also wander into the part, while the deepest layer of cells forms large multi-nucleated cells, which reproduce by division polygonal flat nucleated cells. [In the process of division of the cells, the nucleus plays an important part, and in so doing it shows the usual karyokinetic figures (§ 431).] The **nails** grow from the root forward; those of the fingers in four to five months, and that of the great toe in about twelve months, although growth is slower in the case of fracture of the bones. The matrix is co-extensive with the *lunule*, and if it be destroyed the nail is not reproduced (§ 284). The **eyelashes** are changed in 100 to 150 days, the other hairs of the body somewhat more slowly. If the papilla of the hair follicle be destroyed, the hair is not reproduced. Cut-

ting the hair favors its growth, but hair which has been cut does not grow longer than uncut hair. After hair has grown to a certain length, it falls out. The hair never grows at its apex. The **epithelial cells** of mucous membranes and secretory glands seem to undergo a regular series of changes and renewal. The presence of secretory cells in the milk (§ 231) and in the sebaceous secretion (§ 285) proves this; the spermatozoa are replaced by the action of spermatoblasts. In **catarrhal conditions** of mucous membranes, there is a great increase in the formation and excretion of new epithelium, while many cells are but indifferently formed and constitute mucous corpuscles. The **crystalline lens**, which is just modified epithelium, is reorganized like epithelium; its matrix is the anterior wall of its capsule, with the single layer of cells covering it. If the lens be removed and this layer of cells retained, these cells proliferate and elongate to form lens fibres, so that the whole cavity of the empty lens capsule is refilled. If much water be withdrawn from the body, the lens fibres become turbid. [A turbid or opaque condition of the lens may occur in diabetes, or after the transfusion of strong common salt or sugar solution into a frog.]

3. The **blood vessels** undergo extensive regeneration, and they are regenerated in the same way as they are formed (§ 7, B). Capillaries are always the first stage, and around them the characteristic coats are added to form an artery or a vein. When an artery is injured and permanently occluded, as a general rule the part of the vessel up to the nearest collateral branch becomes obliterated, whereby the derivatives of the endothelial lining, the connective-tissue corpuscles of the wall, and the leucocytes change into spindle-shaped cells, and form a kind of cicatricial tissue. Blind and solid outshoots are always found on the blood vessels of young and adult animals, and are a sign of the continual degeneration and regeneration of these vessels. **Lymphatics** behave in the same way as blood vessels; after removal of a lymphatic gland, a new one may be formed (*Bayer*).

4. The **contractile substance of muscle** may undergo regeneration after it has become partially degenerated. This takes place after amyloid or wax-like degeneration, such as occurs not unfrequently after typhus and other severe fevers. This is chiefly accomplished by an increase of the muscle corpuscles. After being compressed, the muscular nuclei disappear, and at the same time the contractile contents degenerate. After several days, the sarcolemma contains numerous nuclei which reproduce new muscular nuclei and the contractile substance. In fibres injured by a subcutaneous wound, Neumann found that, after five to seven days, there was a bud-like elongation of the cut ends of the fibres, at first without transverse striation, but with striation ultimately. If a large extent of a muscle be removed, it is replaced by cicatricial connective tissue. **Non-striped** muscular fibres are also reproduced; the nuclei of the injured fibres divide after becoming enlarged, and exhibit a well-marked intra-nuclear plexus of fibrils. The nuclei divide into two, and from each of these a new fibre is formed, probably by the differentiation of the perinuclear protoplasm.

5. After a **nerve** is divided, the two ends do not join at once so as to permit the function of the nerve to be established. On the contrary, marked changes occur. If a piece be cut out of a nerve trunk, the peripheral end of the divided nerve degenerates, the axial cylinder and the white substance of Schwann disappear. The interval is filled up at first with juicy cellular tissue. The subsequent changes are fully described in § 325, 4. There seems to be in peripheral nerves a continual disappearance of fibres by fatty degeneration, accompanied by a consecutive formation of new fibres (*Sigm. Mayer*). The regeneration of peripheral **ganglionic cells** is unknown. v. Voit, however, observed that a pigeon, part of whose brain was removed, had within five months reproduced a nervous mass within the skull, consisting of medullated nerve fibres and nerve cells. Eichhorst and Naunyn found that in young dogs, whose spinal cord was divided between the dorsal and lumbar regions, there was an anatomical and physiological regeneration, to such an extent

that voluntary movements could be executed (§ 338, 3). Vaulair, in the case of frogs, and Masius in dogs, found that mobility or motion was first restored, and afterward sensibility. Regeneration of the spinal ganglia did not occur.

6. In many **glands**, the regeneration of their cells during normal activity is very active—sebaceous, mucous, Lieberkühnian, uterine, mammary glands during pregnancy—in others less. If a large portion of a **secretory gland** be removed, as a general rule, it is not reproduced. A gland, if injured, and if suppuration follows, is not regenerated. But the **bile ducts** (§ 173) and the **pancreatic** duct may be reproduced (§ 171). According to Philippeaux and Griffini, if part of the **spleen** be removed it is reproduced (§ 103). Tizzoni and Collucci observed the formation of new liver cells and bile ducts after injury to the **liver** (§ 173), and Pisenti makes the same statement as regards the **kidney.** After **mechanical injury** to the secretory cells of glands (liver, kidney, salivary, Meibomian), neighboring cells undergo proliferation and aid in the restoration of the cells.

7. Among connective tissues, **cartilage,** provided its perichondrium be not injured, reproduces itself by division of its cartilage cells; but usually when a part of a cartilage is removed, it is replaced by connective tissue.

8. When a **tendon** is divided, proliferation of the tendon cells occurs, and the cut ends are united by connective tissue.

9. The reproduction of **bone** takes place to a great extent under certain conditions. If the articular end be removed by excision, it may be reproduced, although there is a considerable degree of shortening. Pieces of bone which have been broken off or sawn off heal again, and become united with the original bone. A **tooth** may be removed, replanted in the alveolus, and become fixed there. If a piece of **periosteum** be transplanted to another region of the body, it eventually gives rise to the formation of new bone in that locality. If part of a bone be removed, provided the periosteum be left, new bone is rapidly reproduced; hence, the surgeon takes great care to preserve the periosteum intact in all operations where he wishes new bone to be reproduced. Even the **marrow** of bone, when it is transplanted, gives rise to the formation of bone. This is due to the osteoblasts adhering to the osseous tissue.

In **fracture of a long bone,** the periosteum deposits on the surface of the ends of the broken bones a ring of substance which forms a temporary support, the **external callus.** At first this callus is jelly-like, soft, and contains many corpuscles, but afterward it becomes more solid and somewhat like cartilage. A similar condition occurs within the bone, where an **internal callus** is formed. The formation of this **temporary callus** is due to an inflammatory proliferation of the connective-tissue corpuscles, and partly to the osteoblasts of the periosteum and marrow. According to Rigal and Vignal, the internal callus is always osseous, and is derived from the marrow of the bone. The outer and inner callus become calcified and ultimately ossified, whereby the broken ends are reunited. Toward the fortieth day a thin layer of bone is formed (**intermediary callus**) between the ends of the bone. Where this begins to be definitely ossified, the outer and inner callus begin to be absorbed, and ultimately the intermediary callus has the same structure as the rest of the bone.

There are many interesting observations connected with the **growth and metabolism of bones.** 1. The addition of a very small amount of *phosphorus* or *arsenious acid* to the food causes considerable thickening of the bones. This seems to be due to the non-absorption of those parts of the bones which are usually absorbed, while new growth is continually taking place. 2. When food *devoid of lime salts* is given to an animal, the growth of the bones is not arrested, but the bones become thinner, whereby all parts, even the organic basis of the bone, undergo a uniform diminution. 3. Feeding with **madder** makes the bones red, as the coloring matter is deposited with the bone salts in the bone, especially in the growing and last formed parts. In birds the shell of the egg becomes colored. 4. The continued use of *lactic acid* dissolves the bones. The ash of bone is thereby diminished. If lime salts be withheld at the same time, the effect is greatly increased, so that the bones come to resemble rachitic bones. (Development of Bone, § 447.)

When a lost tissue is not replaced by the same kind of tissue, its place is always taken by **cicatricial connective tissue.**

When this is the case, the part becomes inflamed and swollen, owing to an exudation of plasma. The blood vessels become dilated and congested, and, notwithstanding the slower circulation, the

amount of blood is greater. The blood vessels are increased, owing to the formation of new ones. Colorless blood corpuscles pass out of the vessels and reproduce themselves, and many of them undergo fatty degeneration, while others take up nutriment and become converted into large uninucleated protoplasm cells, from which giant cells are developed. The newly formed blood vessels supply all these elements with blood.

245. **TRANSPLANTATION OF TISSUES.**—The nose, ear, and even a finger, after having been severed from the body by a clean cut, have, under certain circumstances, become united to the part from which they were removed. The **skin** is frequently transplanted by surgeons, as, for example, to form a new nose. The piece of skin is cut from the forehead or arm, to which it is left attached by a bridge of skin, is then stitched to the part which it is desired to cover in, and when it has become attached in its new situation, the bridge of skin is severed. Reverdin cut a piece of skin into pieces about the size of a pea and fixed them on an ulcerated surface, where they, as it were, took root, grew, and sent off from their margins epithelial outgrowths, so that ultimately the whole surface was covered with epithelium. [White skin transplanted to a negro ultimately becomes pigmented, and black skin transplanted to a white person becomes white.] The excised *spur* of a cock was transplanted and fixed in the comb of the same animal, where it grew (*John Hunter*). P. Bert cut off the tail and legs of rats and transplanted them under the skin of the back of other rats, where they united with the adjoining parts. Ollier found that, when **periosteum** was transplanted, it grew and reproduced bone in its new situation. Even blood and lymph may be transfused (Transfusion, § 102.) [Small portions (1.5 mm.) of epiphyses, costal cartilage, of a rabbit or kitten, when transplanted quite fresh into the anterior chamber of the eye, testis, sub-maxillary gland, kidney, and under the skin of a rabbit, attach themselves and grow, and the growth is more rapid the more vascular the site on which the tissue is transplanted. The cartilage is not essentially different from hyaline cartilage, but the cells are fewer in the centre, while the matrix tends to become fibrous. Small pieces of epiphyseal cartilage introduced into the jugular vein were found as cartilaginous foci in the lungs. Tissues transplanted from embryonic structures grow far better than adult tissues. If a portion of the **cornea** of a rabbit be transplanted to a human eye, provided Descemet's membrane be clear, it will grow and remain clear (*v. Hippell*). A rabbit's nerve has been transplanted to the human subject, but without success.]

Many of these results seem only to be possible between individuals of the *same species*, although Helferich has recently found that a piece of a dog's muscle, when substituted for human muscle, united to the adjoining muscle, and became functionally active. [J. R. Wolfe has transplanted the conjunctiva of the rabbit to the human eye.] Most tissues, however, do not admit of transplantation, *e.g.*, glands and the sense organs. They may be removed to other parts of the body, or into the peritoneal cavity, without exciting any inflammatory reaction; they, in fact, behave like inert foreign matter.

246. **INCREASE IN SIZE AND WEIGHT.**—The **length of the body**, which at birth is usually $\frac{1}{3.5}$ of the adult body, undergoes the greatest elongation at an early period: in the first year, 20; in the second, 10; in the third, about 7 centimetres; while from five to sixteen years the annual increase is about 5½ centimetres. In the twentieth year the increase is very slight. From fifty onward the size of the body diminishes, owing to the intervertebral disks becoming thinner, and the loss may be 6 to 7 centimetres about the eighteenth year. The **weight of the body** ($\frac{1}{20}$ of an adult) sinks during the first five to seven days, owing to the evacuation of the meconium and the small amount of food which is taken at first. Only on the tenth day is the weight the same as at birth.

Age.	Length (Cmtr.).		Weight (Kilo.).		Age.	Length (Cmtr.).		Weight (Kilo.).	
	Man.	Woman.	Man.	Woman.		Man.	Woman.	Man.	Woman.
0	49.6	48.3	3.20	2.91	15	155.9	147.5	46.41	41.30

14	148.7	144.7	40.50	38.10	(Chiefly from Quetelet.)				

The increase of weight is greater in the same time than the increase in length. Within the first year a child trebles its weight. The greatest weight is usually reached about forty, while toward sixty a decrease begins, which at eighty may amount even to 6 kilos. The results of measurements, chiefly by Quetelet, are given on the preceding page.

Between the twelfth and fifteenth years the weight and size of the girl are greater than of the boy. Growth is most active in the last months of fœtal life, and afterward from the sixth to the ninth year until the thirteenth to the sixteenth. The full stature is reached about thirty, but not the greatest weight.

GENERAL VIEW OF THE CHEMICAL CONSTITUENTS OF THE ORGANISM.

247. (A) INORGANIC CONSTITUENTS.—I. Water forms 58.5 per cent. of the whole body, but it occurs in different quantity in the different tissues. The kidneys contain the most water, 82.7 per cent.; bones, 22 per cent.; teeth, 10 per cent.; white enamel contains the least, 0.2 per cent. (§ 229). According to some observers, *peroxide of hydrogen* (H_2O_2) is also present in the body.

[Approximately, **water** forms about two-thirds of the weight of the body, so that a body weighing .75 kilos. (165 lbs.) contains .50 kilos. (110 lbs.) of water. The following table, modified from Beaunis, shows the percentage of water in several tissues and organs:—

Solids.

Tissue or Organ.	Water.	Solids.	Tissue or Organ.	Water.	Solids.	Tissue or Organ.	Water.	Solids.
Enamel,	.2	99.8	Spinal Cord,	69.7	30.3	Thymus,	77.0	23 0
Dentine,	10.0	90.0	White matter of brain,	70.0	30.0	Connective tissue,	79.6	20 4
Bone,	48.6	51.4	Skin,	72.0	28.0	Kidney,	82.7	17.3
Fat,	29.9	70.1	Brain,	75.0	25.0	Gray matter of brain,	85.8	14.2
Elastic tissue,	49.6	50.4	Muscles,	75.7	24.3			
Cartilage,	55.0	45.0	Spleen,	75.8	24.2	Vitreous humor,	98.7	1 3
Liver,	69.3	30.7						

Liquids.

Blood,	79 1	20.9	Lymph,	95.8	4.2	Aqueous humor,	98 6	1.4
Bile,	86.4	13 6	Serum,	95.9	4.1	Cerebro-spinal fluid,	98.8	1.2
Milk,	89.1	10.9	Gastric juice,	97.3	2.7			
Liquor sanguinis,	90.1	9.9	Intestinal juice,	97.5	2.5	Saliva,	99.5	0.5
Chyle,	92.8	7 2	Tears,	98.2	1.8	Sweat,	99.5	0 5

II. Gases.—O, – ozone (§ 37) – H, – N – CO_2 (§ 38). Marsh gas CH_4 (§ 124), NH_3 (§ 30, § 124. § 184), H_2S (§ 184).

III. Salts.—Sodium chloride [is one of the most important inorganic substances present in the body. It occurs in all the tissues and fluids of the body, and plays a most prominent part in connection with the diffusion of fluids through membranes, and its presence is necessary for the solution of the globulins (p. 424). Sometimes it exists in a state of combination with proteid bodies, as in the blood plasma. Common salt is absolutely necessary for one's existence; if it be withdrawn entirely, life soon comes to an end. About 15 grammes are given off in the twenty-four hours, chiefly by the urine. Boussingault showed that the addition of common salt to the food of cattle greatly improved their condition.]

[**Calcium phosphate** ($Ca_3P_2O_8$) is the most abundant salt in the body, as it forms more than one-half of our bones; but it also occurs in dentine, enamel, and to a much less extent in the other solids and fluids of the body. Among secretions, milk contains relatively the largest amount (2.72 per cent.). In milk it is necessary for forming the calcareous matter of the bones of the infant. It gives bones their hardness and rigidity. It is chiefly derived from the food, and, as only a small quantity is given off in the excretions, it seems not to undergo rapid removal from the body.]

[**Sodium phosphate** (PNa_3O_4), *acid sodium phosphate* (PNa_2HO_4), *acid potassium phosphate* (PK_2HO_4). The sodium phosphate and the corresponding potash salt give most of the fluids of the body their alkaline reaction. The alkaline reaction of the blood plasma is partly due to alkaline phosphates, which are chiefly derived from the food. The acid sodium phosphate is the chief cause of the acid reaction of the urine. A small quantity of phosphoric acid is formed in the body owing to the oxidation of lecithin, which contains phosphorus.]

[**Sodium carbonate** (Na_2CO_3) and **sodium bicarbonate** ($NaHCO_3$) exist in small quantities in the food, and are formed in the body from the decomposition of the salts of the vegetable acids.

They occur in the blood plasma, where they play an important part in carrying the CO_2 from the tissues to the lungs.]

[**Sodium and potassium sulphates** (Na_2SO_4 and K_2SO_4) exist in very small quantity in the body, and are introduced with the food, but part is formed in the body from the oxidation of organic bodies containing sulphur.]

[**Potassium chloride** (KCl) is pretty widely distributed, and occurs specially in muscle, colored blood corpuscles, and milk. **Calcium fluoride** ($CaFl_2$) occurs in small quantity in bones and teeth. **Calcium carbonate** ($CaCO_3$) is associated with calcium phosphate in bone, tooth, and in some fluids, but it occurs in relatively much smaller amount. It is kept in solution by alkaline chlorides, or by the presence of free carbonic acid. **Ammonium chloride** (NH_4Cl).—Minute traces occur in the gastric juice and the urine. **Magnesium phosphate** (Mg_3PO_4) occurs along with calcium phosphate, but in very much smaller quantity.]

Table, by Beaunis, of the relative proportions of **Salts.**

Silicic acid,	. .	0.20	0.42	1.27	4.06	. .	0.36	3.13

IV. Free Acids.—**Hydrochloric acid** (HCl) [occurs *free* in the gastric juice, but in combination with the alkalies it is widely distributed as chlorides]. **Sulphuric acid** (H_2SO_4) [is said to occur free in the saliva of certain gasteropods, as Dolium galea. In the body it forms sulphates, chiefly in combination with soda and potash].

V. Bases.—**Silicon** as silicic acid (SiO_2); **manganese, iron,** the last forms an integral constituent of hæmoglobin; **copper** (?), (§ 174).

248. (B) **ORGANIC COMPOUNDS.**—I. The Albuminous or Proteid Substances.—(1) **True Proteids and their allies** are composed of **C, H, O, N,** and **S,** and are derived from plants (see *Introduction*). [The formation of albumin from the elements is accomplished only by plants. What the chemical processes are is quite unknown. We only know that the N is in the first instance obtained from the nitric acid or ammonia of the soil. The former is probably not used directly as such, but serves, perhaps, for the formation of amides or amido acids, from which, by the action of non-nitrogenous bodies, proteids are formed.]

[According to Hoppe Seyler their general percentage composition is—

	O.	H.	N.	C.	S.
From	20.9	6.9	15.2	51.5	0.3
To	23.5	to 7.3	to 17.0	to 54.5	to 2.0.]

They exist in almost all animal fluids and tissues partly in the fluid form, although Brücke maintains that the molecule of albumin exists in a condition midway between a state of imbibition and a true solution—and partly in a more concentrated condition. Besides forming the chief part of muscle, nerve and gland, they occur in nearly all the fluids of the body, including the blood, lymph, and serous fluids, but in *health* mere traces occur in the sweat, while they are absent from the bile and the urine. Unboiled **white of egg** is the type. In the alimentary canal they are changed into peptones. The chief products derived from their oxidation within the body are CO_2, H_2O, and especially **urea**, which contains nearly all the N of the proteids.

Constitution.—Their chemical constitution is quite unknown. The N seems to exist in two distinct conditions, partly loosely combined, so as to yield ammonia readily when they are decomposed, and partly in a more fixed condition. According to Pflüger, part of the N in *living* proteid bodies exists in the form of cyanogen. [Loew supports Pflüger's view that the molecule of living (active) albumin differs from that of dead albumin, as he finds that the living protoplasm of certain algæ can reduce silver in very dilute alkaline solutions, which dead protoplasm cannot do.] The proteid molecule is very large, and is a very complex one; a small part of the molecule is composed of substances from the group of *aromatic* bodies (which become conspicuous during putrefaction), the larger part of the molecule belongs to the *fatty* bodies; during the oxidation of albumin fatty acids especially are developed. *Carbohydrates* may also appear as decomposition products. For the decompositions during digestion see § 170, and during putrefaction § 184. The proteids form a large group of closely related substances, all of which are perhaps modifications of the same body. When we remember that the infant manufactures most of the proteids of its ever-growing body from the casein in milk, this last view seems not improbable.

Characters.—Proteids, the anhydrides of peptones (§ 166) are **colloids** (§ 191), and therefore do not diffuse easily through animal membranes; they are amorphous and do **not crystallize,** and hence are isolated with difficulty; some are soluble, others are insoluble in water; insoluble in alcohol and ether; rotate the ray of polarized light to the *left;* when burned they give the odor of burned horn. Various metallic salts and alcohol precipitate them from their solution; they are **coagulated** by heat, mineral acids, and the prolonged action of alcohol. Caustic alkalies dissolve them (yellow), and from this solution they are precipitated by acids. By powerful oxidizing agents they yield carbamic acid, guanidin, and volatile fatty acids.

Decomposition.—[The number and varieties of these products are exceedingly great, so that it is not easy to separate the several products. In the first place, there is great difficulty in getting in sufficient quantity a perfectly pure proteid, wherewith to institute the necessary experiments. The decomposition products of albumin when acted on by barium hydrate have been most fully investigated. The action of concentrated HCl, potassic permanganate, and bromine has also been studied. The action of the animal or vegetable digestive ferments is very important (§ 170), and especially that of bacteria causing putrefaction (§ 184).] When acted upon in a suitable manner by acids and alkalies, they give rise to the decomposition products—leucin (10 to 18 per cent.), tyrosin (0.25 to 2 per cent.), aspartic acid, glutamic acid, and also volatile fatty acids, benzoic and hydrocyanic acids, and aldehydes of benzoic and fatty acids; also indol (*Hlasiwetz, Hebermann*). Similar products are formed during pancreatic digestion (§ 170) and during putrefaction (§ 184). [Although it is assumed that the proteids have the closest relation to urea, no one, so far, has succeeded in preparing urea by the direct decomposition of albumin. Both by the action of acids and barium hydrate, the splitting up into simpler compounds does not take place at once, but by successive stages, on to the formation of different bodies. Proteids, when fully decomposed, either by acids or alkalies, yield as the final products ammonia, and amido acids; by alkalies also carbonic, acetic, and oxalic acids. The amido acids contain several series including leucin, tyrosin, and glutamic acid. But all proteids do not yield these three bodies, for tyrosin may be absent, while leucin, so far, has been always found. It has therefore been attempted to classify proteids into those that yield tyrosin (*i.e.*, aromatic compounds) and those that do not. Classes I–VII, p. 424, yield when decomposed aromatic bodies (tyrosin, indol, phenol), while gelatin-yielding bodies and spongin yield no aromatic bodies.]

General Reactions.—(1) **Xanthoproteic Reaction.**—Heated with strong nitric acid they give a *yellow,* the addition of ammonia gives a deep orange color.

(2) With **Millon's reagent** they give a precipitate, and when heated with this reagent above

60° C. they give a *red* one, probably owing to the formation of tyrosin. [If the proteids are present in large amount, a red precipitate occurs, but if mere traces are present only the fluid becomes red.]

(3) The addition of a few drops of a dilute solution of **cupric sulphate**, and the subsequent addition of **caustic potash** or soda, give a *violet* color, which depends on boiling; [the same color is obtained by adding a few drops of Fehling's solution (**biuret reaction**)].

(4) They are precipitated after strong acidulation by acetic acid and by potassium ferrocyanide.

(5) When boiled with concentrated hydrochloric acid, they give a violet-red color (**Liebermann's reaction**).

(6) Sulphuric acid containing molybdic acid gives a blue color (*Fröhde*).

(7) Their solution in acetic acid is colored violet with concentrated sulphuric acid, and shows the absorption band of hydrobilirubin (*Adamkiewicz*).

(8) Iodine is a good microscopic reagent, which strikes a brownish yellow, while sulphuric acid and cane sugar give a purplish violet (*E. Schultze*).

[(9) When rendered strongly acid with acetic acid and boiled with an equal volume of a concentrated solution of sodic sulphate, they are precipitated. This method is used for removing proteids from other liquids, as it does not interfere with the presence of other substances. Saturation with sodio-magnesic sulphate precipitates the proteids, but not peptones, and the same is the case with saturation with neutral ammonia sulphate (§ 249).]

[(10) The precipitation of albumin by *acids* is more delicate when the acid is dissolved in alcohol containing 10 per cent. of ether; the precipitate is not dissolved by an excess of the reagent.]

[(11) Most of them are *precipitated* by strong mineral acids, and metaphosphoric acid, tannic acid (in an acid solution), phospho-wolframic and phospho-molybdic acids (in acid solution); potassio-mercuric iodide (in acid solutions); many metallic salts, *e.g.*, of Cu, Pb, Ag, Hg; chloral, phenol, trichloracetic acid, picric acid, alcohol. Taurocholic acid precipitates albumin and syntonin, but not peptone or hemi-albumose (§ 275).]

249. **THE ANIMAL PROTEIDS AND THEIR CHARACTERS.—Class I.—Native Albumins** occur in a natural condition in animal solids and fluids. They are **soluble in water**, and are not precipitated by alkaline carbonates, NaCl, or by very little dilute acids. Their solutions are coagulated by heating at 65° to 73° C. Dried at 40° C., they yield a clear, yellow, amber-colored, friable mass, "**soluble albumin**," which is soluble in water.

(1) **Serum albumin** (§ 32 and § 41).—[Its specific rotatory power is —56°.] Almost all its salts may be removed from it by dialysis, when it is no longer coagulated by heat. It is coagulated by strong alcohol; and not very readily precipitated by hydrochloric acid, while the precipitate so formed is easily dissolved on adding more acid. When precipitated it is readily soluble in strong nitric acid. It is not coagulated when shaken up with ether. The addition of water to the hydrochloric solution precipitates acid albumin. For its presence in urine, see § 264.

(2) **Egg albumin.**—When injected into the blood vessels or under the skin, or even when introduced in large quantity into the intestine, part of it appears unchanged in the urine (§ 192, 4, and § 264). When shaken with ether it is precipitated. These two reactions serve to distinguish it from (1). The specific rotation is —35.5°, *i. e.*, for yellow light. Amount of S, 1.6 per cent.

(**Metalbumin and Paralbumin** have been found by Scherer in ropy solutions in ovarian cysts; they are only partially precipitated by heat. The precipitate thrown down by the action of strong alcohol is soluble in water.)

Class II.—Globulins are native proteids, **insoluble in distilled water**, but **soluble in dilute neu ral saline solutions**, *i.e.*, neutral solutions of the alkalies and alkaline earths, *e.g.*, NaCl, KCl, NH_4Cl, $MgSO_4$, (but not Na_2CO_3, Na_2HPO_4), sodium chloride of 1 per cent., and in magnesium sulphate. These solutions are coagulated by heat, and are precipitated by the addition of a large quantity of water. Most of them are *precipitated* from their sodium chloride solution by the addition of crystals of sodium chloride, and also *by saturating their neutral solution at 30° with crystals of magnesium sulphate.* When acted upon by dilute acids they yield acid albumin, and by dilute alkalies, alkali albumin.

(1) **Globulin** (Crystallin) is obtained by passing a stream of CO_2 through a watery extract of the crystalline lens.

(2) **Vitellin** is the chief proteid in the yolk of egg. It is also said to occur in the chyle (?) and in the amniotic fluid (*Weyl*). Both the foregoing are not precipitated from their neutral solutions by saturation with sodium chloride.

(3) **Paraglobulin** or **Serum globulin** (§ 29), and in urine (§ 264).

(4) **Fibrinogen** (§ 29).—In the clear jelly-like secretion of the vesiculæ seminales of the guinea pig, there is a globulin-like body closely resembling fibrinogen. It contains 29 per cent. of albumin, with scarcely any ash. If it be touched with a trace of blood serum, without mixing them, it gradually and completely forms a solid mass quite like fibrin.

(5) **Myosin** is the chief proteid in dead muscle. Its coagulation in muscle *post-mortem* constitutes rigor mortis. If muscle be repeatedly washed, and afterward treated with a 10 per cent. solution of sodium or ammonium chloride, it yields a viscid fluid which, when dropped into a large

quantity of distilled water, gives a white flocculent precipitate of myosin. It is also precipitated from its NaCl solution by crystals of NaCl. For Kühne's and other methods see § 293.

(6) **Globin** (*Preyer*), the proteid residue of hæmoglobin (§ 18).

Class III.—Derived Albumins (Albuminates).—(1) **Acid albumin or Syntonin.**—When proteids are dissolved in the stronger acids, *e. g.*, hydrochloric, they become changed into acid albumins. They are precipitated from solution by the addition of many salts, sodic chloride, acetate or phosphate, or by neutralization with an alkali, *e. g.*, sodic carbonate, but they are not precipitated by heat. The concentrated solution gelatinizes in the cold, and is redissolved by heat. **Syntonin**, which is obtained by the prolonged action of dilute hydrochloric acid (2 per 1000) upon minced muscles, is also an acid albumin. It is formed also in the stomach during digestion (§ 166, I). According to Soyka, the alkali and acid albumins differ from each other only in so far as the proteid in the one case is united with the base (metal) and in the other with the acid.

(2) **Alkali albumin.**—If egg or serum albumin be acted upon for some time by dilute alkalies, a solution of alkali albumin is obtained. Strong caustic potash acts upon white of egg, and yields a thick jelly, **Lieberkühn's jelly**. The solution is not precipitated by heat, but it is precipitated by the addition of an acid. [Although alkali albumin is precipitated on neutralization, this is not the case in the presence of alkaline phosphates, *e. g.*, sodic phosphate.]

(3) **Casein** is the chief proteid in milk (§ 231.) It is precipitated by acids and by rennet at 40° C. In its characters it is closely related to alkali albuminate, but it contains more N. It contains a large amount of phosphorus (0.83 per cent.). It may be precipitated from milk by diluting it with several times its volume of water and adding dilute acetic acid, or by adding magnesium sulphate crystals to milk and shaking vigorously. Owing to the large amount of phosphorus which it contains, it is sometimes referred to the nucleo-albumins. When it is digested with dilute HCl (0.1 per cent.) and pepsin at the temperature of the body, it gradually yields nuclein.

Class IV.—Fibrin.—(§ 27) and for the fibrin factors (§ 29).

Class V.—Peptones.—For **peptones** and **propeptone** or the **albumoses** (§ 166, I), in urine (§ 264).

Class VI.—Lardacein and Other Bodies.—There fall to be mentioned the "**yelk plates**," which occur in the yelk: **Ichthin** (cartilaginous fishes, frog); **Ichthidin** (osseous fishes); **Ichthulin** (salmon); **Emydin** (tortoise); also the indigestible **amyloid substance** or **lardacein**, which occurs chiefly as a pathological infiltration into various organs, as the liver, spleen, kidneys, and blood vessels. It gives a blue with iodine and sulphuric acid (like cellulose), and a mahogany brown with iodine. It is difficult to change it into an albuminate by the action of acids and alkalies.

Class VII.—Coagulated Proteids.—When any native albumins or globulins are coagulated, *e. g.*, at 70° C., they yield bodies with altered characters, insoluble in water and saline solutions, but soluble in boiling strong acids and alkalies, when they are apt to split up. They are dissolved during gastric and pancreatic digestion to produce peptones.

Appendix: Vegetable Proteid Bodies.—Plants, like animals, contain proteid bodies, although in less amount. They occur either in solution in the juices of living plants or in the solid form. In composition and reaction they resemble animal proteids.

[The **characters** of vegetable proteids have a great resemblance to animal proteids. They have frequently been obtained in a crystalline form, *e. g.*, from the seeds of the gourd and various oleaginous seeds. They occur in greatest bulk in the seeds of plants, **aleurone grains** being for the most part composed of them. In seeds, globulins and "vegetable peptone" form the greater proportion of the proteid constituents.]

[**Globulins.**—These varieties have been described as occurring in the seeds of plants: **vegetable myosin, vitellin** and **paraglobulin** (*Martin*). They have practically the same properties as those found in the animal kingdom; vegetable vitellin has, however, not been sufficiently studied. Paraglobulin has been found in papaw juice (*Martin*). Myosin occurs in the seed of leguminosæ, in flour, and in the potato.]

[**Albumin.**—The existence of a body corresponding to egg or serum albumin in the vegetable kingdom is doubtful (*Kilthausen*). Such a body has been described in papaw juice (*Martin*).]

[**Vegetable Peptone; Albumoses.**—A true peptone has not yet been recognized in plants: what has been described as such is hemi-albumose (*Vines*). Albumoses have been found in the seeds of leguminosæ, in flour, and in papaw juice. In the last, two forms occur, called respectively α- and β- **phytalbumose**. The former, α-phytalbumose, agrees with the hemi-albumose described by Vines, being soluble in cold and boiling water; giving also a biuret reaction, and a precipitate by saturation with sodium chloride only in an acid solution. The latter, β phytalbumose, is soluble in cold, but not in boiling, distilled water; hence it is precipitated by heat. It is also readily thrown down by saturation with sodium chloride, and gives a faint biuret reaction (*Martin*).]

[**Vegetable Casein** is said to occur in the seeds of leguminosæ; and it is slightly soluble in water, but readily so in weak alkalies and in solutions of basic calcic phosphate. A solution of this body is precipitated by acids and rennet. Two varieties have been described—(α) **legumin**, in peas, beans, lentils; acid in reaction, soluble in weak alkalies and very dilute HCl or acetic acid; (β) **conglutin**, a very similar body occurring in hops and almonds. The existence of vegetable casein is denied.

Vines states that both legumin and conglutin are artificial products, being formed from the globulins present by the dilute alkali used in extraction of the proteids. This is denied by Ritthausen.]

[**Gluten and Glutin.**—Gluten is readily prepared from flour by washing and kneading it in a muslin bag under a stream of water. So prepared it is yellowish brown in color, very sticky, and capable of being drawn out into long shreds. It is insoluble in water, soluble (but not completely) by prolonged action in dilute acids and alkalies (.2 per cent. KHO and HCl). The prolonged action of alcohol (80 to 85 per cent.) dissolves part of the substance of gluten, leaving a residue, called by Liebig plant fibrin and by Ritthausen gluten casein. The alcohol contains **gliadin** (glutin), gluten fibrin, and **mucedin.** **Gluten casein** is readily soluble in dilute alkalies, almost insoluble in dilute acetic acid, and quite insoluble in cold and boiling water; the products of its decomposition, by heating with H_2SO_4, are leucin, tyrosin, glutamic, and asparaginic acids. The three bodies dissolved from glutin by alcohol differ chiefly in their solubility in alcohol and water. **Gluten fibrin,** the least soluble, is coagulated by the action of absolute alcohol; it is readily soluble in dilute acids and alkalies, being precipitated by neutralization. **Gliadin** (glutin, plant gelatin) may be prepared by boiling gluten with water: it deposits on cooling the solution Though soluble in water at 100° C. at first, it becomes insoluble by the prolonged action of water at that temperature. It is, like gluten fibrin, soluble in dilute acids and alkalies. **Mucedin** differs from gliadin in being less soluble in strong alcohol. The water used in washing the flour in the preparation of gluten contains hemi-albumose (*Vines*) and a globulin (*Weyl*). Rye flour, as well as wheaten, yields gluten under similar treatment with water.]

[**Nitrogenous Crystalline Principles.**—Leucin, tyrosin, asparagin, and glutamic acid have been found in the seeds of plants.]

250. (2) **THE ALBUMINOIDS.**—These substances closely resemble true proteids in their composition and origin, and are amorphous non-crystalline colloids; some of them do not contain S, but the most of them have not been prepared free from ash. Their reactions and decomposition products closely resemble those of the proteids; some of them produce, in addition to leucin and tyrosin, **glycin** and **alanin** (amido-propionic acid). They occur as organized constituents of the tissues and also in fluid form. It is unknown whether they are formed by oxidation from proteid bodies or by synthesis.

1. **Mucin** is the characteristic substance present in **mucus.** That obtained from the sub-maxillary gland contains—C 52.31, H 7.22, N 11.84, O 28.63. According to Hammarsten it contains S 1.79 and N 13.5 per cent. It dissolves in water, making it sticky or slimy, and can be filtered. It is precipitated by acetic acid and alcohol; and the alcohol precipitate is again soluble in water. It is not precipitated by acetic acid and ferrocyanide of potassium, but HNO_3 and other mineral acids precipitate it. It occurs in saliva (§ 146), in bile, in mucous glands, secretions of mucous membranes, in mucous tissue, in synovia, and in tendons. Pathologically it occurs not unfrequently in cysts; in the animal kingdom, especially in snails and in the skin of holothurians. It yields lucin and 7 per cent. of tyrosin when it is decomposed by prolonged boiling with sulphuric acid. [The precipitate called mucin has not always the same characters, and, in fact, it differs according to the animal from which it is obtained (*Landwehr.*)]

2. **Nuclein** (*Miescher*, § 198)—(C 29, H 49, N 9, P 3, O 22)—contains phosphoric acid, and is slightly soluble in water, easily in ammonia, alkaline carbonates, strong HNO_3; it gives the biuret reaction; no reaction with Millon's reagent; when decomposed it yields phosphorus. It occurs in the nuclei of pus and blood corpuscles (§ 22), in spermatozoids, yelk spheres, liver, brain, and milk, yeast, fungi, and many seeds. It has resemblances to mucin, and is perhaps an intermediate product between albumin and lecithin (*Hoppe-Seyler*). It is prepared by the artificial digestion of pus, when it remains as an indigestible residue; acids precipitate it from an alkaline solution. It gives a feeble xanthoproteic reaction; after the prolonged action of alkalies and acid, substances similar to albumin and syntonin are formed. Hypoxanthin and guanin have been obtained as decomposition products from it (*Kossel*).

3. **Keratin** occurs in all horny and epidermic tissues (epidermic scales, hairs, nails, feathers)—C 50.3–52.5, H 6.4–7, N 16.2–17, O 20.8–25, S 0.7–5 per cent.—is soluble in boiling caustic alkalies, but swells up in cold concentrated acetic acid. When decomposed by H_2SO_4 it yields 10 per cent. leucin and 3.6 per cent tyrosin. **Neuro-keratin** (§ 321).

4. **Fibroin** is soluble in strong alkalies and mineral acids, in ammonio-sulphate of copper; when boiled with H_2SO_4 it yields 5 per cent. tyrosin, leucin, and glycin. It is the chief constituent of the cocoons of insects and threads of spiders.

5. **Spongin,** allied to fibroin, occurs in the bath sponge, and yields, as decomposition products, leucin and glycin (*Stadeler*).

6. **Elastin,** the fundamental substance in elastic tissue, is soluble only when boiled in concentrated caustic potash—C 55–55.6, H 7.1–7.7, N 16.1–17.7, O 19.2–21.1 per cent. It yields 36 to 45 per cent. of leucin and ½ per cent. of tyrosin.

7. **Gelatin** (**Glutin**), obtained from **connective tissues** by prolonged boiling with water; it gelatinizes in the cold—C 52.2–50.7, H 6.6–7.2, N 17.9–18.8, S + O 23.5–25 (S 0.7 per cent.). [The ordinary connective tissues are supposed to contain the hypothetical anhydride **collagen,** while the

organic basis of bone is called **ossein.**] It rotates the ray of polarized light strongly to the left = — 130°. By prolonged boiling and digestion, it is converted into a peptone-like body (gelatin peptone), which does not gelatinize (§ 161, I). [It swells up, but does not dissolve in cold water; when dissolved in warm water, and tinged with Berlin blue or carmine, it forms the usual colored mass which is employed by histologists for making fine transparent injections of blood vessels.] A body resembling gelatin is found in leukæmic blood and in the juice of the spleen (§ 103, I). When decomposed with sulphuric acid it yields glycin, ammonia, leucin, *but no tyrosin.* [It is precipitated from its solution by alcohol, mercuric chloride, metaphosphoric acid, phospho-wolframic acid, taurocholic acid, tannic acid, but the precipitate with the last does not occur when salts are absent. It is readily soluble in dilute acids, even in acetic acid. When boiled with Millon's reagent, it is not colored red. With cupric sulphate and caustic soda it gives a violet color which, on boiling, becomes light red. It gives no color with concentrated H_2SO_4 and acetic acid.]

8. **Chondrin** occurs in the matrix of hyaline **cartilage** and between the fibres in fibro-cartilage. It is obtained from hyaline cartilage and the cornea by boiling. [Its solutions gelatinize on cooling.] It occurs also in the mantle of mollusks—C 49.5–50.9, H 6.6–7.1, N 14.4–14.9, S + O 27.2–29 (S 0.4 per cent.). When boiled with sulphuric acid it yields leucin; with hydrochloric acid, and when digested, chondro-glucose (*Meissner*); it belongs to the glucosides, which contain N. When acted upon by oxidizing reagents it is converted into gelatin (*Brame*). The substance, which yields chondrin is called **chondrogen,** which is perhaps an anhydride of chondrin. The following properties of gelatin and chondrin are to be noted: **Gelatin is precipitated** by tannic acid, mercuric chloride, chlorine water, platinic chloride, and alcohol, but not by acids, alum, or salts of silver, iron, copper, or lead; its specific rotation is = — 130°. [Compare these precipitants with those of albumin.] **Chondrin** is precipitated by acetic acid and dilute sulphuric and hydrochloric acids, by alum, and by salts of silver, iron, and lead; its specific rotation = — 213°.

9 **The hydrolitic ferments** have recently been called **enzymes** by W. Kühne, in order to distinguish them from organized ferments, such as yeast. The enzymes, hydrolytic or organic ferments, act only in the presence of water. They act upon certain bodies, causing them to take up a molecule of water. They all decompose hydric peroxide into water and O. They are most active between 30° to 35° C., and are destroyed by boiling, but when dry they may be subjected to a temperature of 100° without being destroyed. Their solutions, if kept for a long time, gradually lose their properties and undergo more or less decomposition.

(*a*) **Sugar-forming** or **diastatic ferment** occurs in saliva (§ 148), pancreatic juice (§ 170), intestinal juice (§ 183), bile (§ 180), blood (§ 22), chyle (§ 189), liver (§ 174), in human milk (§ 231). **Invertin** in intestinal juice (§ 183). Almost all dead tissues, organic fluids, and even proteids, although only to a slight degree, may act diastatically. Diastatic ferments are very generally distributed in the *vegetable kingdom.*

(*b*) **Proteolytic, or ferments which act upon proteids.**—Pepsin in gastric juice and in muscles (§ 166), in vetches, myxomycetes (*Krukenberg*), trypsin in the pancreatic juice (§ 170), a similar ferment in the intestinal juice (§ 183), and urine (§ 264).

(*c*) **Fat-decomposing** in pancreatic juice (§ 170), in the stomach (§ 166).

(*d*) **Milk-coagulating** in the stomach (§ 166), pancreatic juice (§ 170), and perhaps also in the intestinal juice (?)—(*W. Roberts*).

[The importance of **fermentative processes** has already been referred to in detail under "Digestion." Ferments are bodies which excite chemical changes in other matter with which they are brought into contact. They are divided into two classes:—

(1) **Unorganized**; soluble or non-living.
(2) **Organized,** or living.]

[(1) **The Unorganized Ferments** are those mentioned in the following table. They seem to be nitrogenous bodies, although their exact composition is unknown, and it is doubtful if they have ever been obtained perfectly pure. They are present in many secretions, and are *produced* within the body by the vital activity of the protoplasm of cells. They are termed *soluble* because they are soluble in water, glycerin, and some other substances (§ 148), while they can be precipitated by alcohol and some other reagents. They do not multiply during their activity, nor is their activity prevented by a certain proportion of salicylic acid. They are not affected by oxygen subjected to the compression of many atmospheres (*P. Bert*). They are *non-living.* Their other properties are referred to above.]

[The unorganized ferments present in the body, and their actions (*W. Roberts*):—

Fluid or Tissues.	Ferment.	Actions.
Saliva, ...	1. Ptyalin (§ 148), ...	Converts starch chiefly into maltose.
Gastric juice,	1. Pepsin, ...	Converts proteids into peptones in an acid medium, certain by-products being formed (§ 166).
	2. Milk-curdling, ...	Curdles casein of milk.
	3. Lactic acid ferment, . . .	Splits up milk sugar into lactic acid.
	4. Fat-splitting, ...	Splits up fats into glycerin and fatty acids.
Pancreatic juice,	1. Diastatic or amylopsin, . .	Converts starch chiefly into maltose.
	2. Trypsin, ...	Changes proteids into peptones in an alkaline medium, certain by-products being formed (§ 170).
	3. Emulsive (?), ...	Emulsifies fats.
	4. Fat-splitting or steapsin, . .	Splits fats into glycerin and fatty acids.
	5. Milk-curdling, ...	Curdles casein of milk.
Intestinal juice,	1. Diastatic, ...	Does not form maltose, but maltose is changed into glucose (§ 183).
	2. Proteolytic, ...	Fibrin into peptone (?).
	3. Invertin, ...	Changes cane- into grape sugar.
	4. Milk-curdling, ...	(? in small intestine).
Blood, ... Chyle, ... Liver (?), . . . Milk, ... Most tissues . .	Diastatic ferments	. .
Muscle, . . . Urine, ...	Pepsin and other ferments.	. .
Blood, ...	Fibrin-forming ferment.	. .

[(2) **The Organized** or living ferments are represented by yeast (§ 235). Other living ferments belonging to the schizomycetes, occurring in the intestinal canal, are referred to in § 184. Yeast causes fermentation by splitting up sugar into CO_2 and alcohol (§ 156), but this result only occurs so long as the yeast is *living*. Hence, its activity is coupled with the vitality of the cells of the yeast. If yeast be boiled, or if it be mixed with carbolic or salicylic acid, or chloroform, all of which destroy its activity, it cannot produce the alcoholic fermentation. As yet no one has succeeded in extracting from yeast a substance which will excite the alcoholic fermentation. All the organized ferments grow and **multiply** during their activity at the expense of the substances in which they occur. Thus the alcoholic fermentation depends upon the "life" of the yeast. They are said to be killed by oxygen subjected to the compression of many atmospheres (*P. Bert*). But it is important to note that Hoppe-Seyler has extracted from *dead* yeast (killed by ether) an unorganized ferment which can change cane sugar into grape sugar.]

10. **Hæmoglobin**, the coloring matter of blood, which, in addition to C, H, O, N, and S, contains *iron*, may be taken with the albuminoids (§ 11). [**Hæmocyanin** (§ 32).]

(3) Glucosides containing Nitrogen.

In addition to **chondrin**, the following glucosides containing nitrogen, when subjected to hydrolytic processes, may combine with water, and form sugar and other substances:—

Cerebrin (§ 322) = $C_{87}H_{110}N_2O_{25}$ (*Geoghegan*). [Parcus has shown that cerebrin as originally prepared by W. Müller is a mixture of three bodies, viz., cerebrin, **homocerebrin**, and **encephalin**.]

Protagon—C 66.29, H 10.69, N 2.39, P 1.068, per cent.—occurs in nerves, and contains phosphorus (§ 322).

Chitin, $2(C_{15}H_{26}N_2O_{10})$, is a glucoside containing nitrogen, and occurs in the cutaneous coverings of arthropoda, and also in their intestine and tracheæ; it is soluble in concentrated acids, *e.g.*,

hydrochloric or nitric acid, but insoluble in other reagents. According to Sandwick, chitin is an amin derivative of a carbohydrate with the general formula $n(C_{12}H_{20}O_{10})$. The **hyalin** of worms is closely related to chitin. (Solanin, amygdalin (§ 202), and salicin, etc., are glucosides of the vegetable kingdom.)

(4) Coloring Matters containing Nitrogen.

Their constitution is unknown, and they occur only in animals. They are in all probability derivatives of hæmoglobin. They are (1) **hæmatin** (§ 18, A), **myohæmatin** (§ 232, § 292, *a*), **histohæmatin** (§ 103, IV), and **hæmatoidin** (§ 20). (2) **Bile pigments** (§ 177, 3). (3) **Urine pigments** (except Indican). (4) **Melanin**—$C_{44.2}$, H_3, $N_{9.9}$, $O_{42.6}$—or the black pigment, which occurs partly in epithelium (choroid, retina, iris, and in the deep layers of epidermis in colored races) and partly in connective-tissue corpuscles (Lamina fusca of the choroid). [**Turacin** occurs in the red feathers of Corythaix Buffoni or Plantain Eater. Its ash contains nearly 6 per cent. of copper (*Church*). The reddish spots or parts of feathers burn with a green flame.]

II. Organic Acids free from Nitrogen.

(1) The **fatty acids**, with the formula $C_nH_{2n-1}O(OH)$, occur in the body partly free and partly in combination. Free volatile fatty acids occur in decomposing cutaneous secretions (sweat). In combination, acetic acid and caproic acid occur as amido compounds in glycin (= amido-acetic acid) and leucin (= amido-caproic acid). More especially do they occur united with glycerin to form neutral fats, from which the fatty acid is again set free by pancreatic digestion (§ 170, III).

(2) The acids of the **acrylic acid series**, with the formula $C_nH_{2n-2}O(HO)$, are represented in the body by one acid **oleic acid**, which in combination with glycerin yields the neutral fat olein.

251. FATS.—(1) **Neutral fats** occur very abundantly in animals, but they also occur in all plants; in the latter more especially in the seeds (nuts, almonds, cocoanut, poppy), more rarely in the pericarp (olive) or in the root. They are obtained by pressure, melting, or by extracting them with ether or boiling alcohol. They [*e. g.*, tristearin, $C_{57}H_{110}O_6$] contain much less O than the carbohydrates, such as sugar and starch; they give a greasy spot on paper, and when shaken with colloid substances, such as albumin, they yield an **emulsion**. When treated with superheated steam or with certain ferments (p. 301), they take up water and yield **glycerin** and **fatty acids**, and if the latter be volatile they have a rancid odor. Treated with caustic alkalies they also take up water, and are decomposed into glycerin and fatty acids; the fatty acid unites with the alkali and forms a **soap**, while glycerin is set free. The soap solution dissolves fats.

Glycerin is a triatomic alcohol, $C_3H_5(OH)_3$, and unites with (1) the following monobasic *fatty acids* (those occurring in the body are printed in italics) :—

Acids.	Acids.	Acids.
1. *Formic*, ... CH_2O_2	7. Œnanthylic, . . $C_7H_{14}O_2$	[Margaric, . . $C_{17}H_{34}O_2$
2. *Acetic*, ... $C_2H_4O_2$	8. *Caprylic*, . . . $C_8H_{16}O_2$	is a mixture of
3. *Propionic*, . . . $C_3H_6O_2$	9. Pelargonic, . . . $C_9H_{18}O_2$	13 and 14.]
4. *Butyric*, ... $C_4H_8O_2$	10. *Capric*, ... $C_{10}H_{20}O_2$	14. *Stearic*, ... $C_{18}H_{36}O_2$
[Isobutyric, . . $C_4H_8O_2$]	11. *Laurostearic*, . $C_{12}H_{24}O_2$	15. Arachinic, . . . $C_{20}H_{40}O_2$
5. *Valerianic*, . . $C_5H_{10}O_2$	12. *Myristic*, . . . $C_{14}H_{28}O_2$	16. Hyænic, ... $C_{22}H_{36}O_2$
6. *Caproic*, . . . $C_6H_{12}O_2$	13. *Palmitic*, . . . $C_{16}H_{32}O_2$	17. Cerotinic, . . . $C_{27}H_{54}O_2$

The acids form a homologous series with the formula $C_nH_{2n-1}O(OH)$. With every CH_2 added their boiling point rises 19°. Those containing most carbon are solid, and non-volatile; those containing less C (up to and including 10) are fluid like oil, have a burning acid taste, and a rancid odor. The earlier members of the series may be obtained by oxidation from the later, by CH_2 being removed, while CO_2 and H_2O are formed; thus, butyric acid is obtained from propionic acid. Nos. 13 and 14 are found in human and animal fat, less abundant and more inconstant are 12, 11, 6, 8, 10, 4. Some occur in sweat (§ 287) and in milk (§ 231). Many of them are developed during the decomposition of albumin and gelatin. Most of the above (except 15 to 17) occur in the contents of the large intestine (§ 185).

(2) **Glycerin** also unites with the monobasic **oleic acid**, which also forms a series, whose general formula is $C_nH_{2n-3}O(OH)$, and they all contain 2H less than the corresponding members of the fatty acid series. The corresponding fatty acids can be obtained from the oleic acid series and *vice versâ*. **Oleic acid** (olein elainic acid), $C_{18}H_{34}O_2$, is the only one found in the organism; united with glycerin, it forms the fluid fat, **olein**. The fat of new-born children contains more glyceride of palmitic and stearic acid than that of adults, which contains more glyceride of oleic acid. Oleic acid also occurs united with alkalies (in soaps) and (like some fatty acids) in the lecithins (§ 23). If **lecithin** be acted on with barium hydrate, we obtain insoluble stearic, or oleic, or palmitic acids and barium oleate, together with dissolved **neurin** (§ 322, *b*) and baric glycerin phosphate. It appears as if there were several lecithins, of which the most abundant are the one with stearic acid and that with palmitin + oleic acid radicle (*Diakonow*). Lecithin occurs in the blood corpuscles (§ 23), semen and nerves, while neurin is constantly present in fungi.

The **neutral fats** [palmitin, stearin (both solid), and olein (fluid)], the glycerides of fatty acids, and of oleic acid, are triple ethers of triatomic alcohol glycerin. With the neutral fats may be associated **glycerin-phosphoric acid**, an acid glycerin ether, formed by the union of glycerin and phosphoric acid, with the giving off of a molecule of water ($C_3H_9PO_6$); it is a decomposition product of lecithin (§ 23).

(3) The **glycolic acids** (acids of the lactic acid series) have the formula $C_nH_{2n-2}O(OH)_2$. They are formed by oxidation from the fatty acid series by substituting OH (hydroxyl) for one atom of H of the fatty acids. Conversely, fatty acids may be obtained from the glycolic acids. The following acids of this series occur in the body:—

(*a*) **Carbonic Acid** (oxy-formic acid), $CO(OH)_2$; in this form, however, it only makes salts. Free carbonic acid or carbon dioxide is an anhydride of the same $= CO_2$.

(*b*) **Glycolic Acid** (oxy-acetic acid), $C_2H_2O(OH)_2$, does not occur free in the body. One of its compounds, **glycin** (glycocoll, amido-acetic acid, or gelatin sugar), occurs as a conjugate acid, viz., as glycocolic acid in the bile (§ 177, 2), and as hippuric acid in the urine (§ 260). Glycin exists in complex combination in the gelatin.

(*c*) **Lactic Acid** (oxy-propionic acid) $C_3H_4O(OH)_2$, occur in the body in two isomeric forms—1. The *ethylidene-lactic acid*, which occurs in two modifications—as the right rotatory *sarcolactic acid* (paralactic), a metabolic product of muscle; and as the ordinary optically inactive product of "lactic fermentation," which occurs in gastric juice, in sour milk (sauerkraut, acid cucumber), and can be obtained by fermentation from sugar (§ 184). 2. The isomer, *ethylene-lactic acid*, occurs in the watery extract of muscles (§ 293).

(*d*) **Leucic Acid** (oxy-caproic acid), $C_6H_{12}O_3$, does not occur as such, but only in the form of one of its derivatives, **leucin** (amido-caproic acid), as a product of the metabolism in many tissues, and is formed during pancreatic digestion (§ 170, II). Leucic acid may be prepared from leucin, and glycolic acid from glycin, by the action of nitrous acid.

(4) **Acids of the Oxalic Acid** or **Succinic Acid Series**, having the formula $C_nH_{2n-4}O_2(OH)_2$, are bi-basic acids, which are formed as completely oxidized products by the oxidation of fatty acids and glycolic acid, water being removed. It is important to note their origin from substances rich in carbon, *e.g.*, fats, carbohydrates, and proteids.

(*a*) **Oxalic Acid**, $C_2O_2(OH)_2$, arises from the oxidation of glycol, glycin, cellulose, sugar, starch, glycerin, and many vegetable acids— it occurs in the urine as calcium oxalate (§ 260).

(*b*) **Succinic Acid**, $C_4H_4O_2(OH)_2$, has been found in small amount in animal solids and fluids; spleen, liver, thymus, thyroid; in the fluids of echinococcus, hydrocephalus, and hydrocele, and more abundantly in dog's urine after fatty and flesh food; in rabbit's urine after feeding with yellow turnips. It is also formed in small amount during alcoholic fermentation (§ 150).

(5) **Cholalic Acid** in the bile (§ 177) and in the intestine (§ 182).

(6) **Aromatic Acids** contain the radicle of benzol. **Benzoic acid** (= phenyl-formic acid) occurs in urine united with glycerin, as hippuric acid (§ 260).

III. Alcohols.

Alcohols are bodies which originate from carbohydrates, in which the radical hydroxyl (HO) is substituted for one or more atoms of H. They may be regarded as water, $\left.\begin{matrix}H\\H\end{matrix}\right\}O$, in which the half of the H is replaced by a CH compound. Thus, C_2H_6 (ethyl hydrogen) passes into $\left.\begin{matrix}C_2H_5\\H\end{matrix}\right\}O$ (ethylic alcohol).

(*a*) **Cholesterin**, $\left.\begin{matrix}C_{26}H_{43}\\H\end{matrix}\right\}O$, is a true monatomic alcohol, and occurs in blood, yelk, brain, bile (§ 177, 4), and generally in vegetable cells, and it is the only solid monatomic alcohol in the body.

(*b*) **Glycerin**, $C_3H_5\left\{\begin{matrix}OH\\OH\\OH\end{matrix}\right.$, is a triatomic alcohol. It occurs in neutral fats united with fatty acids and oleic acid; it is formed by the splitting up of neutral fats during pancreatic digestion (§ 170, III), and during the alcoholic fermentation (§ 150).

(*c*) **Phenol** (= phenylic acid, carbolic acid, oxybenzol) (§ 184, III).

(*d*) **Pyrokatechin** (= dioxybenzol) (§ 252).

(*e*) The **Sugars** are closely related to the alcohols, and they may be regarded as poly-atomic alcohols. Their constitution is unknown. Together with a series of closely related bodies they form the great group of the **carbohydrates**, some of which occur in the animal body, while others are widely distributed in the vegetable kingdom.

252. **THE CARBOHYDRATES.**—Occur in plants and animals, and received their name, because in addition to C (at least 6 atoms), they contain H and O, in the proportion in which these occur in water. They are all solid, chemically indifferent, and without odor. They have either a sweet taste (sugars), or can be readily changed into sugars by the action of dilute acids; they rotate the ray of polarized light either to the right or left; as far as their constitution is concerned, they may be regarded as fatty bodies, as hex-atomic alcohols, in which 2H are wanting.

They are divided into the following groups:—

I. Division.—Glucoses ($C_6H_{12}O_6$).—(1) **Grape sugar** (glucose, dextrose, or diabetic sugar) occurs in minute quantities in the blood, chyle, muscle, liver (?), urine, and in large amount in the urine in diabetes mellitus (§ 175). It is formed by the action of diastatic ferments upon other carbohydrates, during digestion. In the **vegetable kingdom**, it is extensively distributed in the sweet juices of many fruits and flowers (and thus it gets into honey). It is formed from cane sugar, maltose, dextrin, glycogen, and starch, by boiling with dilute acids. It crystallizes in warty masses with one molecule of water of crystallization; unites with bases, salts, acids, and alcohols, but is easily decomposed by bases; it **reduces** many **metallic oxides** (§ 149). Fresh solutions have a rotatory power of + 106°. By **fermentation** with yeast it splits up into alcohol and CO_2 (§ 150); with decomposing proteids it splits into 2 molecules of lactic acid (§ 184, I); the lactic acid splits up under the same conditions in alkaline solutions, into butyric acid, CO_2, and H. For the qualitative and quantitative estimation of glucose, see § 149 and § 150. In alcoholic solution, it forms very insoluble compounds with chalk, barium, and potassium, and it also forms a crystalline compound with common salt (Estimation, § 150).

(2) **Galactose**, obtained by boiling milk sugar (lactose) with dilute mineral acids; it crystallizes readily, is very fermentable, and gives all the reactions of glucose. When oxidized with nitric acid it becomes transformed into mucic acid. Its specific rotatory power = + 88.08°.

(3) **Laevulose** (left-fruit-, **invert-**, or mucin sugar) occurs as a colorless syrup in the acid juices of some fruits and in honey; is non-crystallizable, and insoluble in alcohol; specific rotatory power = — 106°. It is formed normally in the intestine (§ 183), and occurs rarely as a pathological product in urine.

II. Division.—This contains carbohydrates with the formula $C_{12}H_{22}O_{11}$, and its members may be regarded as anhydrides of the first division—1. **Milk sugar** or **lactose** occurs only in milk, crystallizes in cakes (with 1 molecule of water) from the syrupy concentrated whey; it rotates polarized light to the right = + 59.3, and is much less soluble in water and alcohol than grape sugar. When boiled with dilute mineral acids it passes into galactose, and can be directly transformed into lactic acid only by fermentation; the galactose, however, is capable of undergoing the alcoholic fermentation with yeast (Koumiss preparation, § 232). For its quantitative estimation (§ 231). Rare in urine (§ 267).

2. **Maltose** ($C_{12}H_{22}O_{11}$) + H_2O (*O'Sullivan*) has 1 molecule of water less than grape sugar ($C_{12}H_{24}O_{12}$), is formed during the action of a diastatic ferment, such as saliva upon starch (§ 148); is soluble in alcohol, right-rotatory power = + 150°; it is crystalline, while its reducing power is only two-thirds that of dextrose. [The ratio of the reducing power of maltose to that of glucose is 100 to 66.]

(3. **Saccharose** (cane sugar) occurs in sugar cane and some plants, it does not reduce a solution of copper, is insoluble in alcohol, is right-rotatory, and not capable of fermentation. When boiled with dilute acids, it becomes changed into a mixture of easily fermentable glucose (right-rotatory) and laevulose (invert sugar, § 183, 5, and § 184, I, 6), which ferments with difficulty and is left-rotatory (§ 183). When oxidized with nitric acid, it passes into glucic acid and oxalic acid.)

(4. **Melitose**, from Eucalyptus manna; **Meleztose**, from Larch manna; **Trehalose** (Mycose), from Ergot: all are right-rotatory, and do not reduce alkaline cupric solutions.)

III. Division.—This contains carbohydrates, with the formula, $C_6H_{10}O_5$, which may be regarded as anhydrides of the second division.

1. **Glycogen**, with a dextro-rotatory power of 211°, does not reduce cupric oxide. It occurs in the liver (§ 174), muscles, many embryonic tissues, the embryonic area of the chick (*Külz*), in normal and pathological epithelium; in diabetic persons it is widely distributed; brain, pancreas, and cartilage; and in the spleen, pancreas, kidney, ovum, brain, and blood, together with a small amount of glucose (*Pavy*). It also occurs in the oyster and some of the mollusks (*Bizio*), and indeed in all tissues and classes of the animal kingdom.

2. **Dextrin** was discovered by Limpricht in the muscles of the horse. It is right-rotatory = + 138°, soluble in water, and forms a very sticky solution, from which it is precipitated by alcohol or acetic acid; it is tinged slightly red with iodine. It is formed in roasted starch (hence it occurs in large quantity in the crust of bread—see *Bread*, § 234), by dilute acids, and in the body by the action of ferments (§ 148). It is formed from cellulose by the action of dilute sulphuric acid. It occurs in beer, and is found in the juices of most plants.

3. **Amylum** or **Starch** occurs in the "mealy" parts of many plants, is formed within vegetable cells, and consists of concentric layers with an eccentric nucleus (Fig. 239). The diameter and characters of starch grains vary greatly with the plant from which they are derived. At 72° C. it swells up in water and forms a mucilage; in the cold, iodine colors it blue. Starch grains always contain more or less cellulose and a substance, **erythrogranulose**, which is colored red with iodine (§ 148). It and *glycogen* are transformed into dextrose by certain digestive ferments in the saliva, pancreatic, and intestinal juices, and artificially by boiling with dilute sulphuric acid.

(4. **Gum**, $C_{10}H_{20}O_{10}$, occurs in vegetable juices (especially in acaciæ and mimosæ), also in the salivary glands, mucous tissue, lungs, and urine; is partly soluble in water (arabin), partly swells

up like mucin (bassorin). Alcohol precipitates it. It is fermentable, and when boiled with dilute acids yields a reducing sugar.)

(5. **Inulin**, a crystalline powder occurring in the root of chicory, dandelion, and specially in the bulbs of the dahlia; it is not colored blue by iodine.)

(6. **Lichenin** occurs in the intercellular substance of Iceland moss (Cetraria islandica) and algæ; is transformed into glucose by dilute sulphuric acid.)

(7. **Paramylum** occurs in the form of granules resembling starch, in the infusoria, Euglena viridis.)

(8. **Cellulose** occurs in the cell walls of all plants (in the exo-skeleton of arthropoda, and the skin of snakes); soluble only in ammonio-cupric oxide; rendered blue by sulphuric acid and iodine. Boiled with dilute sulphuric acid, it yields dextrin and glucose. Concentrated nitric acid mixed

FIG. 239.

a, West Indian arrowroot; *c*, Tahiti arrowroot; *d*, Potato starch.

with sulphuric acid changes it (cotton) into nitro-cellulose (gun cotton), $C_6H_7(NO_2)_3O_5$, which dissolves in a mixture of ether and alcohol and forms **collodion.**)

(9. **Tunicin** is a substance resembling cellulose, and occurs in the integument of the Tunicata or Ascidians.)

IV. Division.—This contains the carbohydrates which do not ferment.

1. **Inosit** (phaseo-mannit, muscle sugar) occurs in muscle (*Scherer*), lung, liver, spleen, kidney, brain of ox, human kidney; pathologically in urine and the fluid of echinococcus. In the vegetable kingdom, in beans (leguminosæ), and the juice of the grape. It is an isomer of grape sugar; optically it is inactive, crystallizes in warts with 2 molecules of water, in long monoclinic crystals; it has a sweet taste, is insoluble in water, does not give Trommer's reaction, is capable of undergoing only the sarcolactic acid fermentation. (Nearly allied are **Sorbin**, from sorbic acid—**Scyllit**, from the intestines of the hag fish and skate—and **Eukalyn**, arising from the fermentation of melitose.)

IV. Derivatives of Ammonia and their Compounds.

The **ammonia derivatives** are obtained from the proteids, and are decomposition products of their metabolism.

(1) **Amines**, *i. e.*, compound ammonias which can be obtained from ammonia (NH_3), or from ammonium hydroxide ($NH_4 — OH$), by replacing one or all the atoms of H by groups of carbohydrates (alcohol radicals). The amine derived from *one* molecule of ammonia is called **monamine.** We are only acquainted with

$\left.\begin{matrix} H \\ H \\ CH_3 \end{matrix}\right\}$ N **Methylamine and Tri-Methylamine.** $\left.\begin{matrix} CH_3 \\ CH_3 \\ CH_3 \end{matrix}\right\}$ N,

as decomposition products of cholin (neurin) and of kreatin. Neurin occurs in lecithin in a very complex combination (see Lecithin, p. 429, and also § 23).

(2) **Amides**, *i. e.*, derivatives of acids, which have exchanged the hydroxyl (HO) of the acids for NH_2. **Urea**, $CO(NH_2)_2$, the bi-amid of CO_2, is the chief end product of the metabolism of the nitrogenous constituents of our bodies (see *Urine*, § 256). Carbon dioxide containing water = $CO(OH)_2$, where both OH are replaced by NH_2—thus we get $CO(NH_2)_2$, urea.

(3) **Amido acids**, *i. e.*, nitrogenous compounds, which show partly the character of an acid and partly that of a weak base, in which the atoms of H of the acid radical are replaced by NH_2, or by the substituted ammonia groups.

(*a*) **Glycin** (or amido-acetic acid, glycocoll, gelatin sugar, § 177, 2) is formed by boiling gelatin with dilute sulphuric acid. It has a sweet taste (gelatin sugar), behaves as a weak acid, but also unites with acids as an amine base. It occurs as glycin + benzoic acid = hippuric acid in urine (§ 260); and also as glycin + cholalic acid = glycocholic acid in bile (§ 177). (*b*) **Leucin**

—(§ 170) = amido-caproic acid. (*c*) **Serin**—(= ? amido-lactic acid) obtained from silk gelatin. (*d*) **Aspartic acid**—(amido-succinic acid); and (*e*) **Glutamic acid**, obtained by the splitting up of proteids (§ 170). Other amido acids are—(*f*) **Cystin** = amido-lactic acid, in which O is replaced by S (§ 268). (*g*) **Taurin**—(§ 177), amido-ethyl-sulphonic acid, occurs (except in certain glands) chiefly in combination with cholalic acid, as taurocholic acid in bile. **Tyrosin** (parahydro-oxyphenyl-amido-propionic acid), an amido acid of unknown constitution, occurs along with leucin during pancreatic digestion (§ 170), is a decomposition product of proteids, and occurs plentifully in the urine in acute yellow atrophy of the liver (§ 269).

To the amido acids are related—(*a*) **Kreatin** in muscle, brain, blood, urine, regarded as methyl-uramido-acetic acid ($C_4H_9N_3O_2$). It has been prepared artificially. When boiled with baryta water, it takes up H_2O, and splits into urea—and (*b*) **Sarkosin** ($C_3H_7NO_2$), methyl-amido-acetic acid. When boiled with water, heated with strong acids, in the presence of putrefying substances, kreatin gives off water, and is changed into **kreatinin** ($C_4H_7N_3O$). This strong base can be rechanged by alkalies into kreatin.

(4) **Ammonia Derivatives of Unknown Constitution.**—**Uric acid** (§ 258); **allantoin** (§ 260), is formed by the oxidation of uric acid by means of potassium permanganate; **cyanuric acid** in dog's urine; **inosinic acid** in muscle; **guanin** in traces in the liver and pancreas, in guano, the excrements of spiders, in the skin of amphibia and reptiles, in the silver sheen of many fishes (*A. Ewald and Krukenberg*) (§ 283); by oxidation it yields urea; **hypoxanthin** or **sarkin** occurs along with **xanthin** in many organs and in urine. Kossel prepared hypoxanthin from nuclein by prolonged boiling of the latter. It may be obtained from fibrin by putrefaction, by gastric and pancreatic digestion, and by dilute acids (*Salomon, H. Krause, Chittenden*); **xanthin** is prepared by oxidation from hypoxanthin. It occurs very rarely in the form of a urinary calculus. **Paraxanthin** in urine and a similar body **carnin** in flesh (§ 233). [**Adenin** ($C_5H_5N_5$), discovered by Kossel in the pancreas, yeast, and tea leaves, has also been isolated from the spleen, lymphatic glands, and kidney; it appears to be present in all highly cellular animal and vegetable tissues. Like the allied bases—xanthin and guanin, it is a derivative of the nuclein of the nuclei.]

Aromatic Substances.

1. **Monatomic phenols**—(*a*) **Phenol** (hydroxyl of benzol) in the intestine (§ 184). Phenyl sulphonic acid in urine (§ 262). (*b*) **Kresol**, in the form of *orthokresol* and *parakresol*, united with sulphonic acid, occur in urine (§ 262). 2. **Diatomic phenols**—(*a*) **pyrokatechin** united with sulphonic acid in urine (§ 262). 3. **Aromatic oxyacids**—(*a*) *Hydroparacumaric acid*; (*b*) *Paraoxyphenylacetic acid* in urine (§ 262). 4. **Indol** and **skatol** in the intestine (§ 184), conjoined with sulphonic acid in urine (§ 262).

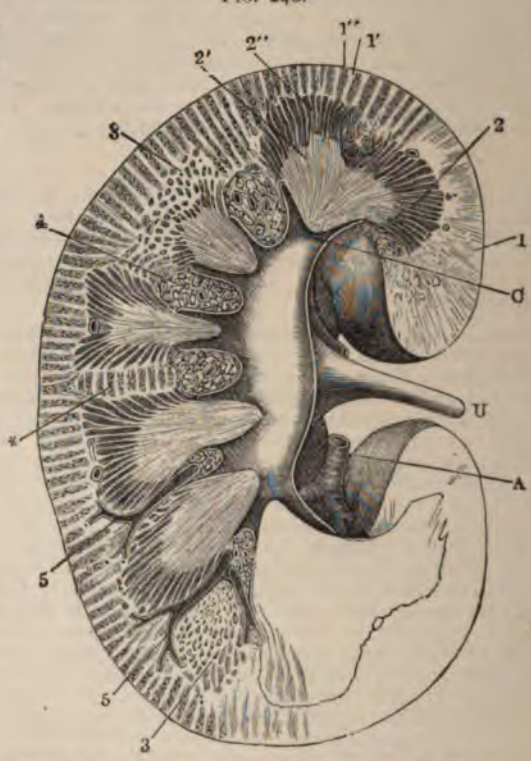
253. **HISTORICAL.**—According to Aristotle, the organism requires food for three purposes—for growth, for the production of heat, and to compensate for the loss of the bodily excreta. The formation of heat takes place in the heart by a process of concoction, the heat so formed being distributed to all parts of the body by means of the blood, while respiration is regarded as an act whereby the blood is cooled. Galen accepted this view in a somewhat modified form; according to him, the metabolic processes may be compared to the processes going on in a lamp; the blood represents the oil; the heart, the wick; the lungs, the fanning apparatus. According to the view of the iatro-chemical school (*van Helmont*), the metabolic processes of the body are fermentations, whereby the food is mixed with the juices of the body. Since the middle of the seventeenth century (*Boyle*), the knowledge of the metabolic processes has followed the development of chemistry. A. v. Haller regarded heat as due to chemical processes—the food continually supplying the waste which is excreted from the body. After the discovery of oxygen (1774, by Priestley and Scheele), Lavoisier formulated the theory of combustion in the lungs, whereby carbonic acid and water were formed. Mitscherlich compared the decomposition processes in the living body with putrefactive processes. Magendie was the first to emphasize the difference between nitrogenous and non-nitrogenous foods, and he showed that the latter alone were not able to support life. Even gelatin alone is not sufficient for this purpose. The greatest advance in the theory of nutrition was made by J. v. Liebig, who laid the foundation of our present knowledge of this subject. According to Liebig, foods may be divided into two classes, viz., the "**plastic**," suitable for the construction of the organism, and the "**respiratory**" for the maintenance of the temperature; to the former class he referred the albuminates or proteids, to the latter, the non-nitrogenous carbohydrates and fats (p. 403). Among recent observers, the Munich School, as represented by v. Bischoff, v. Pettenkofer, and v. Voit, has done most to give us an exact knowledge of this department of physiology.

THE SECRETION OF URINE.

254. STRUCTURE OF THE KIDNEY.—[**Capsule.**—The kidney is a compound tubular gland, and is invested by a thin, tough, fibrous capsule, easily stripped off from the substance of the organ, to which it is attached by fine processes of connective tissue and blood vessels.]

[**Naked Eye Appearances.**—On dividing the kidney longitudinally from the hilum to its outer border, and examining the cut surface with the naked eye, we observe the **parenchyma** of the

FIG. 240.



Longitudinal section through the kidney (*Tyson, after Henle*).

kidney, consisting of an outer **cortical** and an inner **medullary**, or pyramidal portion, the latter composed of about twelve conical papillæ, or **pyramids** of **Malpighi**, with their apices directed toward and embraced by the calices of the pelvis of the kidney (Fig. 240). The medullary portion is further subdivided into the **boundary layer** of Ludwig and the **papillary portion.** According to Klein, the relative proportions of these three parts are—cortex, 3.5; boundary layer, 2.5; and papillary portion, 4. The cortex has a light brown color, and when torn presents a slightly granular aspect, with radiating lines running at regular distances. The granules are due to the presence of the

Malpighian corpuscles, and the striæ to the medullary rays. The boundary zone is darker, and often purplish in color. It is striated with clear and red lines alternating with opaque ones, the former being blood vessels and the latter uriniferous tubules. The papillary zone is nearly white and uniformly striated, the striæ converging to the apex of the pyramid. The medulla is much denser and less friable than the cortex, owing to the presence of a large amount of connective tissue between the tubules. The bundles of straight tubes of the medulla may be traced at regular intervals running outward into the cortex, constituting **medullary rays,** which become smaller as they pass outward in the cortical zone, so that they are conical and form the **pyramids of Ferrein** (Fig. 241, PF). The portion of the cortex lying between the medullary rays is known as the **labyrinth,** from the complicated arrangement of its tubules.]

FIG. 241.

[**Size, Weight.**—The adult kidney is about 11 centimetres (4.4 inches) in length, 5 centimetres (2 inches) wide, and 3 centimetres (1 inch) in thickness. It weighs in the male 113.5 to 170 grms. (4 to 6 oz.), in the female 113.5 to 156 grms. (4 to 5½ oz.). The width of the cortex is usually 5 to 6 millimetres (⅕ to ¼ inch).]

I. The **uriniferous tubules** all rise within the labyrinth of the cortex by means of a globular enlargement, 200 to 300 μ [$\frac{1}{130}$ to $\frac{1}{85}$ inch] in diameter, called **Bowman's capsule** (Figs. 242, 243). After pursuing a complicated course, altering their direction, diameter, and structure, and being joined by other tubules, they ultimately form large collecting tubes, which terminate by minute apertures, visible with the aid of a hand lens, on the apices of the papillæ projecting into the calices of the kidney. Each urinary tubule is composed of a homogeneous **membrana propria,** lined by epithelial cells, so as to leave a lumen for the passage of the urine from the Malpighian corpuscles to the pelvis of the kidney. The diameter and direction of the tubules vary, and the epithelium differs in its characters at different parts of the tube, while the lumen also undergoes alterations in its diameter.

Course and Structure of the Tubules.—In the labyrinth of the cortex, tubules arise in the spherical enlargement known as **Bowman's capsule** (Fig. 242, 1), which invests (in the manner presently to be described) the tuft of capillary blood vessels called a **glomerulus** or **Malpighian corpuscle.** By means of a short and narrow **neck** (2) the capsule becomes continuous with a convoluted tubule, X in Fig. 243. This tubule is of considerable length, forming many windings in the cortex (Fig. 242, 3); the first part of it is 45 μ wide, constituting the **proximal** or first **convoluted tubule.** It becomes continuous with a **spiral tubule** of Schachowa (4), which lies in a medullary ray where it pursues a slightly wavy or spiral course. On the boundary line between the cortical and boundary zone, the spiral tubule suddenly becomes smaller and passes into the **descending portion of Henle's loop** (5), which is 14 μ in breadth, and is continued downward through the boundary zone into the medulla, where it forms the narrow **loop of Henle** (6), which runs backward in the medullary part to the boundary zone. Here it becomes wider (20–26 μ), and as it continues its undulating course, it enters a medullary ray, where it constitutes the **ascending looped tube** (7), which becomes narrower in the cortex. Leaving the medullary ray again, it passes into the labyrinth, where it forms a tube with irregular angular outlines—the **irregular tubule** (10), which is continuous with (Fig. 243, *n*, *n*) the **second** or **distal convoluted tubule** (11), which resembles the proximal tubule of the same name. Its diameter is 40 μ. A short, narrow, wavy **junctional** or **curved collecting** tubule (12) connects the latter with one of the **straight collecting tubes** (13) of a medullary ray. As the collecting tubule proceeds through the boundary zone, it receives numerous junctional tubes, and when it reaches the boundary zone, it forms one of the **collecting tubes** (Fig. 243, O), which unite with one another at acute angles to form the larger straight **excretory tubes** or ducts of Bellini (15), which open on the summit of

the Malpighian pyramids into a calyx of the pelvis of the kidney. In the cortex the collecting tubules are 45 μ in diameter, but where they have formed an excretory tube (O), their diameter is 200 to 300 μ; 24 to 80 of these tubes open on the apex of each of the 12 to 15 Malpighian pyramids. In the lowest and broadest part, the membrana propria is strengthened by the presence of a thick supporting framework of connective tissue.

Structure of the Tubules.—[Below the neck, the tubules are lined everywhere by a **single** layer of nucleated **epithelium.**] **Bowman's capsule**, which is about $\frac{1}{250}$ inch in diameter (Fig. 244, II), consists of a homogeneous basement membrane lined internally by a single continuous layer of flattened cells (*k*). According to Roth, the basement membrane itself is composed of

FIG. 242.

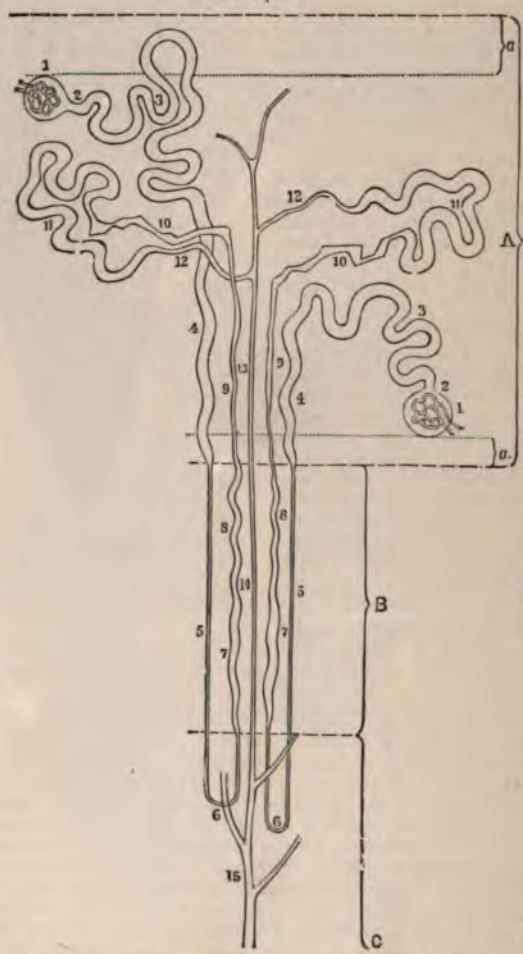

Diagram of the course of two uriniferous tubules (*Klein and Noble-Smith*).

endothelial cells. [In the fœtus the lining cells are more polyhedral.] Within the capsule lies the glomerulus or tuft of blood vessels. The cells lining the capsule are reflected over and between the lobules of which the glomerulus consists. The glomerulus may not completely fill the capsule, so that, according to the activity of the kidney, there may be a larger or smaller space between the glomerulus and the capsule into which the filtered urine passes. The **neck** is lined by cubical cells. These cells, in some animals, *e. g.*, the rabbit, sheep, mouse, and frog, are ciliated.

The **proximal convoluted tubule** is lined by characteristic epithelium. The cells, which are short or polyhedral, contain a turbid or cloudy protoplasm (Fig. 244, III, 1 and 2), which not

unfrequently contains oil globules, and they form a single layer. Each cell consists of two parts; the inner, containing the spherical nucleus, is next the lumen, and granular (III, 2, *g*), while the outer part, next the membrana propria, appears fibrillated, or "**rodded**," from the presence of rods or fibrils placed vertically to the basement membrane (Fig. 245). These appear like the hairs of a brush pressed upon a plate of glass (III, 2). The cells are not easily separated from each other, as neighboring cells interlock by means of the branched ridges on their surfaces (III, 1)—(*Heidenhain, Schachowa*). The lumen is well defined, but its size seems to depend upon the state of imbibition of the cells bounding it.

The **spiral tubule** has similar epithelium and a corresponding lumen, although the epithelium becomes lower and somewhat altered in its characters at the lower part of the tube.

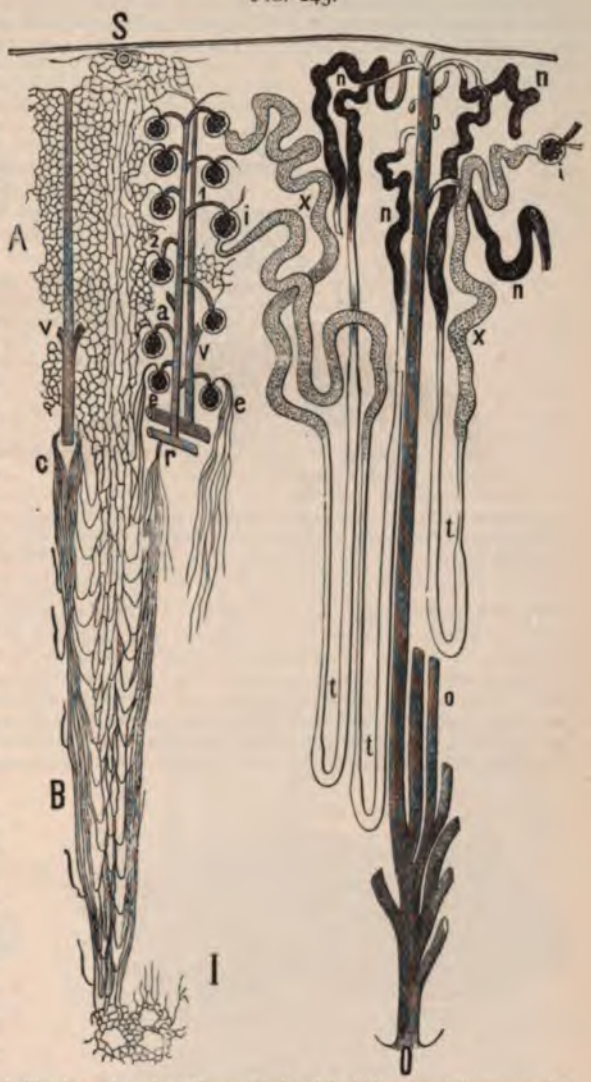
The **descending limb of Henle's loop**, and the **loop** itself with a relatively wide lumen, are bounded by clear, flattened, epithelial cells, with a bulging nucleus (IV, S); the cells lying on one side of the tube being so placed that the bulging part of the bodies of the cells is opposite the thin part of the cells on the opposite side of the tube. [These tubes might be mistaken for blood capillaries, but in addition to their squamous lining, they have a basement membrane, which capillaries have not.] In the **ascending limb**, the lumen is relatively wide, while its epithelium agrees generally with that in the convoluted tubule, excepting that the "rods" are shorter. Sometimes the cells are arranged in an "imbricate" manner.

In the **irregular tubule**, which has a very small lumen, the polyhedral cells lining it contain oval nuclei, and are shorter than those of the convoluted tubules. The cells, again, are very irregular in size, while their "rodded" character is much coarser and more defined (Fig. 246).

The **distal convoluted tubule** closely resembles in its structure the proximal convoluted tubule, and is lined by similar cells. The *curved collecting*, or **junctional tubule**, although narrow, has a relatively wide lumen, as it is lined by clear, somewhat flattened cells.

The **collecting tubes** have a distinct lumen, and are lined by *clear*, somewhat irregular, cubical cells (Fig. 244, V), which in the larger *excretory* tubes are distinctly columnar (VI). The basement membrane is said to be absent in the larger tubes. [Klein describes a thin, delicate, nucleated, centro-tubular membrane lining the surface of the epithelium next the lumen.]

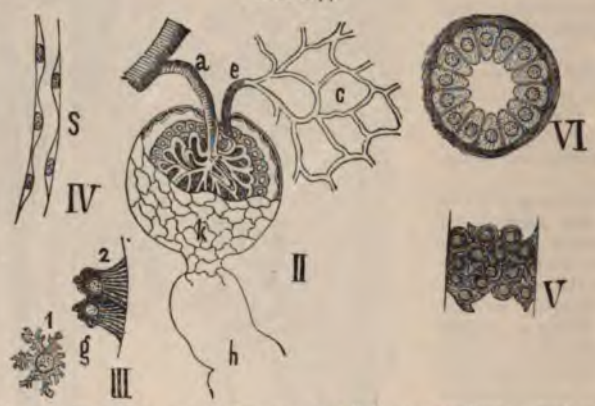
FIG. 243.



I, Blood vessels and uriniferous tubules of the kidney (semi-diagrammatic); A, capillaries of the cortex, B, of the medulla; *a*, inter-lobular artery; 1, vas afferens; 2, vas efferens; *r*, *e*, vasa recta; *c*, venæ rectæ; *v*, *v*, inter-lobular vein; S, origin of a vena stellata; *i*, *i*, Bowman's capsule and glomerulus; X, X, convoluted tubules; *t*, *t*, Henle's loop; *n*, *n*, junctional piece; *o*, *o*, collecting tubes; O, excretory tube.

II. The Blood Vessels.—The **renal artery** (Fig. 250) divides into four or five branches, which pass into the kidney at the hilum. These branches, surrounded by connective tissue continuous with that of the capsule, continue to divide, and pass between the papillæ, to reach the bases of the pyramids on the limits between the cortical and boundary zones, where they form incomplete arches. From these horizontal trunks, the **inter-lobular arteries** (Fig. 243, *a*) run vertically and singly into the cortex, between each two medullary rays, and in their course they give off on all sides the short, undivided **vasa afferentia** (1), each of which enters a Malpighian capsule at the opposite pole from which the urinary tubule is given off. Within the capsule, each afferent artery breaks up into capillaries arranged in lobules and supported by connective tissue, the whole forming a tuft of capillary blood

FIG. 244.



II, Bowman's capsule and glomerulus. *a*, vas afferens; *e*, vas efferens; *c*, capillary network of the cortex; *k*, endothelium of the capsule; *h*, origin of a convoluted tubule. III, "rodded" cells from a convoluted tubule—2, seen from the side, with *g*, inner granular zone; 1, from the surface. IV, cell lining Henle's looped tubule. V, cells of a collecting tube. VI, section of an excretory tube.

vessels, or a **glomerulus.** Each glomerulus is covered on its surface, directed toward the wall of the capsule by a layer of flat, nucleated, epithelial cells (Fig. 229, II), which also dip down between the capillaries. A vein, the **vas efferens** (2), which is always smaller than the afferent arteriole, proceeds from the centre of the glomerulus, and leaves the capsule close to the point at which the afferent vessel enters it (Fig. 244, II). In their structure and distribution all the efferent vessels resemble arteries, as they divide into branches to form a dense, narrow-meshed **capillary network** (Fig. 243, A, and Fig. 244, II, *c*), which ramifies over and between the convoluted tubules. The meshes are elongated around the tubules of the medullary rays, and more polygonal around the convoluted tubules

FIG. 245.

Convoluted tubule (after ammonium chromate) showing "rodded" epithelium.

FIG. 246.

Epithelium of an irregular tubule of the kidney of a dog.

(Fig. 243). Some of the lowest efferent vessels split up into **vasa recta,** which run toward the medulla. The interlobular arteries become smaller as they pass toward the surface of the kidney, and some of their terminal capillaries communicate with the capillaries of the external capsule itself. Venous trunks proceed from the capillary network, to terminate in the **inter-lobular veins** (V), which begin close under the capsule by venous radicals arranged in a stellate manner (constituting the stellulæ Verheynii, or **venæ stellatæ**), and accompany the corresponding artery to the limit between the cortex and boundary zone, where they communicate with the large venous trunks in that situation.

The **blood vessels of the medulla** arise from the **vasa recta** (Fig. 243, *r*), which begin on the limit of the cortex and medulla, either as single, direct, muscular branches (*r*) of the large arterial

trunks, or from those efferent vessels (*e*) which lie next to the medulla. The latter are said to be devoid of muscle. According to Huschke, a few vasa recta are formed by the union of the capillaries of the medullary rays. All the vasa recta enter the boundary layer, where they split up into a leash or pencil of small arterioles, which pass between the straight tubules toward the pelvis, and form in their course a capillary network with elongated meshes. From these capillaries there arise venous radicles, which, as they proceed toward the limit between the cortex and medulla, form the **venæ rectæ** (*c*), and open into the concave side of the venous trunks in this region. At the apex of the papillæ, the capillaries of the medulla form connections with the rosette-like capillaries surrounding the excretory ducts (at 1).

[The circulation through the vasa recta is most important. The cortical system of blood vessels communicates with the medullary, but as most of the vasa recta are derived from the same vessel as the interlobular arteries, it is evident that they may form a side stream through which much of the blood may pass without traversing the vessels of the cortex. Very probably the "short cut" is useful in congestions of the kidney. The amount of distention of these vessels also will influence the size of the tubules lying between them. There are two other channels by which blood can pass through the renal arteries without traversing the glomeruli (1) The anastomoses between the terminal twigs of the renal artery and the subcapsular venous plexus; (2) small branches given off, either by the interlobular arteries or by the afferent vessels before entering the glomeruli (*Brunton*).]

The **blood vessels of the external capsule** are derived partly from the terminal twigs of the interlobular arteries, partly from branches of the suprarenal, phrenic, and lumbar arteries, which anastomose with each other. The capillary network has simple meshes. The venous radicles pass partly into the venæ stellatæ, and partly into the veins of the same name as the arteries. The connection of the area of the renal artery with the other arteries of the capsule explains why, after ligature of the renal artery within the kidney, the blood still circulates in the external capsule (*C. Ludwig, M. Herrmann*); in fact, these blood vessels still supply the kidney with a small amount of blood, which may suffice to permit a slight secretion of urine to take place (*Litten, Pautynski*).

III. The **lymphatics** form a wide-meshed plexus in the capsule of the kidney, while under it they form large spaces (*Heidenhain*). In the parenchyma of the kidney, the lymphatics are said to be represented by large slits devoid of a wall in the tissues, and are more numerous around the convoluted than the straight tubules. The slits pass to the surface of the kidney, and expand under the capsule. When the lymphatics are greatly distended, they tend to compress the uriniferous tubules and the blood vessels (*C. Ludwig and Zawarykin*). According to Ryndowsky, the uriniferous tubules are surrounded by true lymphatics with an endothelial lining, and they even penetrate into the capsule of Bowman along with the vas afferens. [The large blood vessels are also surrounded by lymphatics]. Large lymphatics, provided with valves, pass out of the kidneys at the hilum, while others emerge through the capsule; both sets are connected with the lymph spaces of the capsule of the kidney (*A. Budge*).

IV. The **nerves** form small trunks provided with **ganglia**, and accompany the blood vessels. [They are derived from the renal plexus and the lesser splanchnic nerve.] They contain medullated and non-medullated fibres, and the latter have been traced by W. Krause as far as the apices of the papillæ. Their mode of termination is unknown. *Physiologically*, we are certain that they contain both *vasomotor* and *sensory* fibres; perhaps there may be also vaso-dilator and secretory fibres.

V. The **connective tissue**, or interlobular stroma, forms in the papillæ, especially at their apices, fibrous, concentric layers of considerable thickness between the excretory tubules (Fig. 247). Further outward, the fibrillar character becomes less distinct, while at the same time branched connective-tissue corpuscles occur in greater numbers. In the cortex, the interstitial stroma consists almost entirely of branched corpuscles, which anastomose with each other.

FIG. 247.

Transverse section of apex of Malpighian pyramid. *a*, large collecting tubes; *b*, *c*, *d*, tubules of Henle; *e*, *f*, blood capillaries.

[There is also a small quantity of delicate fibrous tissue around Bowman's capsule, and along the course of the arteries. The connective tissue often plays an important rôle in pathological conditions of the kidney, as interstitial nephritis.] The outer layers of the capsule of the kidney are composed of dense bundles of fibrous tissue, while the deeper layers are more loose, and send processes into the cortical layers. The capsule is easily stripped off. None of the secretory substance is removed with it. Under the capsule in the human kidney, there is a thin plexus of **non-striped muscular fibres.** At the hilum it becomes continuous with the outer fibrous coat of the dilated upper end of the ureter. Smooth muscular fibres also occur in a sphincter-like arrangement round the apex of each papilla, while others proceed from the pelvis between the pyramids along the blood vessels (*Jardet*). The **fat** surrounding the kidney is united to the latter partly by blood vessels and partly by bands of connective tissue. [The subcapsular layer of the cortex, and a thin layer next the boundary zone (Fig. 242, *a*, *a*,), are devoid of Malpighian corpuscles.]

[**Development of a Malpighian Capsule.**—The upper end of the urinary tubule is dilated and closed, and into it there grows a tuft of blood vessels (*a*) pushing one layer of the tube before it (*b*), hence the capillaries become invested by it, just as an organ is surrounded by a serous sac, so that one layer—the reflected one (*b*)—of the tubule is closely applied to the blood vessels, while the other (*c*) lies loosely over it with a space between the two (Fig. 248).]

255. THE URINE.—Physical Characters.—A knowledge of the composition of this secretion is of the greatest value to the physician and surgeon.

1. The **quantity** of urine passed by an adult man in twenty-four hours is between 1000 and 1500 cubic centimetres, or about **50 ozs.**, and in the female 900 to 1200 c.c. The minimum is secreted between 2 to 4 A. M., and the maximum between 2 to 4 P. M. (*Weigelin*).

The amount is **diminished** by profuse sweating, diarrhœa, thirst, non-nitrogenous food, diminution of the general blood pressure, after severe hemorrhage, and in some diseases of the kidneys. The minimum, which may be normal, is 400 to 500 c.c. It is **increased** by increase of the general blood pressure, or of the pressure within the area of the renal artery, by copious drinking, contraction of the cutaneous vessels through the action of cold, the passage of a large amount of soluble substances (urea, salts, and sugar) into the urine, a large amount of nitrogenous food, as well as by various drugs, such as digitalis, alcohol, squills. After taking fluids charged with CO_2, the amount of urine is increased during the following hours (*Quincke*).

The secretion is influenced directly by the **nervous system**, as in the sudden **polyuria** following nervous excitement, such as hysteria [when the person usually passes a large amount of very pale-colored urine]; after an epileptic attack, and also after pleasureable excitement (*Beneke*). We may have polyuria unaccompanied by the presence of sugar in the urine, which follows injury to a certain part of the floor of the fourth ventricle (*Cl. Bernard*). The urine is measured in tall graduated cylindrical vessels (Fig. 249). [In estimating the quantity of urine passed, the patient must, of course, be directed always to empty his bladder at a particular hour, and collect the urine passed during the next twenty-four hours.]

2. The **specific gravity** varies, as a mean, between 1015 and 1025; the minimum, after copious draughts of water, may be 1002; while the maximum, after profuse perspiration and great thirst, may be 1040. The mean specific gravity is about 1020. In newly-born children, the specific gravity falls very considerably during the first three days, which is due to the amount of food taken (*Martin and Ruge*). [The specific gravity of the urine in **infants** is about 1003 to 1006.] A healthy adult excretes about 70 grms. [2½ oz.] daily of solids by the urine, or about 1 grm. of solids per 1 kilo. of body weight.

The **specific gravity is estimated** by means of a urinometer (Fig. 250), the urine being at the temperature of 16° C. [The **urinometer**, when placed in distilled water, ought to float at the mark 0° or zero, which is conventionally spoken of as 1000. Place the urine to be tested in a tall cylindrical glass, of such width that the urinometer, when placed in it, may float freely and not touch the sides. Take care that no air bubbles adhere to the instrument. When reading off the mark on the stem, raise the vessel to the eye and bring the eye on a level with the surface of the water, noting the number which corresponds to this. This rule is adopted because the water rises on the stem in virtue of capillarity. It is essential that a sample of the **mixed urine** of the twenty-four hours be used for ascertaining the mean specific gravity.]

Christison's Formula.—To estimate the amount of solids in the urine. This may be done approximately by means of the formula of Trapp or Haeser, or, as it is called in this country, "Christison's formula," viz., "Multiply the two last figures of a specific gravity expressed in four figures by 2.33" (*Christison and Haeser*), or by 2 (*Trapp*), or 2.2 (*Loebisch*). This gives the

of solids in every 1000 parts. [Suppose a person passes 1200 c.c. urine in twenty-four and the specific gravity is 1022, then

$$22 \times 2.33 = 51.26 \text{ grms. in 1000 c.c.}$$

ertain the amount in 1200 c.c.

$$1000 : 1200 :: 51.26 : \times = \frac{51.26 \times 1200}{1000} = 61.51. \text{ grms.}]$$

ct Estimation of Solids.—Place 15 c.c. of urine in a capsule of known weight, and evapo- over a water bath, afterward completely dry the residue in an air bath at 100° C., and then over concentrated sulphuric acid. During the process a small amount of urea is decomposed, the value obtained is slightly too small. Of course the specific gravity varies with the amount er in the urine. The *most concentrated* (highest specific gravity) urine is the morning urine

FIG. 248.

velopment of a glomerulus and Malpighian capsule. *a*, capillary; *b*, visceral; *c*, parietal layer of capsule.

FIG. 249.

Graduated cylinder and flask for measuring the amount of urine.

FIG. 250.

Urinometer.

a notis), especially after being retained in the bladder, *e.g.*, in prolonged sleep a certain nt of ater is absorbed, so that the urine becomes more concentrated. The most dilute urine reted aer copious drinking (**Urina potus**). Under **pathological conditions**, as in diabetes us (§ 15), the urine is, at the same time, very copious (as much as 10,000 c.c.), and very con- ted, while the specific gravity varies from 1030 to 1060 [due to the presence of a large amount pe sug]. In fever the urine is concentrated, and small in amount. In polyuria, due to cer- ervous onditions, the urine is very dilute and copious, while the specific gravity may be as low 01.

The **olor** of the urine depends on the coloring matters present in it, and s great, but the differences in color are due chiefly to variations in the amount ater. lormally it has a pale straw color, but if it contains more water than

usual it has a very pale tint, and in certain cases (as in the sudden polyuria occurring after an attack of hysteria) it may be as clear as water. Concentrated urine, as after meals, or the first urine passed in the morning, has a darker color; it is a dark yellow or brownish red; while it is usually dark colored in fever.

Fœtal urine, and also the urine first passed after birth, are as clear and colorless as water. The admixture of various substances with the urine alters its color. When mixed with **blood**, according to the degree of decomposition of the hæmoglobin, the urine is red or dark brownish red [more frequently it is *smoky*], especially if the blood comes from the kidneys and the urine is acid. When mixed with **bile pigments**, it is of a deep yellowish brown, with an intense yellow froth; senna taken internally makes it intensely red, rhubarb brownish yellow, and carbolic acid black. Urine undergoing the ammoniacal fermentation may present a dirty bluish appearance, owing to the formation of indigo. The color of urine is estimated by Neubauer and Vogel by means of an empirical "color scale."

Urine, but especially ammoniacal urine, exhibits **fluorescence**, which disappears on the addition of an acid, and reappears after the addition of an alkali.

Normal urine, after standing for several hours, deposits a fine cloud of vesical **mucus** [like delicate cotton wool]. The froth of normal urine is white, and disappears pretty rapidly, while that on an albuminous urine perists much longer. The urine not unfrequently contains some **epithelial cells** from the bladder and urethra.

4. **Consistence.**—Normal urine, like water, is a freely mobile fluid.

Large quantities of sugar, albumin or mucus make it less mobile; while the so-caled chylous urine of warm climates may be like a white jelly.

5. The **taste** is a saline bitter; the **odor** is characteristic and aromatic.

Ammoniacal urine has the odor of ammonia. Turpentine taken internally gives rise to the odor of violets, copaiba and cubebs a strongly aromatic, and asparagus an unpleasant odor. Valerian, assafœtida, and castoreum [but not camphor] also produce a characteristic odor. [The odor of diabetic urine is described as "sweet."]

6. The **reaction** of normal urine is **acid**, owing to the presence of acid salts, chiefly **acid sodic phosphate**, which seems to be derived from basic sodic phosphate, owing to the uric acid, hippuric acid, sulphuric acid, and $C0_2$ taking to themselves part of the soda, so that the phosphoric acid forms an acidsalt. After a diet of flesh, acid potassic phosphate is the cause of the acidity. That the urine

contains no free acid is proved by the fact that it gives no precipitate with sodic hyposulphite (*v. Voit, Huppert*).

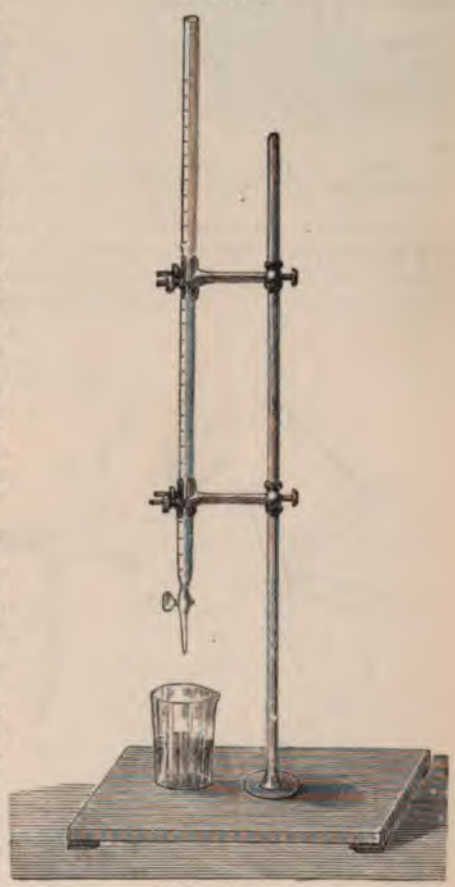
The acid reaction is **increased** after the use of acids, *e.g.*, hydrochloric and phosphoric, also by ammoniacal salts, which are changed within the body into nitric acid; lastly, after prolonged muscular exertion. The morning urine is strongly acid.

The urine becomes **less acid or alkaline**—(1) By the use of caustic alkalies, alkaline carbonates, or alkaline salts of the vegetable acids, the last being oxidized within the body into carbonates. (2) By the presence of calcic, or magnesic carbonate. (3) By admixture with alkaline blood, or pus. (4) By removing the gastric juice through a gastric fistula (p. 291, *Maly*); further, from one to three hours after a meal. [The reaction of urine passed **during digestion** may be neutral, or even alkaline. This is due either to the formation of acid in the stomach (*Bence Jones*), or to a fixed alkali derived from the basic alkaline phosphates taken with the food (*W. Roberts*).] (5) The urine is rarely alkaline in anæmia, owing to a deficiency of phosphoric and sulphuric acids. [(6) The *nature of the food*—vegetable food makes it alkaline. (7) By profuse sweating. (8) By absorption of alkaline transudations (blood, serum).]

[**Method.**—The reaction of urine is tested by means of litmus paper. Normal urine turns blue litmus paper red, and does not affect red litmus. An alkaline urine makes red litmus paper blue, while a neutral urine does not alter either blue or red litmus paper.] Sometimes *violet* litmus paper is used, which becomes red in acid, and blue in alkaline urine.

Estimation of the Acidity.—This is done by determining the amount of caustic soda necessary to produce a neutral reaction in 100 c.c. of urine. A soda solution, containing 0.0031 grm. of soda in each c.c. is used; 1 c.c. of this solution exactly neutralizes 0.0063 grm. oxalic acid. To the 100 c.c. of urine in a beaker, soda solution is added, drop by drop, from a graduated burette (Fig. 251), until violet litmus paper becomes neither red nor blue. The number of c.c. of soda solution is now read off on the burette, and as each c.c. corresponds to 0.0063 grm. oxalic acid, we can easily calculate the amount of oxalic acid which is equivalent to the degree of acidity in 100 c.c. of urine. So that the degree of acidity of the urine is expressed by the equivalent amount of oxalic acid, which is completely neutralized by the same amount of caustic soda.

FIG. 251.



Graduated Burette.

Urine of Mammals.—The urine of **carnivora** is pale, passing into a golden yellow; its specific gravity is high, and its reaction strongly acid. The urine of **herbivora** is alkaline; it shows a precipitate of earthy carbonates (hence, it effervesces on the addition of an acid), and of basic earthy phosphates. During hunger, the urine presents the character of that of carnivora, as the animal in this case practically lives upon its own flesh and tissues.

256. I. THE ORGANIC CONSTITUENTS OF URINE.—Urea, $CO(NH_2)_2$, the diamide of CO_2, or carbamid, is the chief end product of the oxidation of the nitrogenous constituents of the body. Its composition is comparatively simple: 1 carbonic acid + 2 ammonia — 1 water. It **crystallizes** in silky four-sided prisms with oblique ends (rhombic system), without water of crystallization (Fig. 252, 1), if it crystallizes rapidly it forms delicate white needles. It has no action on litmus, is odorless, and has a weak, bitter, cooling taste, like

saltpetre; is readily soluble in water and alcohol, but insoluble in ether. It is an isomer of ammonium cyanate, from which it may be prepared by evaporation, whereby the atoms rearrange themselves (*Wöhler*, 1828). It can be prepared artificially in many other ways.

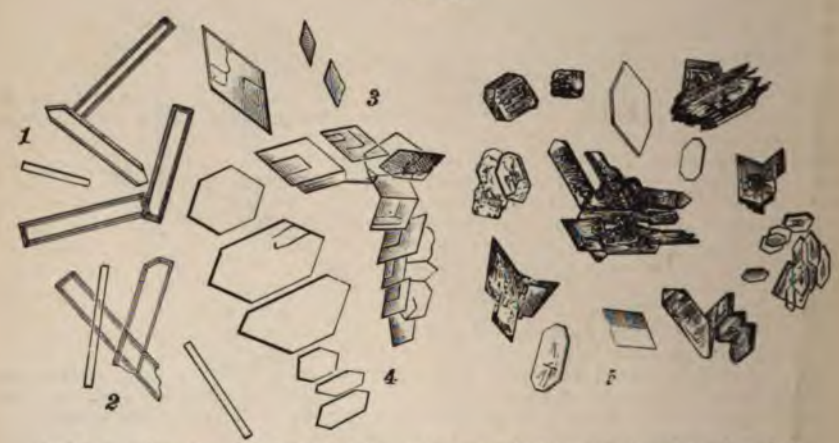
Decomposition.—When heated above 120°, it gives off ammonia vapor, while a glassy mass of biuret and cyanic acid is left. When urine undergoes the alkaline fermentation (§ 263), or when urea is treated with strong mineral acids, or boiled with the hydrates of the alkalies, or superheated with water (240° C.), it takes up two molecules of water and produces ammonium carbonate, thus—

$$CO(NH_2)_2 + 2H_2O = CO(NH_4O)_2.$$

When brought into relation with nitrous acid, it splits up into water, CO_2, and N. The two last decompositions are made the basis of methods for the quantitative estimation of urea (§ 257).

Quantity.—In normal urine, urea occurs to the extent of 2.5 to 3.2 per cent. An **adult** man excretes daily from 30 to 40 grms. [500 grains, or a little over 1 oz.]; women less, **children** relatively more; owing to the relatively greater metabolism in children, the unit weight of body produces more urea than the unit weight of an

FIG. 252.



1, 2, Prisms of pure urea; 3, rhomboidal plates; 4, hexagonal tablets; 5, 6, irregular scales and plates of urea nitrate.

adult, in the proportion of 1.7 : 1. If the metabolism of the body is in a condition of equilibrium (§ 236), the urea excreted contains almost as much N as is taken in with the nitrogenous constituents of the food.

Variations in the Quantity.—The amount of urea increases when the amount of proteids in the food is increased; and also when there is a more rapid breaking up of the nitrogenous tissues of the body itself. As this breaking up is increased by diminution of O, and by loss of blood, so these conditions also increase the urea (§ 41). It is also increased by drinking large draughts of water, by various salts, by frequent urination, and by exposure to compressed air. In diabetic persons, who eat very large quantities of food, it may exceed 100 grms. [over 3 oz.] per day; during hunger it sinks to 6.1 grms. [90 grains] per day During inanition, the maximum amount is excreted toward mid-day, and the minimum in the morning. The daily amount of urea varies with the quantity of urine; three to five hours after a meal, the formation of urea is at a maximum, when it sinks and reaches its minimum during the night. **Muscular exercise**, as a rule, does not increase it (*v. Voit, Fick and Wislicenus*—§ 295), but only when deficiency of O, causing dyspnœa, occurs at the same time (*Oppenheim*).

Pathological.—In acute febrile inflammations, and in fevers generally (§ 22, 3), the urea increases until the crisis is reached, and afterward it diminishes. After the fever has passed off, the amount excreted is often under the normal. In some cases of high fever, although the amount of urea formed is increased, it may not be excreted; there is a *retention of the urea*, which, later on, may lead to an increased excretion (*Naunyn*). In *chronic diseases*, the amount depends largely upon the state of the nutrition, the metabolism, and also upon the degree of fever present. Degenerative changes in the liver, *e.g.*, due to poisoning with phosphorus, may be accompanied by diminished excretion of urea and increased excretion of ammonia (*Stadelmann*). It is increased in man by morphia, narcotin, narcein, papaverin, codein, thebain (*Fubini*), arsenic (*Gäthgens*), compounds of antimony, and small doses of phosphorus (*Bauer*), which favor the decomposition of proteids, and by substances which increase the bile formation in the liver (*N. Paton*). Quinine, which "spares" the proteids, diminishes it.

Occurrence.—Urea occurs in the blood (1 : 10,000), lymph, chyle (2 : 1000), liver, lymph glands, spleen, lungs, brain, eye, bile, saliva, amniotic fluid, and pathologically in sweat, *e.g.*, in cholera, in the vomit and sweat of uræmic patients, and in dropsical fluids.

Formation.—It is certain that it is the chief end product of the metabolism of the **proteids.** Less oxidized products are uric acid, guanin, xanthin, hypoxanthin, alloxan, allantoin. Uric acid administered internally appears in the urine as urea; alloxan and hypoxanthin can be changed directly into urea. The urea excretion is increased by the administration of leucin, glycin, aspartic acid, or ammonia salts (*Schulzen, Nencki*). As yet it has not been definitely determined where urea is formed, but the **liver** and, perhaps, the lymph glands, are organs where it is produced (§ 178).

In **birds**, the liver forms uric acid from ammonia. The liver can be readily excluded from the circulation in birds, and Minkowski found that after this operation the uric acid was diminished and the ammoniacal salts were increased (§ 178).

Antecedents.—During digestion, the proteids are converted into leucin, tyrosin, glycin, and aspartic acid. If the amido acids, glycin, leucin, or aspartic acid, or ammoniacal salts, be given to an animal, the amount of urea excreted is increased. As the molecule of the amido acids contains only one atom of N, and the molecule of urea contains two of N, it is probable that urea may be formed *synthetically* from these acids. It is possible that the amido acids meet with nitrogenous residues in the juices of the body, *e. g.*, carbamic acid or cyanic acid. The union of these may produce urea. According to Salkowski, feeding with these substances causes the breaking up of the proper proteids of the body so as to provide the necessary components. Schmiedeberg is of opinion that urea is formed in the body from ammonia carbonate by the removal of water; and v. Schröder found that, when he passed blood containing ammonia carbonate through a fresh liver, the urea in the blood was greatly increased Drechsel succeeded in producing urea at ordinary temperatures by the rapid alternating oxidation and reduction of a watery solution of ammonia carbonate. [We know that the greater part of the urea exists in the blood, and that the renal epithelium removes it from the blood. Although it is surmised that some of the nitrogenous bodies named above, more especially leucin, and perhaps also kreatin, are the precursors of urea, yet we cannot say definitely how or where the transformation takes place. Perhaps this is effected in the liver, and, it may be, also in the spleen (§ 193).]

Preparation.—Urea may be prepared from **dog's urine** (especially after a diet of flesh) by evaporating it to a syrupy consistence, extracting it with alcohol, and again evaporating the filtrate to a syrupy consistence. The crystals which separate are washed with water to remove any extractives that may be mixed with them, and dissolved in absolute alcohol. It is then filtered, and allowed to crystallize slowly. Or, **human urine** may be evaporated to one-sixth of its volume and cooled to 0°, and excess of strong nitric acid added, which precipitates urea nitrate mixed with coloring matter. This precipitate is pressed in blotting paper, then dissolved in boiling water containing animal charcoal, and filtered while hot. When it cools, colorless crystals of urea nitrate separate (Fig. 252). These crystals are redissolved in warm water, and barium carbonate added until effervescence ceases; urea and barium carbonate are formed. Evaporate to dryness, extract with absolute alcohol, filter, and allow evaporation to take place, when urea separates.

Compounds of Urea.—Urea combines with acids, bases, and salts. The following are the most important combinations:—

1. **Urea nitrate** (CH_4N_2O, HNO_3) is easily soluble in water, and not so soluble in water containing nitric acid. It forms characteristic rhombic crystals (Fig. 252, 3, 4, 5, 6). Sometimes the formation of these crystals is used to determine **microscopically** the presence of urea in a fluid. If a fluid is suspected to contain minute traces of urea, it is concentrated and a drop of the fluid is put on a microscopic slide. A thread is placed in the fluid, and the whole is covered with a cover-

glass. A drop of concentrated nitric acid is allowed to flow under the cover-glass, and after a time crystals of urea nitrate adhering to the thread may be detected with the microscope.

2. **Urea oxalate** ($CH_4N_2O)_2$, $C_2H_2O_4 + H_2O$, is made by mixing a concentrated solution of urea with oxalic acid. The crystals form groups of rhombic tables, often of irregular shape. It is only slightly soluble in cold water, and still less so in alcohol (Fig. 253).

3. **Urea phosphate** (CH_4N_2O, H_3PO_4), forms large, glancing, rhombic crystals, very easily soluble in water. It is obtained by evaporating the urine of pigs fed on dough.

4. **Sodic chloride + urea** (CH_4N_2O, $NaCl + H_2O$) forms rhombic, shining prisms, which are sometimes deposited in evaporated human urine.

5. **Urea + mercuric nitrate** is obtained as a white cheesy precipitate, when mercuric nitrate is added to a solution of urea. Liebig's titration method for urea depends on this reaction (§ 257, II).

257. QUALITATIVE AND QUANTITATIVE ESTIMATION OF UREA.—I. The qualitative Estimation of Urea.—(1) *It may be isolated as such.* If *albumin* be present, add to the fluid three or four times its volume of alcohol, and, after several hours, filter. Evaporate the filtrate over a water bath, and dissolve the residue in a few drops of water.

(2) The crystals of **urea nitrate** may be detected microscopically (Fig. 252).

II. Quantitative Estimation.—(1) **Sodic hypobromite** decomposes urea into CO_2, H_2O, and N. On this reaction depends the Knop-Hüfner method of quantitative estimation. The N rises in

FIG. 253.

Perfect crystals of oxalate of urea.

FIG. 254.

Ureameter of Charteris.

the form of small bubbles in the mixed fluid, while the CO_2 is absorbed by the caustic soda. [The reaction is the following:—

$$N_2H_4CO + 3NaBrO = 3NaBr + CO_2 + 2H_2O + N.$$

The nitrogen is collected and estimated in a graduated tube, and the amount of urea calculated from the volume of nitrogen. The uric acid is also decomposed, but that can be estimated separately and a correction made. We may use the apparatus of Russell and West, or Dupré, or that of Charteris (Fig. 254).]

[**Ureameter.**—Make a solution of hypobromite of soda by mixing 100 grammes NaHO in 250 c. c. of water, and adding 25 c. c. of bromine. It is better to be made fresh, as it decomposes by keeping. The graduated tube is placed in a cylindrical vessel, filled with water, and depressed until the zero on the tubes coincides with the level of the water. Introduce 15 c. c. of the hypobromite solution into the pyramidal-shaped bottle, while into a short test-tube are placed 5 c. c. of urine. The test-tube with the urine is introduced into the bottle by means of a pair of forceps in such a way that it does not spill. Close the bottle tightly with the caoutchouc stopper, through which passes a glass tube to connect it with the graduated burette. Incline the bottle so as to allow the urine to mix with the hypobromite solution when the gases are given off, and pass into the collecting tube, which is gradually raised until the surfaces of the liquids, outside and in, coincide. Time should be allowed to permit the whole apparatus to have the same temperature. Read off the amount of gas N

evolved, for the CO_2 is absorbed by the caustic soda. The collecting tube is usually graduated beforehand, so that each division of the tube is = 0.1 per cent. of urea, or 0.44 gr. per fluid oz. Thus, suppose that 50 oz. of urine are passed in twenty-four hours, and that 5 c. c. of urine evolve 18 measures of N, then $0.44 \times 18 \times 50 = 396$ grs. of urea. If, however, the tube be graduated into c. c., then 30.3 c. c. of N = 0.1 grm. of urea at the ordinary temperature and pressure.]

III. Volumetric Method (*Liebig*).—By means of a graduated pipette (Fig. 255), 40 cubic centimetres of the urine are placed in a beaker; add 20 cubic centimetres of **barium mixture** to precipitate the sulphuric and phosphoric acids. The barium mixture consists of 1 vol. of a cold saturated solution of barium nitrate and 2 vols. of a cold saturated solution of barium hydrate. Filter through a *dry* filter, and take 15 cubic centimetres of the filtrate, *which correspond to* 10 c. c. *of urine*, and place in a beaker. Allow a titrated **standard solution** of **mercuric nitrate** to drop from a burette into the urine until a precipitate no longer occurs. The mercuric nitrate is made of such a strength that 1 cubic centimetre of it will combine with 10 milligrammes of urea. Test a drop of the mixture from time to time in a watch glass or piece of glass blackened on its under surface, with a solution of **sodic carbonate**, which is called the **indicator**. Whenever the slightest excess of mercuric nitrate is added, the mixture strikes a *yellow* color with the soda. The standard solution must be added drop by drop until this result is obtained. Read off the number of cubic centimetres of the standard solution used; as each centimetre corresponds to 10 milligrammes of urea, multiply by ten, and the amount of urea in 10 cubic centimetres of urine is obtained.

FIG. 255.

Graduated Pipette.

This method does not give quite accurate results even in normal urine. To urine containing much phosphates is added an equal volume of the barium mixture. Very acid urines may require several volumes to be added. Urine containing albumin or blood must be boiled, after the addition of a few drops of acetic acid, to remove the albumin. The sodic chloride in the urine also interferes with the accuracy of the process, as on adding mercuric nitrate to urine, mercuric chloride and sodic nitrate are formed, so that the urine does not combine until the sodic chloride is decomposed. When the urine contains, as is usually the case, 1 to 1½ per cent. NaCl, deduct 2 c. c. from the number of c. c. of the S.S. added to 10 c. c. of urine.

Estimation of the total N in Urine.—Pflüger and Bohland recommend the following modification of the method of *Kjeldahl*. Five c.c. of a urine of medium concentration are allowed to flow from a burette into Erlenmeyer's flask, capable of containing about 300 c.c., and to it are added 20 c.c. of concentrated sulphuric acid. The whole is boiled until all the water and gases are driven off. The fluid at first becomes black from the action of the sulphuric acid, but when it has become of brownish tone lessen the heat of the Bunsen burner. About half an hour suffices to heat it, when the fluid at last becomes bright yellow. Allow it to cool, dilute it with water to 200 c.c., and place the whole in a flask, add 80 c.c. of caustic soda (S.g. 1.3), cork the flask as quickly as possible, and distill its contents. The distillate must pass over into sulphuric acid, which must be titrated beforehand. The quantity of sulphuric acid not combined with ammonia must be estimated by titration with caustic soda.

The **N in the Urine** may be estimated approximately thus. To 10 c.c. of the urine add from a burette Liebig's mercuric nitrate solution, and test the mixture in a black glass plate with dry sodic bicarbonate until a yellow speck remains. Multiply the number of c.c. of the burette fluid used by 0.04 (*Pflüger and Bohland*).

258. URIC ACID = $C_5H_4N_4O_3$ is the nitrogenous substance which, next to urea, carries off most of the N from the body; in twenty-four hours 0.5 grm. (7 to 10 grains); during hunger, 0.24 grm. (4 grains); after a strongly animal diet, 2.11 grm. (30 to 35 grains) are excreted. The proportion of urea to uric acid is 45 : 1. If a mammal be fed with uric acid, part of it becomes more highly oxidized into urea, while the oxalic acid in the urine is also increased (§ 260); in fowls, feeding with leucin, glycin, or aspartic acid (*v. Knieriem*), or ammonia carbonate (*Schroeder*), increases the amount of uric acid. When urea is administered to fowls, it is *reduced* chiefly to uric acid.

It is the chief nitrogeneous product in the urine of birds, reptiles, and insects, while it is absent from herbivorous urine.

Properties.—It is dibasic, colorless, and crystallizes in various forms (Figs. 256 and 257), belonging to the **rhombic system** (1). When the angles are rounded, the *whetstone* form (2) is produced, and if the long surfaces be flattened, six-sided tables occur. Not unfrequently diabetic urine deposits spontaneously, large, yellow, transparent rosettes (6, 8). If 20 c.c. of HCl, or acetic acid, be added to 1 litre of

urine, crystals (9) are deposited, like cayenne pepper, on the surface and sides of the glass, *after several hours*. [The HCl decomposes the urates, and liberates the acid, which does not crystallize at once, owing to the presence of the phosphates in the urine. Crystals of uric acid are usually yellowish in color from the pigment of the urine, and they are soluble in caustic potash.]

Solubility.—It is tasteless and odorless; reddens litmus; is soluble in 18,000 parts of cold and in 15,000 of boiling water, and insoluble in alcohol and ether. Horbaczewski prepared it synthetically by melting together glycin, or, as it is also called, glycocin, and urea. It is freely soluble in alkaline carbonates, borates, phosphates, lactates, and acetates, these salts at the same time removing a part of the base; thus, there are formed acid urates and acid salts from the neutral salts. It is soluble in concentrated sulphuric acid, from which it may be precipitated by the addition of water.

Decomposition.—During dry distillation it decomposes into urea, cyanuric acid, hydrocyanic acid, and ammonium carbonate. Superoxide of lead converts it into urea, allantoin, oxalic acid, and CO_2; while ozone forms the same substances, with the addition of alloxan. When it is reduced by H *in statu nascendi*, as by sodium amalgam, it forms xanthin and sarkin. It is a less oxidized metabolic product than urea, but it is by no means proved that uric acid is a precursor of urea.

FIG. 256.

Forms of uric acid. 1, Rhombic plates; 2, whetstone forms; 3, quadrate forms; 4, 5, prolonged into points; 6, 8, rosettes; 7, pointed bundles; 9, barrel forms precipitated by adding hydrochloric acid to urine.

Occurrence.—Uric acid occurs dissolved in the urine in the form of **acid urates of soda and potash.** These salts occur also in urinary calculi, gravel, and in gouty deposits. Ammonium urate occurs in very small quantity in a deposit of **"urates,"** but is formed in considerable amount when urine becomes ammoniacal from decomposition (Fig. 261). *Free uric acid* occurs in normal urine only in the very smallest amount. It is sometimes deposited *after a time* (Fig. 260). It frequently forms urinary calculi and gravel.

The urine of newly-born children contains much uric acid. Uric acid and its salts are **increased** after severe muscular exertion, accompanied by perspiration, in catarrhal and rheumatic fevers, and such conditions as are accompanied by disturbance of the respiration; in leukæmia and tumors of the spleen, cirrhotic liver, and generally in cases of catarrah of the stomach and intestinal tract, following the excessive use of alcohol. [It is also increased during ague and fevers, and perhaps this has some relation to the congestion of the spleen which accompanies these conditions.] It is **diminished** after copious draughts of water, after large doses of quinine, caffein, potassic iodide, common salt, sodic and lithic carbonates, sodic sulphate, inhalation of O, slight muscular exertion. In gout, the amount excreted in the urine is small. In chronic tumors of the spleen, anæmia, and chlorosis, when the respiration is not at the same time embarrassed, it is also diminished.

Urates.—Uric acid forms salts—chiefly *acid* urates—with several bases, which dissolve with difficulty in cold water, but are easily soluble in warm water. Neutral urates are changed by CO_2 into acid salts. Hydrochloric and acetic acids break up the compounds, and crystals of uric acid separate.

(1) **Acid sodic urate** usually appears as a brick-red deposit in urine; more rarely gray or white (lateritious deposit), tinged with uroërythrin, in catarrhal conditions of the digestive organs, and in rheumatic and febrile affections. **Microscopically,** it is completely amorphous, consisting of granules, sometimes disposed in groups (Fig. 260, *b*)—sometimes the granules have spines on them. The corresponding potash salt occurs not unfrequently under the same conditions, and presents the same characters.

(2) **Acid ammonium urate** (Fig. 261, *a*) always occurs as a sediment in ammoniacal urine, either with (1), or mixed with free uric acid, accompanied by a triple phosphate. Microscopically, it is the same as (1). (1) *and* (2) *are distinguished by the sediment dissolving when the urine is heated.* If a drop of hydrochloric acid be added to a microscopic preparation of the sediment, crystals of uric acid separate.

(3) **Acid calcic urate** occurs sometimes in calculi, and is a white, amorphous powder, slightly soluble in water. When heated on platinum it leaves an ash of calcium carbonate. Magnesium urate rarely occurs in urinary calculi.

259. ESTIMATION OF URIC ACID.—I. Qualitative.—1. Microscopic Characters.—The appearances presented by uric acid and its salts under the microscope. It is deposited from urine after several hours, on adding acetic or hydrochloric acid.

2. **Murexide Test.**—Gently heat a urate or uric acid in a porcelain vessel along with nitric acid. Decomposition takes place and the color changes to yellow. N and CO_2 are given off; urea and alloxan ($C_4H_2N_2O_4$) remain. Evaporate slowly and allow the yellowish-red stain to cool; on adding a drop of dilute ammonia a *purplish-red* color of murexide is obtained, it becomes blue on the addition of caustic potash. If potash or soda be added instead of ammonia, a violet color is obtained.

3. **Schiff's Test.**—Dissolve uric acid or a urate in a solution of an alkaline carbonate, and drop it upon blotting-paper saturated with a solution of *silver nitrate;* reduction of the silver takes place at once, and a black spot is formed.

4. On boiling a solution of uric acid or a urate in an alkali, with Fehling's solution (§ 149, 2), at first white urate of the suboxide of copper is deposited, while later, red copper suboxide is formed.

II. Quantitative Estimation.—Add 5 cubic centimetres of concentrated HCl to 100 c.c. of urine, and allow it to stand for forty-eight hours in the dark, when the uric acid is precipitated like fine cayenne pepper crystals. All the uric acid is not precipitated by the HCl, even after standing for a time. [E. A. Cook uses sulphate of zinc to precipitate the uric acid as urate of zinc. Caustic soda is added to precipitate the phosphates, and then to the clear fluid zinc sulphate solution, which precipitates urate of zinc as a white gelatinous deposit.]

Fokker-Salkowski Method.—Make 200 c.c. of urine strongly alkaline with sodic carbonate, and after an hour add 200 c.c. of a concentrated solution of ammonium chloride, whereby acid urate of ammonium is precipitated. After forty-eight hours filter, through a small weighed filter, and wash it several times. Fill the filter with dilute HCl and collect the filtrate. Do this until all the acid urate is dissolved. From the total filtrate after a time all the uric acid separates. It is collected in the same filter, washed with water and alcohol until the acid reaction disappears, dried at 100° C. and weighed. To the weight in excess of the filter add 0.030 grm.

260. KREATININ AND OTHER SUBSTANCES.—**Kreatinin,** $C_4H_9N_3O_2$, is derived from the kreatin of muscle by the removal of a molecule of water, and partly from flesh food. The **quantity** excreted daily is 0.6 to 1.3 gramme (8 to 18 grains).

It is **diminished** in progressive muscular atrophy, tetanus, anæmia, marasmus, chlorosis, consumption, paralysis; and is **increased** in typhus, inflammation of the lung; it is absent from the urine of sucklings.

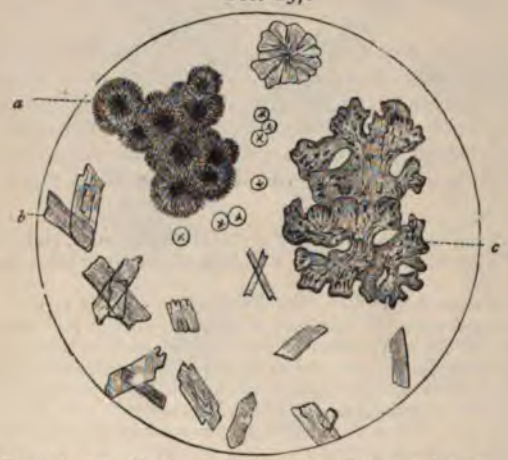
Properties.—Kreatinin is alkaline, easily soluble in water and hot alcohol. It forms colorless, oblique rhombic columns; unites with acids and salts, silver nitrate, mercuric chloride, and especially with *zinc chloride.* **Kreatinin-zinc chloride** (Fig. 257) is used to detect its presence. **Weyl's Test.**—Add to urine a few drops of a slightly brownish solution of nitro-prusside of soda, and then weak caustic soda solution, producing a Burgundy-red color, which soon disappears.

When heated with glacial acetic acid, the color changes to green, which after a time changes to blue (*Salkowski*). [The blue color—Berlin blue—is due to the formation of an iron salt, ferrocyanide of sodium, from the decomposition of the nitro-prusside. The reaction also succeeds with formic acid—instead of glacial acetic acid—if some time be allowed to elapse after Weyl's reaction.]

Xanthin = $C_5H_4N_4O_2$ occurs only to the amount of 1 gramme in 300 kilos. of urine. It is a substance intermediate between sarkin and uric acid. Guanin and hypoxanthin may be changed into xanthin; in contact with water and ferments it passes into uric acid. When evaporated with nitric acid, it gives a yellow stain, which becomes yellowish-red on adding potash, and violet-red on applying more heat. It is an amorphous, yellowish-white powder, fairly soluble in boiling water. It has also been found in traces in muscles, brain, liver, spleen, pancreas and thymus. The crystalline body **paraxanthin** (dimethylxanthin) and the amorphous **heteroxanthin** (methylxanthin) occur in traces in the urine (*Salomon*).

Sarkin or Hypoxanthin, $C_5H_4N_4O$.—As yet this substance has been found only in the urine of leukæmic patients (*Jakubasch*), and it has been prepared in the form of needles or flattened scales from muscle, spleen, thymus, brain, bone, liver and kidney. In *normal* urine a body nearly related to, and possibly identical with, hypoxanthin occurs (*E. Salkowski*). Hypoxanthin closely resembles xanthin, and can be changed into it by oxidation. Nascent hydrogen, on the other hand, reduces uric acid to xanthin and hypoxanthin. When evaporated with nitric acid it gives a light yellow stain, which becomes deeper, but not reddish-yellow, on adding caustic soda. It is more easily soluble in water than xanthin, and by this means the two substances can be separated from each other. Guanin is insoluble in water.

FIG. 257.



Kreatinin-zinc chloride. *a*, balls with radiating marks; *b*, crystallized from water; *c*, from alcohol.

FIG. 258.

Oxalate of lime. *a*, *b*, octahedra; *c*, compound forms; *d*, dumb bells.

Oxaluric acid ($C_3H_4N_2O_4$) occurs in *very small quantity* combined with ammonia in uri[illegible]ne. Physiologically, it is interesting on account of its relation to uric acid. It is a white powder sligh[illegible]tly soluble in water. Ammonia oxalurate can be prepared from uric acid.

Oxalic Acid ($C_2H_2O_4$) occurs, but not constantly, to the amount of 20 mil[illegible]li-grammes daily as **oxalate of lime,** which is known by the "envelope" shape of the crystals (Fig. 258); insoluble in acetic acid, and forming transparent octahedr[illegible]ra. More rarely it assumes a biscuit or sand-glass form. The genetic relation of oxal[illegible]lic acid to uric acid is shown by the fact that dogs fed with uric acid excrete muc[illegible]ach oxalate of lime. Oxalic acid may also be produced by the oxidation of produc[illegible]cts derived from the fatty acid series (p. 430).

Oxaluria.—The eating of substances containing oxalate of lime (rhubarb) increases the exc[illegible]re-tion. Increased excretion is called oxaluria; it is regarded as a sign of retarded metabolism (*Benek[illegible]br*), and it may give rise to the formation of a calculus. In oxaluria the uric acid is also often increas[illegible]sed in amount. Perhaps, in the first instance, there is an increased formation of uric acid, from whi[illegible]nich oxalic acid, urea, and CO_2 may be formed. The amount of oxalic acid is increased after the use [illegible]of wine and sodic bicarbonate.

Hippuric Acid = $C_9H_9NO_3$ (Benzoylamidoacetic acid) occurs in large amount in the urine of herbivora, and in them is the chief end product of the metabolism of nitrogenous substances; in human urine the daily **quantity** is small, 0.3 to 3.8 grms. (5 to 50 grains). It is an odorless monobasic acid with a bitter taste, crystallizing in colorless four-sided prisms (Fig. 259). Readily soluble in alcohol, and soluble in 600 parts of water.

[Crystals of hippuric acid when **heated** in a test-tube are decomposed, and a sublimate of benzoic acid and ammonic benzoate condenses on the upper cool part of the tube, while there is an odor of new hay, and oily drops remain in the tube.]

It is a conjugated acid, and is formed in the body from benzoic acid, or some nearly related chemical body, such as the cuticular substance of plants, or from oil of bitter almonds, cinnamic or chinic acid, which easily pass by reduction (chinic acid) or by oxidation (cinnamic acid) into benzoic acid; glycin uniting with it, with the formation of water—

$$\underset{\text{Benzoic acid}}{C_7H_6O_2} + \underset{\text{Glycin}}{C_2H_5NO_2} = \underset{\text{Hippuric acid}}{C_9H_9NO_3} + \underset{\text{Water.}}{H_2O}$$

[**Formation.**—When benzoic acid is introduced into the alimentary canal of an animal (rabbit or dog), it appears in the urine as hippuric acid; while nitro-benzoic acid appears as nitro-hippuric acid. As the benzoic acid passes through the body, it becomes conjugated with glycin or glycocin, chiefly in the kidneys. The hippuric acid in the urine of herbivora is chiefly derived from some substance with a benzoic acid residue present in the cuticular coverings of the food. That hippuric acid, in part at least, is **formed in the kidneys** is shown by the following considerations: If arterialized blood, containing benzoic acid and glycin, or even benzoic acid alone, be passed through the blood vessels of a fresh, living, excised kidney, hippuric acid is found in the blood after it is perfused. Even after forty-eight hours, if the kidney be kept cool, the synthesis takes place. If the kidney be kept too long, the conjugation does not take place. If the fresh kidney be chopped up, and kept at the temperature of the body with benzoic acid and glycin, hippuric acid is formed. Oxygen seems to be necessary for the process, for, if blood or serum containing carbonic oxide be used, there is no formation of hippuric acid.]

FIG. 259.

Hippuric Acid.

According to this view, it is derived chiefly from the food of herbivorous animals, and hence it is absent from the urine of sucking calves, as well as after feeding with grain devoid of husk. But it is also formed in the body from the proteids. In the dog, the formation of hippuric acid occurs in the kidney (*Schmiedeberg and Bunge*), and in the frog also outside the kidney. Kühne and Hallwachs thought it was formed in the liver, and Jaarsveld and Stockvis in the kidney, liver, and intestine. The observation of Salomon that, after excision of the kidneys in rabbits, and injection of benzoic acid into the blood, hippuric acid was found in the muscles, blood, and liver, goes to show that it must be formed in other organs beside the kidneys. The power of changing benzoic acid introduced into the human body into hippuric acid, may even be abolished in disease of the kidney. Under certain circumstances it seems that hippuric acid, already formed, may be again decomposed in the tissues.

It is greatly **increased** after eating pears, plums and cranberries; in icterus, some liver affections,

and in diabetes. When boiled with strong acid or alkalies, or with putrid substances, it takes up H_2O and splits into benzoic acid and glycin.

Preparation.—Add milk of lime to the *fresh* urine of horses or cows to form calcic hippurate. Filter, evaporate the filtrate to a small bulk, and precipitate the hippuric acid with excess of hydrochloric acid. To purify the hippuric acid, crystallize it several times from a hot watery solution.

Cyanuric Acid.—$C_{20}H_{14}N_2O_6 + H_2O$ occurs in the urine of dogs (*J. v. Liebig*).

Allantoin, $C_4H_6N_4O_3$, which occurs in the amniotic fluid of the cow, is found in minute traces in normal urine after flesh food, and is more abundant during the first weeks of life, and during pregnancy.

After large doses of tannic acid, the amount is increased (*Schottin*), while in dogs feeding with uric acid also increases it (*Salkowski*).

Properties.—It forms shining prismatic crystals; from the urine of sucking calves it crystallizes in transparent prisms. It is decomposed by ferments into urea, ammonium oxalate, and carbonate, and another as yet unknown body. **Preparation**—(*a*) the urine is precipitated with basic lead acetate, the lead in the filtrate is removed by sulphuretted hydrogen, and the filtrate itself is then evaporated to a syrup, from which the crystals separate, after standing for several days. They are then washed with water, and recrystallized from the water (*Salkowski*).

261. COLORING MATTERS OF THE URINE.—1. **Urobilin** is most abundant in the highly colored urine of fevers, but it also occurs in normal urine (*Jaffé*). It is identical with the hydrobilirubin of Maly (§ 117, 3, *g*). It is a derivative of hæmatin, which also yields the *bile pigments* (§ 177). It gives a *red* or *reddish-yellow* color to urine, which becomes yellow on the addition of ammonia.

[MacMunn, chiefly from spectroscopic observations, finds that two entirely different substances have been included under the name of "urobilin," viz., that of normal and that of pathological urine, and that hydrobilirubin is not identical with either. The pathological urobilin seems to be closely connected with stercobilin (§ 185).]

Preparation.—Prepare a chloroform extract of urine containing urobilin—add iodine to the extract, and remove the iodine by shaking the mixture with dilute caustic potash, which forms potassic iodide. This potash solution becomes yellow or brownish-yellow, and exhibits beautiful green *fluorescence* (*Gerhardt*).

Urobilin may be extracted from many urines by ether (*Salkowski*). When subjected to the action of reducing agents, *e.g.*, sodium amalgam, a colorless product is obtained, which on exposure to the air absorbs O, and becomes re-transformed into urobilin. This colorless body is identical with the chromogen which Jaffé found in urine.

If urine is treated with soda or potash, the characteristic absorption band lying between *b* and F passes nearer to *b*, becomes darker and more sharply defined. According to Hoppe-Seyler, urobilin is formed in urine after it is voided, from another urobilin-forming body (Jaffé's chromogen) absorbing oxygen. If urine containing urobilin be made alkaline with ammonia, and zinc chloride be added, it exhibits marked *fluorescence*; it has a *green* shimmer by reflected light. When urobilin is *isolated*, it fluoresces without the addition of zinc chloride. In cases of jaundice (§ 180), where Gmelin's test sometimes fails to reveal the presence of bile pigments, urobilin occurs. This "urobilin-icterus" (*Gerhardt*) occurs chiefly after the absorption of large extravasations of blood. According to Cazeneuve, the urobilin is increased in all diseases where there is increased disintegration of blood corpuscles.

2. **Urochrome** (*Thudichum*) is regarded as the chief coloring matter of urine. It may be isolated in the form of yellow scales, soluble in water, and in dilute acids and alkalies. The watery solution oxidizes, and when exposed to air becomes red, owing to the formation of **uroerythrin.** When acted on by acids, new decomposition products are formed, *e.g.*, **uromelanin.** Uroerythrin gives the red color to deposits of urates (§ 258).

3. A brown pigment containing iron is carried down with uric acid, which is precipitated on the addition of hydrochloric acid (§ 258). By repeatedly adding sodic urate to the urine, and precipitating the uric acid by hydrochloric acid, a considerable amount may be obtained (*Kunkel*).

4. Urine boiled with HCl yields a garnet-red crystalline pigment, **urorubin,** to ether.

In cases of melanotic tumors, there has been occasionally observed urine, which becomes dark, owing to **melanin** (§ 250, 4), or to a coloring matter containing iron (*Kunkel*).

262. INDIGO, PHENOL, KRESOL, PYROKATECHIN, AND SKATOL-FORMING SUBSTANCES.—1. **Indican** [$C_8H_7NSO_4$], or indigo-forming substance (*Schunck*), is derived from indol, C_8H_7N, the basis of

indigo, which is formed in the intestine by the pancreatic digestion of proteids (§ 170, II), but it also arises as a putrefactive product (§ 184, 6). Indol, when united with the radical of sulphuric acid, HSO_3, and combined with potassium, forms the so-called *indigogen* or *indican* of urine (*Brieger, Baumann*). This substance ($C_8H_6NSO_4K$ = potassium indoxyl-sulphate) forms white glancing tablets and plates; readily soluble in water, and less so in alcohol. By oxidation it forms indigo-blue; 2 indican + O_2 = $C_{16}H_{10}N_2O_2$ (indigo blue) + $2HKSO_4$ (acid potassic sulphate). It is more abundant in the urine in the tropics, and it is absent from the urine of the newly born (*Senator*).

Tests.—(1) Add to 40 drops of urine 3 to 4 c.c. of strong fuming hydrochloric acid, and 2 to 3 drops of nitric acid. Boil, a *violet red* color (with the deposition of true *crystalline indigo blue* (rhombic) and indigo red attest its presence. Putrefaction causes a similar decomposition in indican; hence, we not unfrequently observe a bluish-red pellicle of microscopic crystals of indigo blue, or even a precipitate of the same. (2) Mix in a beaker equal quantities of urine and hydrochloric acid, and add two drops of solution of chlorinated lime; the mixture at first becomes clear, then blue (*Jaffé*). Add chloroform, and shake the mixture vigorously for some time; the chloroform dissolves the blue coloring matter, which is obtained as a deposit, when the chloroform evaporates (*Senator, Salkowski*). (3) Heat to 70° one part of urine with two parts of nitric acid, and shake up with chloroform; the chloroform dissolves the indigo which is formed, assumes a violet color, and gives an absorption band between C and D, slightly nearer D (*Hoppe-Seyler*). **Quantity.**—Jaffé found in 1500 c.c. of normal human urine 4.5 to 19.5 milligrammes of indigo; horse's urine contains 23 times as much. The subcutaneous injection of indol increases the indican in the urine (*Jaffé*). E. Ludwig obtained indican by heating hæmatin or urobilin with a caustic alkali and zinc dust. It has also been found in the sweat (*Bizio*).

Pathological.—The indican in the urine is **increased** when much indol is formed in the intestine (§ 172, II), *e.g.*, in typhus, lead colic, trichinosis, catarrh, and hemorrhage of the stomach, cholera, carcinoma of the liver and stomach; obstruction of the bowel or ileus, peritonitis, and diseases of the small intestine.

2. **Phenol**, C_6H_6O (carbolic acid, § 252), was discovered by Städeler in human urine (more abundant in horse's urine). It does not occur as carbolic acid, but in combination with a substance from which it is separated by distillation with dilute mineral acids. The "phenol-forming substance" is, according to Baumann, "**phenolsulphonic acid**" (C_6H_5O,SO_3H), which in urine is united with potash.

Phenol is derived from the decomposition of proteids by pancreatic digestion (§ 172, II), and also from putrefaction (§ 184, 6), the mother substance being tyrosin. Hence the formation of phenolsulphonic acid is analogous to the formation of indican.

If in the employment of carbolic acid it be absorbed, the phenolsulphonic acid becomes greatly increased in amount, so that sulphuric acid must be united with it; hence, alkaline sulphates are decomposed in the body, so that the latter may be absent from the urine (*Baumann*). Living muscle or liver, when digested in a stream of air for several hours with blood to which phenol and sodic sulphate are added, yields phenolsulphonic acid; while, under the same circumstances, pyrokatechin forms ethersulphonic acid.

Carboluria.—When carbolic acid is used externally or internally, and it is absorbed, it causes a *deep, dark colored* urine, due to the oxidation of phenol into **hydrochinon** (orthobioxybenzol = $C_6H_6O_2$), which for the most part appears in the urine as ethersulphonic acid (*Baumann and others*).

3. **Parakresol** (hydroxyltoluol, C_7H_8O), with its isomers **ortho-** and **meta-kresol** (the latter in traces), is more abundant in urine (*Baumann, Preusse*). It also occurs in combination with sulphonic acid.

Test for phenol (and also kresol): Distill 150 c.c. urine with dilute sulphuric acid. The distillate gives a brown crystalline deposit of tribromophenol with bromine water, as well as a red color with Millon's reagent.

Hydroxybenzol (pyrokatechin, hydrochinon) is obtained from urine, when it is heated for a long time with hydrochloric acid.

Resorcin, which is an isomer of hydrochinon, when administered internally, also appears in the urine as ethersulphonic acid. Toluol and naphthalin behave similarly. Benzol is oxidized to phenol.

4. **Pyrokatechin** = $C_6H_6O_2$ (metadihydroxylbenzol), is formed along with

hydrochinon from phenol, and is an isomer of the former. It behaves like indol and phenol, for when united with sulphonic acid, it yields the pyrokatechin-forming substance. Small quantities sometimes occur in human urine; it is more abundant in the urine of children; it becomes darker when the urine putrefies.

5. **Skatol,** which is crystalline, and is formed during putrefaction in the intestine, also appears in the urine as a compound of sulphonic acid (§ 252). On feeding a dog with skatol, Brieger found much potassic skatol-oxysulphate.

Test.—Skatol compounds are recognized by adding dilute nitric acid, which causes a violet color, or fuming nitric acid, which precipitates red flakes (*Nencki*). Its quantity is regulated by the same conditions as indican.

The **aromatic oxyacids, hydroparacumaric acid,** and **paraoxyphenylacetic acid** (the former a putrefactive product of flesh, the latter obtained by E. and H. Salkowski from putrid albumin) occur in the urine (*Baumann*, § 252). Shake the urine treated with a mineral acid with ether, evaporate the latter, and dissolve the residue in water. If aromatic oxyacids are present, they give a red color with Millon's reagent.

Baumann gives the following series of bodies, which are formed from tyrosin by decomposition and oxidation; most of the substances are formed both during the decomposition of albumin, and also in the intestine, whence they pass into the urine: Tyrosin, $C_9H_{11}NO_3 + H_2 = C_9H_{10}O_3$ (hydroparacumaric acid) $+ NH_3$. $C_9H_{10}O_3 = C_8H_{10}O$ (paraethylphenol, not yet proved) $+ CO_2$. $C_8H_{10}O + O_3 = C_8H_8O_3$ (paraoxyphenylacetic acid) $+ H_2O$. $C_8H_8O_3 = C_7H_8O$ (parakresol) $+ CO_2$. $C_7H_8O + O_3 = C_7H_6O_3$ (paraoxybenzoic acid, not yet proved) $+ H_2O$. $C_7H_6O = C_6H_6O$ phenol $+ CO_2$.

Potassium sulphocyanide, derived from the saliva, also occurs in urine. After acidulation with hydrochloric acid, its presence may be detected by the ferric chloride test (§ 146—*Gscheidlen and J. Munk*). One litre of human urine contains 0.02 to 0.08 gramme combined with an alkali.

Succinic Acid ($C_4H_6O_4$) occurs chiefly after a diet of flesh and fat, and almost disappears after a vegetable diet. It is a decomposition product of asparagin, and occurs in considerable amount in the urine after eating asparagus. It is also a product of the alcoholic fermentation (§ 150), and as it passes out of the body unchanged, it occurs in the urine of those who imbibe spirituous liquors. It passes unchanged into the urine (*Neubauer*).

Lactic acid ($C_3H_6O_3$) is a constant constituent of urine. Other observers have found fermentable lactic acid in diabetic urine; sarcolactic acid after poisoning with phosphorus and in trichinosis. Occasionally traces of **volatile fatty acids** are present. Some **animal gum** occurs in urine (p. 431), and Bechamp's "**nephrozymose**" consists for the most part of gum (*Landwehr*). This substance is precipitated from urine by adding to it three times its volume of 90 per cent. alcohol. It is not a simple body, but at 60° to 70° C. it transforms starch into sugar (*v. Vintschgau*).

Ferments.—Traces of **diastatic, peptic,** and **rennet** ferment have been found, especially in urine of high specific gravity. Trypsin is said not to occur normally (*Leo*).

Traces of **sugar** (*Brücke, Bence Jones*), to the amount of 0.05 to 0.01 per cent., occur in normal urine. After the ingestion of milk-, cane-, or grape sugar, (50 grms.) these varieties of sugar appear in small quantity in the urine (*Worm-Müller*—§ 267, 7).

Kryptophanic acid ($C_9H_9NO_5$), according to Thudichum, occurs as a free acid in urine, but Landwehr regards it as an animal gum.

Aceton (C_3H_6O) is formed when normal urine is oxidized with potassic bichromate and sulphuric acid, and it is formed from a reducing substance present in normal urine (apparently derived from the grape sugar of the blood). Aceton occurs in traces as a normal urinary constituent, which is increased during increased decomposition of the tissues, *e.g.*, carcinoma, inanition. It has also been found in the blood in fever (*v. Jacksch*). **Lieben's Test.**—Acidulate half a litre of urine with HCl and distill; when treated with tincture of iodine and ammonia there is a turbidity due to iodoform.

II. THE INORGANIC CONSTITUENTS OF THE URINE.—The inorganic constituents are either taken into the body as such with the food and pass off unchanged in the urine, or they are formed in the body, owing to the sulphur and phosphorus of the food being oxidized and the products uniting with bases to form salts, The **quantity** of salts excreted daily in the urine is 9 to 25 grammes [¼ to ¾ oz.].

1. **Sodic chloride**—to the **amount** of 12 (10 to 13) grammes [180 grains]—is excreted daily. It is **increased,** after a meal, by muscular exercise, drinking of water, and generally, when the quantity of urine is increased, by the free use of large quantities of common salt, but by potash salts also; it is **diminished** under the opposite conditions.

In **disease** it is greatly **diminished**; in pneumonia and other inflammations accompanied by

effusions, in continued diarrhœa and profuse sweating, constantly in albuminuria and in dropsies. [In cases of pneumonia, sodic chloride may at a certain stage almost disappear from the urine, and it is a good sign when the chlorides begin to reappear.] In other chronic diseases, the amount of NaCl excreted runs nearly parallel with the amount of urine passed. In conditions of excitement the amount of sodic chloride is diminished, and potassic chloride increased; in conditions of depression the reverse is the case (*Zeulzer*).

Test.—Add to the urine nitric acid and then nitrate of silver solution, which gives a white curdy precipitate of chloride of silver. In albuminous urine the albumin must first be removed. *Microscopically* look for the step-like forms of common salt, and also for the crystals of sodic chloride and urea (§ 256, 4).

2. **Phosphoric acid** occurs in urine as **acid sodic phosphate** and **acid calcic** and **magnesic phosphates** to the **amount** of about 2 grammes daily [30 grains]; it is more abundant after an animal than after a vegetable diet. The amount increases after a midday meal until evening, and falls during the night until next day at noon. It is partly derived from the alkaline and earthy phosphates of the food, and partly as a decomposition product of lecithin and nuclein. As phosphorus is an important constituent of the nervous system, the relative increase of phosphoric acid is due to increased metabolism of the nervous substance.

Pathological.—In fevers, the increased excretion of potassic phosphate is due to a consumption of blood and muscle (§ 220, 3.) It is also **increased** in inflammation of the brain, softening of the bones, diabetes, and oxaluria; after the administration of lactic acid, morphia, chloral, or chloroform. It is **diminished** during pregnancy, owing to the formation of the fœtal bones; also after the use of ether and alcohol, and in inflammation of the kidney.

[**Tests.**—To urine add nitric acid and solution of ammonium molybdate and boil, a canary yellow precipitate of ammonium phosphomolybdate indicates the presence of phosphoric acid. Or, add half its volume of caustic potash to urine, and boil. The earthy phosphates are precipitated, but not the alkaline phosphates.]

Earthy phosphates are precipitated by heat in some pathological urines. This precipitate is distinguished from albumin, which is also precipitated by heat, by being soluble in nitric acid, which precipitated albumin is not. [The earthy phosphates are not precipitated until near the boiling point.]

Quantitative.—The *amount* of phosphoric acid is estimated by titration with a *standard solution of uranium acetate; ferrocyanide of potassium* being the *indicator*. The indicator gives a brownish red color when there is an excess of free uranium acetate.

In addition to phosphoric acid, phosphorus occurs in an incompletely oxidized form in the urine, *e.g.*, **glycerinphosphoric acid** (§ 251, 2), which occurs to the amount of 15 milligrammes in a litre of urine; it is **increased in nervous** diseases and after chloroform narcosis.

3. **Sulphuric acid** occurs in the urine, the greater part in combination with the *alkalies*, and the remainder united with indol, skatol, and pyrokatechin, in the form of *aromatic ethersulphonic compounds*, the ratio being 1 : 0.1045. All conditions which favor the formation of indol, skatol, or pyrokatechin, increase the amount of combined sulphuric acid. The total daily **amount** of sulphuric acid is 2.5 to 3.5 grammes [37 to 52 grains]. It is increased by the administration of sulphur (*Krause*). The sulphuric acid is chiefly derived from the decomposition of proteids, and hence its amount runs parallel with the amount of urea excreted. The amount of alkaline sulphates in the food is, as a rule, very small.

An **increased** excretion of sulphuric acid in fevers indicates an increased metabolism of the tissues of the body. In renal inflammation it has been observed to be diminished, and in eczema it is greatly increased. Feeding with taurin (which contains sulphur), in the case of rabbits, (but not in carnivora or man), increases the sulphuric acid in the urine (*Salkowski*). According to Zülzer, a copious secretion of bile lessens the relative amount of sulphuric acid in the urine.

Test.—Barium chloride gives a copious white heavy precipitate of barium sulphate, insoluble in nitric acid.

In addition to sulphuric acid, sulphur ($\frac{1}{5}$) occurs in an incompletely oxidized form in the urine (potassium sulphocyanide, cystin, and sulphur-bearing compounds derived from the bile) (*Kunkel, v. Voit*—§ 177, 6). *Hyposulphurous acid*, as an alkaline salt, is an *abnormal* constituent in typhus; and so is sulphuretted hydrogen, which is recognized by the blackening of a piece of paper moistened with lead acetate and ammonia, held over the urine.

4. Excessively minute traces of **silicic acid** and **nitric acid** derived from drinking water have been found in urine. *Organic acids, e.g.*, citric and tartaric, when taken internally, increase the amount of *carbonates* in the urine. The urine may effervesce on the addition of an acid.

The **sodium** in the urine is chiefly combined with chlorine, but a small part of it is united with phosphoric and uric acids; **potassium** (which is about ⅓ of the sodium) is chiefly combined with chlorine. In fevers, more potash is excreted than soda, and during convalescence, the reverse is the case; **calcium** and **magnesium** exist in normal **acid** urine as chlorides or acid phosphates. If the urine is **neutral**, neutral calcium phosphate and magnesium phosphate are precipitated. Ebstein found the latter in alkaline urine, as large, clear, four-sided prisms, in diseases of the stomach. If the urine is **alkaline**, calcium carbonate (Fig. 281) and tribasic calcic phosphate are deposited as such, while the magnesium is precipitated in the form of ammonio-magnesium phosphate, or triple phosphate. The calcium is derived from the food, and depends upon the amount of lime salts absorbed from the intestine. **Free ammonia** is said to occur (0.72 gramme, or 7 grains daily) in perfectly fresh urine (*Neubauer, Brücke*), and the amount is greater with an animal than with a vegetable diet (*Coranda*). The amount of fixed ammonia is increased by the administration of mineral acids (*Walter, Schmiedeberg, Gäthgens*). **Iron** (1 to 11 milligrammes per litre) is never absent. There is a trace of **hydric peroxide** (*Schonbein*), which is detected by its decolorizing indigo solution on the addition of iron sulphate.

Gases.—24.4 c.c. of gas was obtained from one litre of urine—100 volumes of the gases pumped out consisted of 65.40 vol. CO_2, 2.74 O, 13.86 N. After severe muscular action, the amount of CO_2 may be doubled; digestion also increases it, copious drinking diminishes it.

263. FERMENTATIONS OF URINE.—Acid Fermentation.

When perfectly fresh urine is set aside, it gradually becomes more acid from day to day. This is called the "**acid fermentation.**" It seems to be due to the development of special fungi (Fig. 260, *a*), and the process is accompanied by the

FIG. 260.

Deposit in "acid fermentation" of urine. *a*, fungus; *b*, amorphous sodium urate; *c*, uric acid; *d*, calcium oxalate.

FIG. 261.

Deposit in ammoniacal urine (alkaline fermentation). *a*, acid ammonium urate; *b*, ammonio-magnesium phosphate; *c*, bacterium ureæ.

deposition of *uric acid* (*c*), *acid sodium urate*, in amorphous grains (*b*), and *calcium oxalate* (*d*). According to Scherer the fungus and the mucus from the bladder decompose part of the urinary pigment into lactic and acetic acids. The latter set free uric acid from neutral sodium urate, so that free uric acid and sodium urate must be formed. *Butyric* and *formic acids* have been found as abnormal decomp

sition products of other urinary constituents. When the acid fermentation begins, the urine absorbs oxygen (*Pasteur*). According to Brücke, it is the lactic acid, formed from the minute traces of sugar present in urine, which causes the acidity. According to Röhmann, who recognizes the acid fermentation as an exceptional phenomenon, the acids are formed from the decomposition of sugar, and from alcohol which may be present accidentally. While the urine is still acid, it becomes turbid and contains nitrous acid, whose source is entirely unknown. According to v. Voit and Hofmann, phosphoric acid and a basic salt are formed from acid sodium phosphate, whereby part of the uric acid is displaced from sodium urate, thus causing the formation of an acid urate.

Alkaline Fermentation.—When urine is exposed for a still longer time, more especially in a warm place, it becomes neutral and ultimately ammoniacal, *i.e.*, it undergoes the **alkaline fermentation** (Fig. 261).

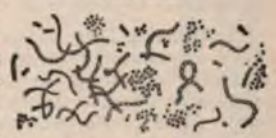
This condition is accompanied by the formation of the **micrococcus ureæ** (Fig. 262) (*Pasteur, Cohn*) and Bacterium ureæ (Fig. 261), which causes the urea to take up water and decompose into CO_2 and ammonia.

Urea $[CO(HN_2)_2 + 2(H_2O) =$ ammonium carbonate $[(NH_4)_2CO_3]$.

The property of decomposing urea belongs to many different kinds of bacteria, including even the sarcina of the lungs—whose germs seem to be universally diffused in the air. These organisms produce a **soluble ferment** (*Musculus*), which, however, only passes from the body of the cells into the fluid after the cell or organism has been killed by alcohol (*Lea*).

The presence of ammonia causes the urine to become turbid, and those substances which are insoluble in an alkaline urine are precipitated—**earthy phosphates,** consisting of the amorphous **calcic phosphate, acid ammonium urate** (Fig. 261, *a*), in the form of small, dark granules covered with spines; and, lastly, the large, clear, knife-rest or "coffin lid" form of **ammonio-magnesic phosphate, or triple phosphate** (Fig. 282). [The last substance does not exist *as such* in normal urine, but it is formed when ammonia is set free by the decomposition of urea, the ammonia uniting with the magnesium phosphate. Its presence, therefore, always indicates ammoniacal fermentation of the urine.] In cases of **catarrh** or **inflammation of the bladder,** this decomposition may take place within the bladder, when the urine always contains pus cells (Fig. 267) and detached epithelium. When much pus is present, the urine contains albumin. Ammoniacal urine forms white fumes of ammonium chloride, when a glass rod dipped in hydrochloric acid is brought near it. [When ammonia is added to normal urine, triple phosphate is precipitated in a *feathery* form (Fig. 283).]

FIG. 262.



Micrococcus ureæ.

[**Significance of Triple Phosphate.**—If urine be alkaline when it is passed, and the alkalinity be due to a *volatile alkali*, *i.e.*, to NH_3, then decomposition of the urine has taken place, and this kind of urine is a sure sign that there is disease of the genito-urinary mucous membrane.]

264. ALBUMIN IN URINE OR ALBUMINURIA.—**Serum albumin** is the most important **abnormal** constituent in urine which engages the attention of the physician. It occurs in blood (§ 32), and its characters are described in § 249.

Causes of Albuminuria.—1. Serum albumin may appear in urine without any apparent anatomical or structural change of the renal tissues. This condition has been called by v. Bamberger "*Hæmatogenous albuminuria.*" It occurs but rarely, however, and sometimes in healthy individuals when there is an excess of albumin in the blood plasma (*e.g.*, after suppression of the secretion of milk), and after too free use of albuminous food. 2. As a result of *increased blood pressure* in the renal vessels, *e.g.*, after copious drinking. It may be temporary, or it may be persistent, as in cases of congestion following *heart disease*, emphysema, chronic pleuritic effusions, infiltrations of the lungs, and after compression of the chest, causing congestion in the pulmonary circuit, which extends even into the renal veins, etc. 3. After section or paralysis of the *vasomotor nerves* of the kidneys, which causes great congestion of these organs. The albuminuria, which accompanies intense and long-continued abdominal pain, is brought about owing to a reflex paralysis of the renal vessels.

4. After violent muscular exercise. [Senator found that forced marches in young recruits were very frequently followed by the appearance of albumin in the urine, which persisted for several days.] *Convulsive* disorders, *e.g.*, epilepsy, the spasms of dyspnœa after strychnin poisoning, in shock of the brain, apoplexy, spinal paralysis, and violent emotions; the excessive use of morphia, which, perhaps, acts on the vasomotor centres. 5. It may accompany many acute febrile diseases, *e.g.*, the exanthemata (scarlet fever), typhus, pneumonia, and pyæmia. In these cases, it may be due to the increase of temperature paralyzing the vessels, but more probably the secretory apparatus of the kidney is so changed (*e.g.*, cloudy swelling of the renal epithelium) that the albumin can pass through the renal membrane. 6. Certain degenerations and inflammations of the kidneys at several of their stages. 7. Inflammation or suppuration in the ureter or urinary passages. 8. Certain chemical substances which irritate the renal parenchyma, *e.g.*, cantharides, carbolic acid. 9. The complete withdrawal of common salt from the food. The albumin disappears when the common salt is given again. 10. The *epithelium* may be in such a condition that it *cannot retain the albumin within the vessels*, due to imperfect nourishment and functional weakness of the excretory elements. This includes the albuminuria of ischæmia, and that after hemorrhage, in anæmia, scorbutus, icterus, diabetes. [Grainger Stewart finds that albuminnria is more common among presumably healthy people than was formerly supposed.]

[Besides being derived from the secreting parenchyma of the kidney, albumin may be present owing to admixture with the secretions from any part of the urinary tract, including the vagina and uterus in the female. In some cases the transudation of albumin is favored by changes in the capillary walls, the albumin being forced through by the intra-vascular pressure. Sometimes albuminuria occurs during the course of severe typhoid fever, and in acute fevers generally, where the temperature is persistently above 40° C. (104° F.). The high temperature alters the filtering membrane and permits the filtration of albumin.]

[**Physiological Albuminuria.**—This term has been applied to that condition of the urine, where traces of albumin are found in individuals *apparently* in perfect health. Johnson and Pavy cite such cases, while Posner asserts that all urine—even healthy urine—contains traces of proteids, whose presence is ascertained after concentrating the urine. It is safe to assume that normal urine should give no reaction with the usual tests for albumin. Posner precipitated the urine with alcohol, washed the precipitate, dissolved it in acetic acid, and tested it with the ferrocyanide test for albumin. He finds that minute traces of proteid are detected by the following modification of the biuret test: Make the urine alkaline, and by the "contact method" bring a layer of very dilute cupric sulphate over it; when the two fluids touch, a reddish-violet ring is obtained.]

The **tests for albumin in urine** depend upon the facts that it is **coagulated** by **heat** in neutral or acid solutions, and it is **precipitated** by various reagents.

[(1) **Heller's Test.**—Place 10 c.c. of the urine in a test-glass, and pour in pure colorless HNO_3 so as to run down the side of the glass, forming a layer beneath the urine. A white zone of coagulated albumin indicates the presence of albumin. In this test it is important to wait a certain time for the development of the reaction. In urines of high specific gravity, a haziness due to *acid urates* may be formed above where the two fluids meet, but its upper edge is not circumscribed. The acid decomposes the neutral urates and forms a more insoluble acid salt. This cloud of acid urates is readily dissolved by heat, while the albumin is not; the latter is always a sharply-defined zone between the two fluids. In very concentrated urine (rare), nitric acid may gradually precipitate *crystalline* urea nitrate. In patients taking copaiba, nitric acid, by acting on the resin, causes a slight milkiness.]

[(2) **Boiling and Nitric Acid.**—Place 10 c.c. of urine in a test-tube and boil. If albumin be present in small quantity, a faint haziness, which may be detected in a proper light, will be produced. Add 10 to 12 drops of HNO_3. If the turbidity disappears it is due to phosphates, while if it remain it is due to albumin. If albumin be present in large quantity, a copious whitish coagulum is obtained. **Precautions.**—(*a*) In all cases, if the urine be turbid, filter it before applying any test. (*b*) *How to boil.*—Boil the upper strata of the liquid, and take care, if any coagulum be formed, that it does not adhere to the side of the tube, else the tube is liable to break. (*c*) In performing this test with a *neutral* solution, note when the precipitate falls, for albumin is precipitated about 40° C., phosphates not till about the boiling point. (*d*) *Amount of Acid.*—If too little (2 or 3 drops) HNO_3 be added, or too much (30 or 40 drops), we may fail to detect albumin, although it is present.

(3) **Ferrocyanide Test.**—By the addition of *acetic acid* and *potassium ferrocyanide*. [If albumin be present, a white flocculent precipitate separates in the cold. Dr. Pavy has introduced **pellets**, consisting of a mixture of citric acid and sodic ferrocyanide. All that is required is to add a pellet to the suspected urine. **Oliver's papers.**—Dr. Oliver uses papers, one saturated with citric acid and another with ferrocyanide of potassium. The two papers are added to the clear filtered urine. Other precipitants of albumin, such as small pieces of paper impregnated with potassio-mercuric iodide, are used by Oliver.]

(4) **Boiling Acid Urine.**—If the urine be alkaline, although albumin may be present, it is not precipitated by heat alone. We require to add acetic acid until a slightly acid reaction is obtained. Boiling may give a precipitate of earthy phosphates in an **alkaline** urine, owing perhaps to the

being driven off. This precipitate might be mistaken for albumin, but on adding acetic or nitric acid, the earthy precipitate is dissolved, while the precipitate of albumin is not dissolved. In testing for albumin, always use *clear* urine. If it is turbid, filter it.

[(5) **Metaphosphoric acid** is dissolved in water just before it is to be used and added to clear urine (*Hindenlang*). Graham pointed out that metaphosphoric acid precipitated albumin. A 20 per cent. solution of the ordinary glacial phosphoric acid is a good test for albumin, but it also precipitates peptones. It, however, changes into ordinary phosphoric acid by keeping, and then it no longer precipitates albumin.]

[(6) **Sodic Sulphate and Acetic Acid.**—Acidulate 10 c.c. of urine with acetic acid, and add ⅙ of its volume of a concentrated solution of sulphate of soda or magnesia. On heating, if albumin be present, a distinct cloudiness is obtained.]

[(7) In **picric acid**, according to Dr. Johnson, we have a more delicate test for minute traces of albumin than either heat or nitric acid, or than both these tests combined. It is used either in the form of crystals or powder, or as a saturated aqueous solution. Take a four-inch column of urine in a test-tube, hold the tube in a slanting direction, and pour an inch of the picric acid solution on the surface of the urine, where in consequence of its low specific gravity (1005) it mixes only with the upper layer of the urine. It coagulates any albumin present. The precipitate occurs at once, and is increased by heat, while the urate of soda, which is sometimes precipitated, is soluble on heating.]

[Dr. Roberts regards any test for albumin which requires strong acidulation with an *organic* acid, citric, acetic, or lactic, as unsatisfactory, since it precipitates mucin. For this reason he rejects the tungstate, mercuric iodide, and potassic ferrocyanide tests. Dr. Roberts regards the heat test, with the addition of a small definite quantity of acetic acid, as the best test for the detection of small quantities of albumin.]

1. **Quantitative Estimation of Albumin.**—100 c.c. of urine are boiled in a capsule, some acetic acid being ultimately added, whereby the albumin is precipitated in flakes. The precipitate is collected on a weighed, dried (110°), ash-free filter, and repeatedly washed with hot water, then with alcohol, and dried in an air bath at 110°. The weight of the filter is deducted, and finally the dried filter with the albumin is burned in a weighed platinum capsule, and the weight of the ash also deducted. [This method is not available for the busy practitioner on account of the time it takes. Practically, it is sufficient to compare from day to day the proportion that the precipitated albumin bears to the bulk of the urine tested. A graduated tube may be used, so that after the prepipitate has subsided, the physician may see what proportion of the whole the precipitate occupies.]

FIG. 263.

Esbach's Albumimeter.

Esbach's Albumimeter (Fig. 263).—A glass cylinder is filled with the urine up to the mark U, and to R with the precipitant (20 citric acid, 10 picric acid, 970 water). The vessel is corked and then shaken. After twenty-four hours the coagulated albumin subsides, when the graduation on the tube indicates the number of grms. of albumin per 1000 c.c. of urine. Very albuminous urine must be previously diluted.

2. **Globulin** occurs only in albuminous urine, and is frequently present. Its **presence** is ascertained by adding powdered magnesium sulphate in excess to the urine; when it is present it is precipitated (§ 32). The more globulin there is in the presence of albumin, the more difficult it is to precipitate it. [Sometimes, when an albuminous urine is dropped into a large cylinder of water, each drop as it sinks is followed by a milky train, and when a sufficient number of drops has been added, the water becomes opalescent, the opalescence disappearing on adding an acid. The globulin is kept in solution by common salt and other neutral salts, but when these are largely diluted, the globulin is precipitated (*Roberts*).]

3. **Peptone** occurs in some specimens of albuminous urine, but also in non-albuminous urine. Maixner found it constantly in the urine in all cases where suppuration is present, and even in phthisis, constituting **pyogenic peptonuria.** Peptone occurs in pus, and the **peptonuria** in these cases is a sign of the breaking up of the pus cells (*Hofmeister*). Also when many leucocytes are broken up in the blood (**hæmatogenic**). It occurs in cases where there is great disintegration of albuminous tissues, *e.g.*, in cancer. It is frequently found after childbirth. Ammonium sulphate precipitates all proteids except peptones (p. 294).

Test.—Separate the albumin by boiling and the addition of acetic acid. Treat the filtrate with three volumes of alcohol; this precipitates the peptone, which, when dissolved in water, gives the characteristic reactions for peptone (§ 166, I).

4. **Propeptone**, or **Hemialbumose**, occurs very rarely *e.g.*, in osteomalacia and intestinal tuberculosis (*Bence Jones*). The urine is treated to saturation with NaCl and a large quantity of acetic acid added, and filtered while hot, to separate the albumin and globulin. In the cold filtrate propeptone forms a turbidity, which is redissolved by heat. The precipitate thrown down by HCl and HNO_3 is soluble by heat (*Kühne*). The precipitate is isolated by filtration, and dissolved in a little warm water, when it gives with HNO_3 a yellow reaction; like peptone the solution gives the biuret reaction (p. 293).

5. **Egg albumin** appears in the urine when much egg albumin is taken in the food, and also

when it is injected into the blood vessels (§ 192, 4). According to Semmola, the albumin present in the urine in Bright's disease has undergone a molecular change (similar to egg albumin), and hence it is excreted.

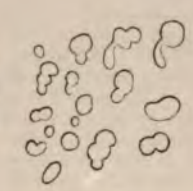
6. **Mucus** is present in large amount, especially in catarrh of the bladder. It contains numerous mucus corpuscles, which are scarcely distinguishable from pus corpuscles. They contain albumin, so that urine containing much mucus is albuminous; mucin is not precipitated by heat, but acetic acid gives a flocculent precipitate in clear urine. [Minute traces of mucin occur normally in urine. If clear, normal urine be set aside for a short time, a flocculent haziness, like a cloud of cotton wool, is seen floating in the urine. This is mucus entangling a few epithelial cells from the genito-urinary tract. **Mucin Reaction.**—According to W. Roberts, the addition of a concentrated solution of citric acid to urine, as in Heller's test (§ 264, *a*), where the two fluids meet, causes an opalescent zone gradually to be formed above the layer of acid.]

265. **BLOOD IN URINE (HÆMATURIA)—HÆMOGLOBINURIA.—I. Source of the Blood.**—(1) In **hæmaturia**, the blood may come from any part of the urinary apparatus, 1. In hemorrhage from the **kidney**, the amount of blood is usually small and well mixed with the urine. The presence of "blood cylinders," long microscopic blood coagula, casts of the uriniferous tubules, washed out of them by the urine, is characteristic when they are found in the urine (Fig. 275). The urine usually has a **smoky** appearance. [The urine slowly dissolves out the coloring matter, the stroma of the corpuscles after a time being deposited as a brownish sediment. The smoky hue occurs

FIG. 264.

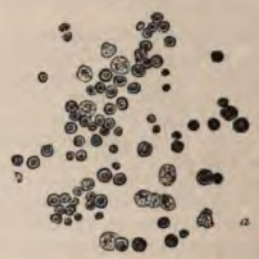
Crenated red blood corpuscles in urine, × 350.

FIG. 265.



Peculiar changes of the red blood corpuscles in renal hæmaturia.

FIG. 266.



Colored and (*a*) colorless blood corpuscles of various forms.

only in acid urine; if the urine becomes alkaline, the hue becomes brighter red.] The blood corpuscles show peculiar changes of form [they become crenated] (Fig. 264), and exhibit evidence of division, due to the action of urea on them (§ 5). Large coagula are never found in urine mixed with blood derived from the kidney. 2. In hemorrhage from the **ureter**, we occasionally find worm-like masses of clotted blood, casts of the canal of the ureter. 3. The relatively largest coagula occur in hemorrhage from the **bladder**. In all cases where blood is present, we must examine microscopically for the blood corpuscles, and it may be for coagula of fibrin. In acid urine, blood corpuscles, but never arranged in rouleaux, may be found after two to three days. The blood corpuscles settle as a red sediment at the bottom. If the hemorrhage is copious many retain their original shape, but if the urine is very concentrated, they may become crenated.

FIG. 267.

Shriveled blood corpuscles in urine (catarrh of the bladder), with numerous lymph corpuscles, and crystals of triple phosphate, × 350.

When there is a small and slow hemorrhage from ruptured small capillaries, the red blood corpuscles are of unequal size, many ½ to ⅓ the size of normal, while the pigment has become brownish-yellow (Fig. 265).

If a hemorrhage of this kind be accompanied by **catarrhal inflammation of the bladder**, there is found between the red, numerous shriveled leucocytes (Fig. 265), which in freshly passed urine often exhibit lively amœboid movements. If the urine be alkaline, as it usually is, crystals of triple phosphate also occur.

If the remains of the red blood corpuscles become very pale, their presence may be frequently ascertained by adding iodine in a solution of KI (Fig. 265). Blood is constantly present in the urine during menstruation.

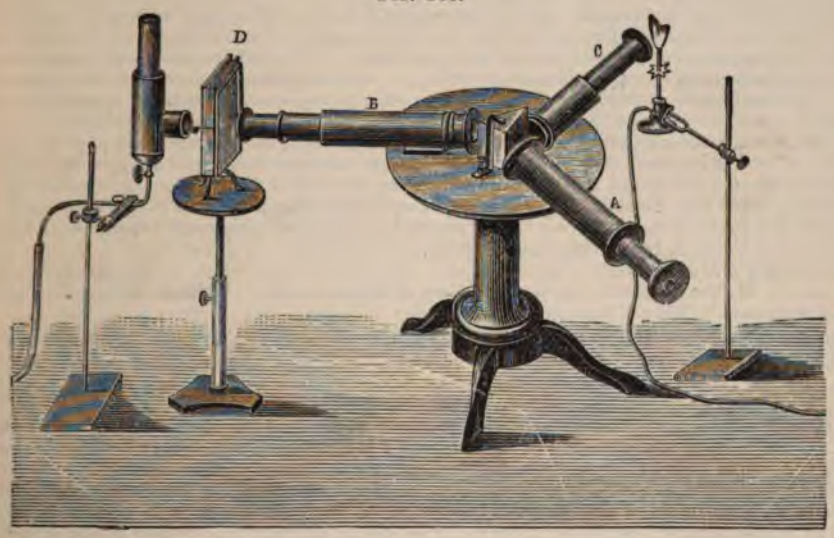
II. Hæmoglobinuria is quite distinct from hæmaturia. It depends upon the excretion of **hæmoglobin as such** through the kidneys, and it is produced when hæmoglobin occurs free

within the blood vessels, as in cases where the colored blood corpuscles have been dissolved inside the blood vessels (hæmocytolysis). It occurs when foreign blood is transfused, *e. g.*, when lamb's blood is transfused into man. The foreign blood corpuscles are dissolved in the blood of the recipient, and the hæmoglobin appears in the urine (§ 102). In addition, microscopic "**cylinders**," or "**casts**," consisting of a globulin-like body tinged yellow with hæmoglobin, may likewise be found in the urine. It also occurs in cases of severe burns (§ 10, 3); after decomposition of the blood in pyæmia, scorbutus, purpura, severe typhus, after respiring arseniuretted hydrogen, and after the passage of azobenzol, naphthol, pyrogallic acid, potassic chlorate, chloral, phosphorus, or carbolic acid into the circulation. [The injection of laky blood, water, ether, glycerin (*Adams*), or toluylendiamin (*Afanassiew*), also causes it, and in such cases Afanassiew asserts that the Hb passes out through the glomeruli, while brown degeneration products of the red blood corpuscles, which are dissolved by these agents, were found in the convoluted tubules.] These substances dissolve the red blood corpuscles. Sometimes it occurs **periodically** from causes and conditions as yet but little understood, *e. g.*, the application of cold to the skin.

Tests for Blood in Urine.—1. The **color** of bloody urine shows every tint, from a faint red to a dark blackish-brown, according to the amount of blood present. The urine is often turbid.

2. Urine containing blood or blood pigment contains **albumin.**

FIG. 268.



Spectroscope for investigating the presence of hæmoglobin in urine.

3. **Heller's Blood Test.**—Add to urine half its volume of solution of caustic potash, and heat gently. The earthy phosphates are precipitated, and they carry the hæmatin with them, falling as garnet-red flocculi. [This is not a reliable test.]

4. **Hæmin Test.**—The colored earthy phosphates may be collected on a filter, and from them hæmin may be prepared as directed in § 19.

5. **Almén's Test.**—Add to urine, freshly prepared tincture of guaiacum and ozonized ether; a blue color indicates the presence of blood (§ 37).

6. **Spectroscope** (see § 14). Fig. 268 shows the arrangement of the apparatus. The urine is placed in a glass vessel, D, with parallel sides, 1 centimetre apart (**hæmatinometer**). Light from a lamp, E, passes through the fluid. The lamp, F, illuminates the scale which is seen by the observer through the telescope, A. (*a*) **Fresh urine containing blood** gives the spectrum of **oxyhæmoglobin** (Fig. 17). (*b*) When bloody urine is exposed for some time, especially in a warm place, it becomes more *acid*, and assumes a dark, brownish black color. The hæmoglobin becomes changed into **methæmoglobin** (§ 15). It is precipitated by lead acetate, which does not precipitate oxyhæmoglobin; the spectrum of methæmoglobin resembles that of hæmatin in an acid solution (§ 15, Fig. 17). The spectra may be combined. (*c*) The **microscopic** investigation must never be omitted. The shape of the corpuscles may vary considerably (Figs. 264 to 266).

266. **BILE IN URINE (CHOLURIA).**—The physiological conditions which cause the bile constituents to appear in the urine are mentioned in part at § 180.

Hæmatogenic, or Anhepatogenic Icterus (*Quincke*), occurs when bilirubin (§ 20) is formed from extravasated blood by the action of the connective-tissue corpuscles, so that bile pigments, in addition to coloring the tissues, pass into the urine.

I. Bile Pigments.—Their presence is ascertained by **Gmelin-Heintz's test.** *Green* (Biliverdin) is the characteristic hue in the play of colors obtained with this test, which is fully described in § 177.

Modifications of the Test.—1. If icteric urine be filtered through filtering or blotting paper, a drop of nitric acid containing nitrous acid, when applied to the inner surface of the spread-out filter, gives a yellowish-colored ring (*Rosenbach*). 2. In order that the reaction may not take place too rapidly, add a concentrated solution of sodic nitrate, and then slowly pour in sulphuric acid (*Fleischl*). 3. On shaking 50 c.c. of icteric urine with 10 c.c. of chloroform, the bilirubin is dissolved by the latter. On adding bromide water, a beautiful ring of colors is obtained (*Maly*). If the chloroform extract be treated with ozonized turpentine and dilute caustic potash, a green color, due to biliverdin, occurs in the watery fluid (*Gerhardt*).

In slight degrees of jaundice, **urobilin** alone may be found (§ 261, 1) (*Quincke*).

In persistent high fever, the urine contains especially **biliprasin** (*Huppert*). If it contains **cholетelin** alone, add to the urine some hydrochloric acid, and examine it with the spectroscope, which gives a pale absorption band between *b* and F (§ 177, 3, *f*).

Hæmatoidin.—Sometimes crystals of *hæmatoidin* (§ 20, Fig. 14) appear in the urine, especially when blood corpuscles are dissolved within the blood stream; occasionally in scarlet fever and typhus, and sometimes in cases of periodic hæmoglobinuria. The breaking up of old blood clots in the urinary passages, as in pyonephrosis (*Ebstein*), or the dissolution of necrotic areas (*Hofmann and Ultzmann*) produces them, and similar crystals occur in analogous cases in the sputum (§ 138). In jaundice due to congestion (§ 180), the identical crystalline substance, bilirubin, is found.

II. Bile acids occur in largest amount in absorption jaundice, but they are never present to any extent. The **test** is described at § 177, 2, the cane-sugar solution consisting of 0.5 grm. to 1 litre of water. If the urine be dilute, it is advisable to concentrate it on a water bath. [It is rare to get a satisfactory result with Pettenkofer's test in ordinary icteric urine.] v. Pettenkofer's test may be used with the alcoholic extract of the nearly dry residue, but no albumin must be present. Dragendorff found 0.8 grm. in 100 litres of *normal* urine.

Strassburg's Modification.—Dip filter paper into the urine, to which a little cane sugar has been added; dry the paper and apply to it a drop of sulphuric acid. A violet-red color is obtained after a short time. [**Hay's Reaction** (§ 177).]

267. **SUGAR IN URINE (GLYCOSURIA).**—**Diabetes Mellitus.**—The excessively minute trace of **grape sugar** or **dextrose,** which is constantly present in normal urine, sometimes becomes greatly increased and constitutes the conditions of **diabetes mellitus** and **glycosuria.** The physiological conditions which determine this result are given at § 175. In this condition, the **quantity** of urine is greatly increased, it may reach 10 or more litres. Many pints may be passed daily. [The usual abnormal amount of sugar is from 1 to 8 per cent., although 15 per cent. has been found, *i. e.*, found from 5 to 50 grs. per fluid oz., or 300 to 4000 grs. in twenty-four hours.] The **specific gravity** is also increased (1030 to 1040). [In a case where a large amount of urine is passed of a *pale* color and a specific gravity above 1030, always suspect sugar.] A diabetic person gives off relatively more water by the kidneys and less by the skin (and lungs ?) than a healthy person. The **color** is very pale yellow, although the amount of pigment is by no means diminished—it is only diluted [the depth of the color being inversely as the quantity passed]. The amount of the nitrogenous urinary excreta is increased. The sugar is increased by a diet of carbohydrates and diminished by an albuminous diet. The uric acid and oxalate of lime are often increased at the commencement of the disease, while yeast cells are constantly present after the urine has been exposed to the air for some time.

Sugar has been found *occasionally* after poisoning with or after the use of morphia, CO, chloral, chloroform, curara; after the injection of ether and amyl nitrite into the blood; and in gout, intermittent fever, cholera, cerebro-spinal meningitis, hepatic cirrhosis, and cardiac and pulmonary affections.

[There is no doubt that normal healthy human urine contains a reducing agent, which reduces cupric oxide to the same extent as if the urine on an average contained 6 grains of glucose in every 10 fluid ounces of urine, or 1.34 grms. per litre. As this substance does not cause alcoholic fermentation in its solutions, its identity with glucose appears to be doubtful. The most active reducing agent is probably kreatinin (*G. S. Johnson*).]

Tests.—Any of the tests described at § 149 may be used, but the urine must be free from albumin. The quantitative estimation by fermentation and the titration methods are described in § 149. [The tests for grape sugar described in § 149 are (1) Trommer's; (2) Fehling's; (3) Moore & Heller's; (4) Böttger's; (5) Mulder & Neubauer's; (6) Fermentation test.]

Worm-Müller recommends the following modification of Fehling's test: Use a 2.5 per cent. solution of cupric sulphate solution, and another of 10 parts of sodio-potassic tartrate in 100 parts of 4 per cent. solution of soda. Boil 5 c.cm. of urine in a test-tube, while in a second test-tube is

boiled 1 to 3 c.cm. of the copper solution and 2.5 c.cm. of the potassio-tartrate solution. The boiling of both fluids is stopped simultaneously, and after 20 to 25 seconds the contents of one test-tube are added to those of the other, but without shaking the mixture, the reduction taking place spontaneously.

8. **Nylander's** modification of Böttger's test is also good (§ 149).

[9. **Picric Acid and Potash Test.**—Braun showed that grape sugar, when boiled with picric acid and potash, reduces the yellow picric acid to the deep red picramic acid, the depth of the color depending on the amount of sugar present. Dr. Johnson uses this test for detecting the presence of sugar in urine, and also for estimating the amount of sugar present, the depth of the red color obtained in boiling being compared with a standard dilution of ferric acetate. In doing the test, use 1 drachm of urine, ½ a drachm of liquor potassæ, and 10 minims of picric acid solution; make up to 2 drachms with distilled water, and boil the mixture for one minute. This test indicates the presence of 0.6 grain of sugar per fluid ounce of normal urine. Dr. Johnson claims for this test that it possesses all the advantages of the other tests, while it is not affected by uric acid or any other normal ingredient of urine; neither does the presence of albumin interfere with the action of the test as it does with all the forms of copper testing.]

[10. **Indigo-carmine Test.**—A blue solution of this substance, when boiled with diabetic urine containing sodic carbonate, changes from a blue to a violet, purple, red, yellow, and finally, straw-yellow color. After cooling and exposure to the air, the various colors are obtained in the reverse order until the mixture becomes blue again. Dr. Oliver uses this test in the form of **test papers.** One bibulous paper is impregnated with the indigo carmine and the other with sodic carbonate. Drop one of the test papers and a sodic-carbonate paper into a test-tube containing 1½ inches of water, heat gently, when a blue solution is obtained. Add the urine slowly, one drop at a time, and boil the mixture, observing any change of color by holding the tube against a white surface below the level of the eye, Uric acid and urates, which reduce Fehling's solution, do not affect the carmine test, nor does kreatinin, although it reacts with the picric acid test.]

[**Quantitative Estimation.**—(*a*) **Fermentation Test** (§ 150). Take 4 oz. (120 c.c.) of the urine; add a lump of German yeast, about the size of a walnut, lightly cork the bottle, and place it aside for twenty-four hours in a moderately warm place, *e. g.*, on the mantelpiece. Take the specific gravity before and after the fermentation. Thus, if the specific gravity be 1038 before and 1013 afterward, the difference or "density lost" is 25, which gives 25 grs. of sugar per fluid oz. (*Roberts*). If it be desired to get the percentage, multiply the density lost by 0.23, thus $25 \times 0.23 = 5.69$ in 100 parts.]

[(*b*) **Volumetric Analysis.**—10 c.c. of Fehling's solution = .05 of sugar.

1. Ascertain the quantity of urine passed in twenty-four hours. 2. Filter the urine, and remove any albumin present by boiling and filtration. 3. Dilute 10 c.c. of Fehling's solution with about twenty times its volume of distilled water, and place it in a white porcelain capsule on a wire gauze support under a burette. (It is diluted because any change of color is more easily observed.) 4. Take 5 c.c. of the urine, and 95 c.c. of distilled water, and place the diluted urine in a burette. 5. Gradually boil the diluted Fehling's solution, and while it is boiling gradually add the diluted urine from the burette, until all the cuprous oxide is precipitated as a reddish powder, and the supernatant fluid has a straw-yellow color, not a trace of blue remaining. Read off the number of c.c. of *dilute* urine employed. Say 36 c.c. were used—that, of course, represents 1.8 c.c of the original urine. Suppose the patient passes 1550 c.c., as 1.8 c.c. of urine reduced all the cupric oxide in the 10 c.c. of Fehling's solution, it must contain .05 gramme sugar, hence,

$$1.8 : 1550 :: .05 : \frac{1550 \times .05}{1.8} = 237.5 \text{ grammes of sugar passed in 24 hours.}]$$

[**Preparation of Fehling's Solution.**—34.64 grammes of pure crystalline cupric sulphate are powdered and dissolved in 200 c.c. of distilled water; in another vessel dissolve 173 grammes of Rochelle salts in 480 c.c. of pure caustic soda, specific gravity 1.14. Mix the two solutions, and dilute the deep colored fluid which results to 1 litre. *N.B.*—Fehling's ought not to be kept too long; it is apt to decompose, and should therefore be preserved from the light, or protected with opaque paper pasted on the bottle. Some other substances in urine, *e.g.*, urates and uric acid, reduce cupric oxide.]

(*c*) According to Worm-Müller, the polarization method is almost valueless for diabetic urine.

[**Picro-Saccharimeter.**—G. Johnson uses a stoppered bottle 12 inches long and ¾ inch wide, graduated in $\frac{1}{10}$ and $\frac{1}{100}$ (Fig. 269). To it is fixed a shorter bottle containing the standard iron solution for comparison, a standard solution, composed of liquor ferri perchloride ℥ j, liq. ammon. acetatis ℥ iv, glacial acetic acid ℥ iv, liq. ammoniæ ℥ j, and water to make up ℥ iv. All B. P. preparations give a color identical with a solution containing 1 gr. of grape sugar per oz., reduced by picric acid and afterward diluted four times, so that this tint = ¼ gr. of sugar per oz. After reducing the sugar with the picric acid, pour into the tall tube the dark saccharine liquid produced by boiling to occupy ten divisions of the tube, and add distilled water cautiously until the color approaches that of the standard; read off the level of the fluid. The amount of sugar present is determined from the amount of water added. In making the test, the picric acid must be added in proportion to the amount of sugar present.]

If large quantities of dextrose are taken in the food, a part of it (and more in diabetic persons) appears in the urine. Lævulose, when taken internally, does not increase the amount of sugar in diabetes. The free use of starch does not cause glycosuria in health, but in diabetes it increases the amount of

FIG. 269.

Picro-saccharimeter of G. Johnson.

FIG. 270.

Inosit crystallized partly from alcohol and partly from water (after *Funke*).

sugar. A large consumption of cane or milk sugar causes the passage of small quantities of both of these sugars into the urine in health, while in diabetes the amount of dextrose is increased (*Worm-Müller*). According to Külz, in diabetic persons cane sugar splits up into grape and fruit sugar, the latter being used up in the body, the former partly excreted; and the same is the case with milk sugar.

In severe cases of diabetes mellitus, Külz found the left-rotatory β-oxybutyric acid (the next highest analogue of lactic acid) in the urine, from which acetic acid is formed by oxidation (§ 175), which in its turn readily yields CO_2 and aceton. α-Crotonic acid is formed in urine by the removal of water from oxybutyric acid in the urine in diabetes (*Stadelmann*). The administration of aceton causes albuminuria, and this may in part explain in some cases the complication of albuminuria in diabetes (*Albertoni and Pisenti*).

Aceton, or aceton-yielding substance, probably aceto-acetic acid, is sometimes found in diabetic urine. It has a peculiar vinous odor, and it has been detected in the urine during fever. Gerhardt described a peculiar substance in diabetic urine, which gave a deep red color with perchloride of iron. This substance is probably diacetic ether, and he considered it to be the source of aceton; but it is more probably derived from aceto-acetic acid. **Test for Aceton.** (1) Perchloride of iron = Burgundy red color; but this is not reliable. (2) Lieben suggested an iodoform test. Dissolve 20 grains of KI in a fluid drachm of liq. potassæ and boil the fluid. Pour the suspected urine on the surface, when a ring of phosphates is deposited from the urine by the hot alkaline solution. If aceton be present, after a time the deposit becomes yellow, and yellow granules of iodoform appear and sink to the bottom of the test-tube. The only other substance which may be met with in the urine giving this reaction is lactic acid.

Milk sugar is sometimes found in the urine of women who are nursing, when the secretion of milk is arrested, absorption taking place from the breasts (*Kirsten, Spiegelberg*). **Lævulose** is sometimes found in diabetic urine (§ 252).

Dextrin has also been found in diabetic urine. **Inosit, or muscle sugar** (§ 252), is sometimes found in diabetes, in polyuria, and albuminuria. It is found in traces, even in normal urine. Occasionally, after the piqûre in animals (§ 175), inosit, instead of grape sugar, appears in the urine (Fig. 270). In testing for inosit, remove the grape sugar by fermentation, and the albumin by heat after the addition of a few drops of acetic acid and sodic sulphate. Some of the filtrate is evaporated nearly to dryness on a capsule. To the residue add two drops of mercuric nitrate (Liebig's titration fluid for urea), which gives a yellow precipitate. When this colored residue is spread out and carefully heated, a *dark red* color, which disappears on cooling, is obtained (*Gallois, Külz*). [Inosit gives a green when boiled with Fehling's solution.]

268. **CYSTIN.**—This left-rotatory body, $C_6H_{12}N_2S_2O_4$, occurs very seldom in large amount in urine, although it seems to be a constituent of normal urine. It may be in solution or in the form of hexagonal crystals (Fig. 271, A). It is insoluble in water, alcohol, and ether, but easily soluble

in ammonia, from which solution it may be crystallized. According to Baumann and Preusse there are intermediate products of the metabolism, from which are furnished the materials necessary for the formation of cystin. During normal metabolism these materials undergo further changes, and the sulphur appears oxidized in the urine as sulphuric acid. In rare cases these oxidations do not take place, and then the sulphur appears in the cystin of the urine (*Stadthagen*).

269. **LEUCIN** $= C_6H_{13}NO_2$. **TYROSIN** $= C_9H_{11}NO_3$.—Both bodies occur in the urine in **acute yellow atrophy of the liver,** and in poisoning by phosphorus. (Their formation during pancreatic digestion has been referred to in § 170, II.) As the urea excreted is usually diminished at the same time, it is assumed that, in these diseases, the further oxidation of the derivatives of the

proteids is interfered with. **Leucin,** which is either precipitated spontaneously or obtained after evaporating an alcoholic extract of the concentrated urine, occurs in the form of yellowish-**brown balls** (Fig. 272, *a*, *a*), often with concentric markings, or with fine spines on their surface. When heated, it sublimes without fusing.

Tyrosin forms silky, **colorless sheaves of needles** (Fig. 272, *b*, *b*). When boiled with mercuric nitrate and nitric acid it gives a red color, and afterward a brownish-red precipitate. **Piria's Test.**—When slightly heated with a few drops of concentrated sulphuric acid, it dissolves with a temporary deep red color. On diluting with water, adding barium carbonate until it is neutralized, boiling, filtering, and adding dilute ferric chloride, a violet color is obtained (*Piria*, *Städeler*).

270. **DEPOSITS IN URINE.**—Deposits may occur in normal and in pathological urine, and they may be either "**organized**" or "**unorganized.**"

I. Organized Deposits.

A. Blood: red and white blood corpuscles and sometimes fibrin (Figs. 264–266).

B. Pus, in greater or less amount in catarrh or inflammation of the urinary passages. Pus cells exactly resemble colorless blood corpuscles (Figs. 9, 267). **Donné's Test.**—Pour off the supernatant fluid and add a piece of caustic potash to the deposit; if it be pus it becomes gelatinous, ropy, and more viscid (alkali-albuminate). **Mucus,** when so acted on, becomes more fluid and mixed with flocculi.

C. Epithelium of various forms occurs, but it is not always possible to say whence it is derived.

D. Spermatozoa may be present.

E. Lower organisms occur in the urinary passages very seldom, but they may be present, *e.g.*, in the bladder, when germs are introduced from without by means of a dirty catheter. [Before introducing a catheter into the bladder one ought always to make sure that the instrument is perfectly aseptic.] Micrococci are found in the urine in certain diseases, *e.g.*, diphtheria. The following forms are distinguished:—

1. **Schizomycetes** (§ 184). *Normal* human urine contains neither schizomycetes nor their spores. In pathological conditions, however, fungi may pass from the blood into the urinary tubules and thus reach the urine (*Leube*). During the alkaline fermentation of urine, **micrococci**, rod-shaped **bacteria** or **bacilli** (Fig. 273) appear. **Sarcinæ** belong to the group (§ 186).

FIG. 273.

Fungi in urine. *e*, mould; *f*, yeast; *d*, *g*, micrococci and bacilli; *a*, *b*, *c*, uric acid.

2. **Saccharomycetes** (fermentation fungi): (*a*) The fungus of the acid urine fermentation (S. urinæ) consists of small bladder-like cells arranged either in chains or in groups (Figs. 260, *a*; 273, *f*). (*b*) Yeast (S. fermentum) occurs in diabetic urine, as oval cells with dotted eccentrically-placed nucleus (Fig. 237).

3. **Phytomycetes** (moulds) occur in putrid urine (Fig. 273, *e*). They are without clinical significance.

F. Tube Casts.—The occurrence of tube casts, *i. e.*, casts of the uriniferous tubules (*Henle*, 1837), is of great importance in the diagnosis of renal diseases. If these structures are relatively thick and straight, they probably come from the collecting tubules, but if they are smaller and twisted, they probably come from the convoluted tubules. There are various forms of tube casts: 1. **Epithelial casts**, consisting of the actual cells of the

uriniferous tubules. They indicate that there is no very great change going on, but only that, as in catarrhal inflammation of any mucous membrane, the epithelium is in process of desquamation. 2. **Hyaline casts** (Fig. 280) are quite clear and homogeneous, usually long and small; sometimes they are "finely granular," from the presence of fat or other particles. They are best seen after the addition of a solution of iodine. They are probably formed from albumin, which passes into the uriniferous tubules. They are dissolved in alkaline urine, while acid urine favors their formation. They usually occur in the late stages of renal disease, after the tubular epithelium has been shed. 3. **Coarsely granular casts** (Fig. 279) are brownish-yellow, opaque, and granular, usually broader than 2. There are various forms. Not unfrequently there are **fatty** granules, and, it may be, epithelial cells in them. 4. **Amyloid casts** occur in amyloid degeneration of the kidneys (Fig. 280). They are refractive and completely homogeneous, and give a blue color (amyloid reaction) with sulphuric acid and iodine. 5. **Blood casts** occur in capillary hemorrhage of the kidney, and consist of coagulated blood entangling blood corpuscles (Fig. 275). When tube casts are present, the urine is always *albuminous*.

Leucocyte casts occur in suppurating conditions of the urinary tubules (Fig. 280). The urates in the form of casts (Fig. 277) are without significance.

II. Unorganized Deposits.

Some of these are **crystalline** and others are **amorphous**, and they have been referred to in treating of the urinary constituents.

271. SCHEME FOR DETECTING URINARY DEPOSITS.—I. In **acid urine** there may occur—

1. An **amorphous granular deposit**:—
   (*a*) Which is dissolved by heat and reappears in the cold; the deposit is often reddish in color = **urates** (Fig. 260).
   (*b*) Which is not dissolved by heat, but is dissolved by acetic acid, but without effervescence = probably **tribasic calcic phosphate.**
   (*c*) Small bright refractive granules, soluble in ether = **fat or oil granules** (§ 41), (Lipæmia). Fat occurs in the urine, especially when the round worm, Filaria sanguinis hominis, is present in the blood; sometimes, along with sugar, in phthisis, poisoning with phosphorus, yellow fever, pyæmia, after long-continued suppuration, and lastly, after the injection of fat or milk into the blood (§ 102). It occurs also in fatty degeneration of the urinary apparatus, admixture with pus from old abscesses, and after severe injuries to bones. In these cases attention ought to be directed to the presence of cholesterin and lecithin. Very rarely is the fat present in such amount in the urine as to form a cream on the surface (**chyluria**).

FIG. 282.

Ammonio-magnesic phosphate.

FIG. 283.

Imperfect forms of the same.

2. A **crystalline** deposit may be—
   (*a*) **Uric acid** (Fig. 256).
   (*b*) **Calcium oxalate** (Fig. 258)—octahedra insoluble in acetic acid.
   (*c*) **Cystin** (Fig. 271).
   (*d*) **Leucin** and **tyrosin**—very rare (Fig. 272).

II. In **alkaline urine** there may occur—

1. *A completely* **amorphous granular deposit**, soluble in acids without effervescence = **tribasic calcic phosphate.**

2. *Sediment*, **crystalline**, *or with a characteristic form.*

(*a*) **Triple phosphate** (Figs 282, 283), soluble at once in acids.

(*b*) **Acid ammonium urate**—dark-yellowish, small balls often beset with spines, also amor- phous (Fig. 284).

(*c*) **Calcium carbonate**—small whitish balls or biscuit-shaped bodies. Acids dissolve them with effervescence (Fig. 281).

(*d*) **Leucin** and **tyrosin** (Fig. 272)—very rare.

(*e*) **Neutral calcic phosphate** and long plates of tribasic magnesic phosphate (Fig. 285).

Organized deposits may occur both in alkaline and in acid urine; pus cells are more abunda- ant in alkaline urine, and so are the lower vegetable organisms.

272. URINARY CALCULI.—Urinary concretions may occur in granules the size of sa- nd, or in masses as large as the fist. According to their size they are spoken of as **sand, grav-** el, **stone**, or **calculi**. They occur in the pelvis of the kidney, urete- rs, bladder, and sinus prostaticus.

We may classify them as follows (*Ultzmann*):—

1. Calculi whose nucleus consists of the sedimentary deposits t- hat occur in **acid urine** (primary formation of calculi). They are all

FIG. 284.

Acid ammonium urate.

FIG. 285.

Basic magnesic phosphate.

formed in the kidney, and pass into the bladder, where they enlarge by the deposition of m- alter on their surface.

2. Calculi which are either sedimentary forms from **alkaline urine**, or whose nucleus consi- ts of a *foreign body* (secondary formation of calculi). They are formed in the bladder.

The **primary** formation of calculi begins with free uric acid in the form of sheaves (Fig. 256) which form a nucleus, with concentric layers of oxalate of lime. The **secondary** formation oc- curs in *neutral* urine by the deposition of calcic carbonate and crystalline calcic phosphate; in *alk- aline* urine, by the deposition of acid ammonium urate, triple phosphate, and amorphous calcic phosp- hate.

Chemical Investigation.—Scrape the calculus, burn the scrapings on platinum foil to asce- rtain if they are burned or not.

I. Combustible concretions can consist only of organic substances.

(*a*) Apply the murexide test (§ 259, 2), and, if it succeeds, **uric acid** is present. Uric acid calculi are very common, often of considerable size, smooth, fairly hard, and yellow to red- dish-brown in color.

(*b*) If another portion, on being boiled with caustic potash, gives the odor of ammonia (or w- when the vapor makes damp turmeric paper brown, or if a glass rod dipped in HCl and held over it g- gives white fumes of ammonium chloride), the concretion contains **ammonium urate**. If *b* gives- s no result, pure uric acid is present. Calculi of ammonium urate are rare, usually small, of an ea- rthy consistence, *i. e.*, soft and pale yellow or whitish in color.

(*c*) If the **xanthin** reaction succeeds (§ 260), this substance is present (rare). **Indigo** has b- been found on one occasion in a calculus (*Ord*).

(*d*) If, after solution in ammonia, hexagonal plates (Fig. 271, A) are found, **cystin** is present- t.

(*e*) Concretions of **coagulated blood** or **fibrin**, without any crystals, are rare. When bur- rned they give the odor of singed hair. They are insoluble in water, alcohol and ether; but are sol- oluble in caustic potash, and are precipitated therefrom by acids.

(*f*) **Urostealith** is applied to a caoutchouc-like, soft elastic substance, and is very rare. W- When dry it is brittle and hard, brown or black. When warm it softens, and if more heat be applie- ed it melts. It is soluble in ether, and the residue after evaporation becomes violet on being heated. - It is soluble in warm caustic potash, with the formation of a soap.

II. If the concretions are only **partly combustible**, thus leaving a residue, they contain org- ganic and inorganic constituents.

(*a*) Pulverize a part of the stone, boil it in water, and filter while hot. The urates are dissol- olved. To test if the uric acid is united with soda, potash, lime, or magnesia, the filtrate is evaporated - and burned. The ash is investigated with the spectroscope (§ 14), when the characteristic band- ds of

sodium or potash are observed. Magnesic urate and calcic urate are changed into carbonate by burning. To separate them, dissolve the ash in dilute hydrochloric acid, and filter. The filtrate is neutralized with ammonia, and again redissolved by a few drops of acetic acid. The addition of ammonium oxalate precipitates **calcic oxalate.** Filter, and add to the filtrate sodic phosphate and ammonia, when the magnesia is precipitated as **ammonio-magnesic phosphate.**

(*b*) **Calcic oxalate** (especially in children, either as small, smooth, pale stones, or in dark, warty, hard "mulberry calculi") is not affected by acetic acid, is dissolved by mineral acids without effervescence, and again precipitated by ammonia. Heated on platinum foil it chars and blackens, then it becomes white, owing to the formation of calcic carbonate, which effervesces on the addition of an acid.

(*c*) **Calcic carbonate** (chiefly in whitish-gray, earthy, chalk-like calculi, somewhat rare) dissolves with effervescence in hydrochloric acid. When burned it first becomes black, owing to admixture with mucus, and then white.

(*d*) **Ammonio-magnesic phosphate** and **basic calcic phosphate** usually occur together in soft, white, earthy stones, which occasionally are very large. These stones show that the urine has been ammoniacal for a very long time. The first substance when heated gives the odor of ammonia, which is more distinct when heated with caustic potash; is soluble in acetic acid without effervescence, and is again precipitated in a crystalline form from this solution on the addition of ammonia. When heated it fuses into a white enamel-like mass [hence it is called "fusible calculus"]. **Basic calcic phosphate** does not effervesce with acids. The solution in hydrochloric acid is precipitated by ammonia. When ammonium oxalate is added to the acetic acid solution, it yields calcic oxalate.

(*e*) **Neutral calcic phosphate** is rare in calculi, while it is frequent in the form of gravel. Physically and chemically, these concretions resemble the earthy phosphates, only they do not contain magnesia.

273. THE SECRETION OF URINE.—[The **functions of the kidney** are—

1. To excrete waste products, chiefly nitrogenous bodies and salts;

2. To excrete water;

3. And perhaps also to reabsorb water from the uriniferous tubules, after it has washed out the waste products from the renal epithelium.

The chief parts of the organs concerned in 1, are the epithelial cells of the convoluted tubules; the glomeruli permit water and some solids to pass through them, while the constrictions of the tubules may prevent the too rapid outflow of water, and thus enable part of it to be reabsorbed.]

Theories.—The two chief older theories regarding the secretion of urine are the following: 1. According to **Bowman** (1842), through the glomeruli are filtered only the *water* and some of the highly diffusible and soluble salts present in the blood, while the specific urinary constituents are secreted by the activity of the epithelium of the urinary tubules, and are extracted or removed from the epithelium by the water flowing along the tubules. This has been called the "vital" theory. 2. **C. Ludwig** (1844) assumes that *very dilute urine* is secreted or filtered through the glomerulus. As it passes along the urinary tubules it becomes more concentrated, owing to endosmosis. It gives back some of its water to the blood and lymph of the kidney, thus becoming more concentrated, and assuming its normal character. [This is commonly known as the "mechanical" theory.]

The secretion of urine in the kidneys does not depend upon definite physical forces *only*. A great number of facts force us to conclude that the vital activity of certain secretory cells plays a foremost part in the process of secretion (*R. Heidenhain*).

The secretion of urine embraces (1) The **water,** and (2) the **urinary constituents** therein dissolved; both together form the urinary secretion. The **amount of urine** depends chiefly upon the amount of water which is filtered through or secreted by the glomeruli; the **amount of solids** dissolved in the urine determines its **concentration.**

(**A**) The **amount of urine,** which is secreted chiefly within the Malpighian capsules, *depends primarily upon the blood pressure in the area of the renal artery,* and follows, therefore, the laws of **filtration** (§ 191, II) (*Ludwig and Goll*). [In this respect the secretion of urine differs markedly from that of saliva, gastric juice, or bile. We may state it more accurately thus, that the amount of urine depends

very closely upon the differences of pressure between the blood in the glomeruli and the pressure within the renal tubules. If the ureter be ligatured, the secretion of urine is ultimately arrested, even although the blood pressure be high. The secretion may also be arrested by ligature of the renal vein; and in some cases of cardiac or pulmonary disease the venous congestion thereby produced may bring about the same result.]

Glomerular Epithelium.—The amount of urine secreted does not depend upon the hydrostatic pressure alone, but it seems that the epithelial cells covering the glomerulus also participate *actively* in the process of secretion. Besides the water, a certain amount of the salts present in the urine is excreted through the glomeruli. The *serum albumin of the blood, however, is prevented from passing through.* With regard to the secretory activity of these cells, the quantity of water must also depend upon the amount of the urinary constituents and water present in the blood (*R. Heidenhain*).

Only when the vitality of the secretory cells is intact, is there **independent activity** of these secretory cells (*Heidenhain*). When the renal artery is closed temporarily, their activity is paralyzed, so that the kidneys cease to secrete, and even after the compression is removed and the circulation re-established, secretion does not take place for some time (*Overbeck*).

That the secretion depends **in part upon the blood pressure** is proved by the following considerations:—

1. *Increase of the total contents of the vascular system, so as to increase the blood pressure,* increases the amount of water which filters through the glomeruli. The injection of water into the blood vessels, or drinking copious draughts of water, acts partly in this way. If the blood pressure rises above a certain height, albumin may pass into the urine. The *active participation* of the cells of the glomeruli is rendered probable by the fact that, after very copious drinking, the blood pressure is not always raised (*Pawlow*); further, after *copious transfusion,* the quantity of urine is not increased. Conversely, the loss of water, owing to profuse sweating or diarrhœa, copious hemorrhage, or prolonged thirst, diminishes the secretion of the urine.

2. *Diminution of the capacity of the vascular system,* provided the pressure within the renal area be thereby increased, acts in a similar manner. This may be produced by contraction of the cutaneous vessels, owing to the action of cold, stimulation of the vasomotor centre, or large vasomotor nerves, ligature, or compression of large arteries (§ 85, *e*), or enveloping the extremities in tight bandages. All these conditions cause an increase in the amount of urine, and of course the opposite conditions bring about a diminution of urine, *e. g.*, the action of heat on the skin causing redness and dilatation of the cutaneous vessels, weakening of the vasomotor centre, or paralysis of a large number of vasomotor nerves.

3. *Increased action of the heart,* whereby the tension and rapidity of the blood in the arteries are increased (§ 85, *c*), augments the amount of urine; conversely, feeble action of the heart (paralysis of motor cardiac nerves, disease of the cardiac musculature, certain valvular lesions) diminishes the amount. Artificial stimulation of the vagi in animals, so as to slow the action of the heart, and thus diminish the mean blood pressure from 130 to 100 mm. Hg, causes a diminution in the amount of urine to the extent of one-fifth (*Goll, Cl. Bernard*); when the pressure in the aorta falls to 40 mm. the secretion of urine ceases. [If the medulla oblongata be divided (dog), there is an immediate fall of the *general* blood pressure, and although, as a general rule, the secretion of urine is arrested when the pressure falls to 40 to 50 mm. Hg, yet secretion has been observed to take place with a lower pressure than this.]

4. The amount of urine secreted *rises or falls according to the degree of fullness of the renal artery* (*Ludwig, Max Hermann*); even when this artery is moderately constricted in animals, there is a decided diminution in the amount of urine.

Pathological.—In fever the renal vessels are less full, and there is consecutive diminution of urine (*Mendelson*). It is most important, in connection with certain renal diseases, to note that ligature of

the renal artery, even when it is obliterated for only two hours, causes necrosis of the epithelium of the uriniferous tubules. When the arterial anæmia is kept up for a long time, the whole renal tissue dies (*Litten*). After long-continued ligation of the renal artery, the epithelium of the glomeruli becomes greatly changed (*Ribbert*).

5. Most **diuretics** act in one or other of the above mentioned ways.

[Some diuretics act by increasing the *general* blood pressure (digitalis and the action of cold on the skin), others may increase the blood pressure *locally* within the kidney, and this they may do in several ways. The nitrites are said to paralyze the muscular fibres in the vasa afferentia, and thus raise the blood pressure within the glomeruli But some also act on the *secretory epithelium*, such as urea and caffein. Brunton recommends the combination of diuretics in appropriate cases, and the diuretics must be chosen according to the end in view—as we wish to remove excess of fluids from the tissues and serous cavities, or as we wish to remove injurious waste products, or merely to dilute the urine.]

[6. The amount of urine also depends upon the *composition of the blood.* Drinking a large quantity of water, whereby the blood becomes more watery, increases the amount of urine, but this is true only within certain limits. It is not merely the increase of volume of the blood acting mechanically which causes this increase, as we know that large quantities of fluid may be transfused without the general blood pressure being materially raised thereby.]

[Heidenhain argues, that it is not so much the *pressure* of the blood in the glomeruli as its **velocity**, which determines the process of the secretion of water in the kidney. He contends that, while increase of the pressure in the renal artery causes an increased flow of urine, ligature of the renal vein, whereby the pressure in the glomeruli is also increased, arrests the secretion altogether. In both cases the pressure is increased within the glomeruli, and the two cases differ essentially in the *velocity* of the blood current through the glomeruli.]

Pressure in the Vas Afferens.—The pressure in each *vas afferens* must be relatively great, because (1) the double set of capillaries in the kidney offers considerable resistance, and (2) the lumen of the vas efferens is narrower than that of the vas afferens. Hence, owing to the high blood pressure in the capillaries of the renal glomeruli, filtration must take place from the blood into the Malpighian capsules. When the vasa afferentia are dilated, the filtration pressure is increased, while, when they are contracted, the secretion is lessened. When the pressure becomes so diminished as to retard greatly the blood stream in the renal vein, the secretion of urine begins to be arrested. **Occlusion of the renal vein** completely suppresses the secretion (*H. Meyer, v. Frerichs*). Ludwig concluded from this observation, that the filtration or excretion of fluid could not take place through the renal capillaries *proper*, as, owing to occlusion of the renal vein, the blood pressure in these capillaries must rise, which ought to lead to increased filtration. Such an experiment points to the conclusion that the *filtration must take place through the capillaries of the glomeruli.* The venous stasis distends the vas efferens, which springs from the centre of the glomerulus, and compresses the capillary loops against the wall of the Malpighian capsule, so that filtration cannot take place through them. It is not decided whether any fluid is given off through the convoluted urinary tubules.

Venous congestion in the kidneys diminishes the quantity of urine and the urea. The NaCl remains constant, but pathological albumin is increased (*Senator and Munk*).

Pressure in Ureter.—As the blood pressure in the renal artery is about 120 to 140 mm. Hg, and the urine in the ureter is moved along by a very slight propelling force, so that a counter-pressure of from 10 (*Löbell*) to 40 mm. of Hg is sufficient to arrest its flow, it is clear that the blood pressure can also act as a *vis a tergo* to propel the urine through the ureter. The pressure in the ureter is measured by dividing the ureter transversely and inserting a manometer in it.

(B) Secretory Activity of the Renal Epithelium.—The degree of concentration of the urine depends upon the quantity of the dissolved constituents which has passed from the blood into the urine. The secretory cells of the convoluted tubules, by their own proper vital activity, seem to be able to take up,

or secrete, some at least of these substances from the blood (*Bowman, Heidenhain*). The watery part of the urine, containing only easily diffusible salts, as it flows along the tubules from the glomeruli, extracts or washes out these substances from the secretory epithelium of the convoluted tubules.

Experiments.—1. Sulphindigotate of soda and sodium urate when injected into the blood, pass into the urine, and are found in the protoplasm of the *cells* of the *convoluted tubules* [only in those parts lined by "rodded" epithelium] but not in the Malpighian capsules (*Heidenhain*). A little later these substances are found in the *lumen* of the urinary tubules, from which they are washed out by the watery part of the urine coming from the glomeruli. If, however, two days before the injection of these substances into the blood, the cortical part of the kidney containing the Malpighian capsules be cauterized, [*e. g.*, by nitrate of silver], or sliced off, the blue pigment remains within the convoluted tubules. It cannot be carried onward, as the water which should carry it along has ceased to be secreted, owing to the destruction of the glomeruli. This experiment also goes to show that, through the *glomeruli* the *watery part* of the urine is *chiefly excreted*, while through the *convoluted tubules the specific urinary constituents* are excreted. *Uric acid salts*, injected into the blood, were observed by Heidenhain to be excreted by the convoluted tubules. Von Wittich had previously observed that in *birds*, crystals of uric acid were excreted by the epithelium of the convoluted tubules. [The presence of crystals of uric acid in the renal epithelium was observed by Bowman, and used as an argument to support his theory.] Nussbaum, in 1878, stated that *urea* is secreted by the urinary tubules and not by the glomeruli.

The same is true for the *bile pigments*, for the *iron salts* of the vegetable acids when injected subcutaneously, and for hæmoglobin. After injection of *milk* into the blood vessels, numerous fatty granules occur within the epithelium of the urinary tubules (§ 102).

[**Nussbaum's Experiments.**—In the frog and newt, the kidney is supplied with blood in a manner different from that obtaining in mammals. The glomeruli are supplied by branches of the renal artery. The tubules are supplied by the renal-portal vein. The vein coming from the posterior extremities divides at the upper end of the thigh into two branches, one of which enters the kidney, and breaks up to form a capillary plexus which surrounds the uriniferous tubules, but this plexus is also joined by the efferent vessels of the glomeruli. These two systems are partly independent of each other. After ligaturing the renal artery, Nussbaum asserted that the circulation in the glomeruli was cut off, while ligature of the renal-portal vein excluded the functional activity of tubules. By injecting a substance into the blood, after ligaturing either the artery or renal-portal vein, and observing whether it occurs in the urine, he infers that it is given off either by the glomeruli or the tubules. *Sugar*, *peptones*, and *egg albumin* rapidly pass through an intact kidney, but if the renal artery be tied they are not excreted. *Urea* when injected into the circulation is excreted after the artery is tied, so that it is excreted through the tubules, but at the same time it takes with it a considerable quantity of water. Thus, water is excreted in *two* ways from the kidney, by the glomeruli and also from the venous plexus around the tubules along with the urea. *Indigo carmine* merely passes into the tubular epithelium of the convoluted tubules, but it does not cause a secretion of urine. *Albumin* passes through the glomeruli, but only after their membranes have been altered in some way, as by clamping the renal artery for a time.]

[**Adami's Experiments** on the kidney of the frog tend to show that Nussbaum's conclusions are not justified, for Adami found that if the renal arteries in the frog be ligatured, within a few hours a collateral circulation is established, and a certain amount of blood flows through the kidney. He proved this by injecting into the blood, carmine or painter's vermilion, in a state of fine suspension, and after ligature of the renal arteries, he found it in many of the glomeruli, while laky blood similarly injected revealed its presence as menisci of Hb in the Malpighian corpuscles. Even secretion of some urine may go on after ligature of the renal arteries. It is evident, then, that

Nussbaum's method is not a reliable one for locating the parts of the kidney through which certain substances are excreted. Adami's experiments also give some support to Heidenhain's view, that the glomerular epithelium "possesses powers of a selective secretory nature," for he finds that in frogs, after ligature of the renal arteries, where, of course, the pressure in the glomeruli is just nearly that in the veins, and in the dog after section of the spinal cord, so that the blood pressure has fallen below 40 mm. Hg, whereby the secretion of urine is arrested, the injection of laky blood causes Hb to appear in the capsules, although there is no simultaneous excretion of water.]

Excretion of Pigments.—Only during very **copious excretion** does the capsule participate. After the introduction of a large amount of sodic sulphindigotate, and when the experiment has lasted for a long time, the epithelium of the capsule becomes blue. **In albuminuria,** the abnormal excretion of urine takes places first in the urinary tubules, and afterward in the capsules; Hb is partly found in the capsules. According to Nussbaum, egg albumin passes out through the capsule.

2. Even when the secretion of the *watery part* of the urine is completely *arrested*, either by ligature of the ureter, or after a very great fall of the blood pressure in the renal artery [as after section of the cervical spinal cord], the before-mentioned substances, when injected into the blood, are found in the cells of the convoluted tubules. The injection of urea under these circumstances causes renewed secretion. These facts show that, independently of the filtration pressure, the *secretory activity of these cells* is still maintained.

The independent **vital activity of the secretory cells** of the urinary tubules, which as yet we are unable to explain on purely physical grounds, renders it probable that the tubules are not to be compared to an apparatus provided with physical membranes. This is proved by the following experiment: Abeles caused arterial blood to circulate through freshly excised living kidneys. A pale, urine-like fluid dropped from the ureter. On adding some urea or sugar to the blood, the secretion became more concentrated. Thus, the **excised living kidney** also excretes substances in a more concentrated form than those supplied to it in the diluted blood streaming through it. J. Munk obtained similar results in excised kidneys with common salt, nitre, caffein, grape sugar, glycerin, with increase in the amount of urine secreted. The addition of caffein or theobromin to the perfused blood increases the secretion, exciting the secretory cells to greater activity (*v. Schroeder*).

Salts and Gases.—The vital activity explains why the serum albumin of the blood does not pass into the urine, while egg albumin and dissolved hæmoglobin readily do so. Among the *salts* which occur in the blood and blood corpuscles, of course only those in solution can pass into the urine. Those which are united with proteid bodies, or are fixed in the cellular elements, cannot pass out, or at least only after they have been split up. Thus, we may explain the difference between the salts of the urine and those of the blood. Similarly, the urine can only contain the absorbed and not the chemically united *gases*.

Ligature of the Ureter.—If the secretion be arrested by compression or by ligature of the ureter, the lymph spaces of the kidney become filled with fluid, which may pass into the blood, so that the organ becomes œdematous, owing to the passage of fluid into its lymph spaces. The secretion undergoes a change, as, first, water passes back into the blood, then the sodic chloride, sulphuric, and phosphoric acids diminish, and lastly the urea (*C. Ludwig, Max Hermann*). Kreatinin is still present in considerable amount. There is no longer secretion of proper urine (*Löbell*).

Non-symmetrical Renal Activity.—It is remarkable that both kidneys do not secrete symmetrically—there is an alternate condition of hyperæmia and secretory activity on opposite sides (§ 100). One kidney secretes a more watery urine, which at the same time contains more NaCl and urea. Von Wittich observed that the secretion of uric acid was not uniform in all the urinary tubules of the same bird. **Extirpation** of one kidney, or disease of one kidney in man, does not seem to diminish the secretion (*Rosenstein*). The remaining kidney becomes more active and larger.

Reabsorption in the Kidney.—In discussing the secretion of the kidney, we must attach considerable importance to the variations in the calibre of the renal tubules in their course. Perhaps in the narrowing of the descending part of the looped tubule of Henle there may be either a reabsorption of water, so that the urine becomes more concentrated, or there may be absorption even of albumin, which may perhaps pass through the glomeruli in small amount. [That reabsorption of fluid takes place within the kidney was part of Ludwig's theory, which is practically a process of filtration and reabsorption. Hüfner pointed out that the structure of the kidneys of various classes of vertebrates corresponded closely with the requirements for reabsorption of water. The experiments of Ribbert show that the urine actually secreted in the cortex of the kidney is more watery than that secreted normally by the entire organ. He extirpated the medullary portion in rabbits, leaving the cortical part intact, and in this way collected the dilute urine from the Malpighian corpuscles before it passed through Henle's loops.]

274. FORMATION OF THE URINARY CONSTITUENTS.—The question has often been discussed, whether all the urinary constituents are merely excreted through the kidneys, *i. e.*, that they exist preformed in the blood;

or whether some of them do *not* exist preformed in the blood, but are formed within the kidneys, as a result of the activity of the renal epithelium.

Urea is formed Outside the Kidney.—Urea exists preformed in the blood, from which it is separated by the activity of the kidney. This is proved by the following considerations :—

1. The blood contains one part of urea in 3000 to 5000 parts, but the **renal vein** contains less urea than the blood of the corresponding artery.

2. After **extirpation** of the kidneys, or **nephrotomy**, or after ligature of the renal vessels, the amount of urea accumulates in the blood, and increases with the duration of the experiment to $\frac{1}{150}$ to $\frac{1}{100}$. At the same time there is vomiting and diarrhœa, and the fluids so voided contain urea (*Cl. Bernard*). Animals die in from one to three days after the operation.

3. After ligature of the ureters, the secretion of urine is soon arrested. Urea accumulates in the blood, but not to a greater extent than after nephrotomy. It is possible, however, that the kidneys, like other organs, may form a small amount of urea, due to the metabolism of their own tissues.

[**Urea exists in the blood**; whence does the blood derive it? It can only obtain it from one or more of several organs—(1) muscle, (2) nervous system, and (3) glands, of which the liver is the most prominent. This is best stated by the method of exclusion.]

[1. That urea is not formed in muscle is shown, among other considerations, by the fact that only a trace of urea occurs in muscle (§ 293), and that the amount is not increased by exercise. Blood which has been transfused through a muscle, or the blood after circulating in a muscle during violent exercise, does not contain an increase of urea, nor does the addition of ammonia carbonate to blood circulating through muscle show any increase of urea. Again, muscular exertion does not (as a rule) increase the amount of urea in the urine, as shown by the experiments of Fick and Wislicenus (§ 294), Parkes, and others. The excretion chiefly increased by muscular exertion is the pulmonary CO_2 (§ 127).]

[2. From what we know of the nervous system, it is not formed there. We are therefore forced to consider the evidence as to the **liver**, as the organ, or, at least, the chief organ in which it is formed. This evidence is in some respects contradictory, but it is partly **experimental** and partly **clinical**. Although Hoppe-Seyler denies the existence of urea in the liver, its existence there was proved by Gscheidlen; and Cyon, on passing blood through an excised liver by the "perfusion" method of Ludwig, found that blood, after being passed several times through the organ, contained an *increased* amount of urea. The objection to these experiments is that Cyon's method of estimating the urea was unreliable. But von Schroeder, using a similar method, finds that if blood be perfused through the liver of a dog in full digestion, there is a great increase in the amount of urea, while there is none in the liver of a fasting dog. If ammonia carbonate be added to the blood, there is a very much greater amount of urea in the blood of the hepatic vein. This last fact is confirmed by Salomon. The experiments of Minkowski on the liver of the goose (§ 386) show that, when the liver is excluded from the circulation, lactic acid takes the place of uric acid in this bird. Brouardel further states, that if the region of the liver be so beaten as to cause congestion of that organ, there is an increase of the urea in the urine.]

[The **clinical** evidence points strongly to the formation of urea in the liver. Parkes pointed out that in hepatic abscess, during the early congestive stage, the urea in the urine is increased, while it is diminished in the suppurative stage, when the hepatic parenchyma is destroyed. The urea is also diminished in cancer of the liver, phthisis, and some forms of hepatic cirrhosis, while it is increased during hepatic congestion, and specially so in some cases of diabetes mellitus. The most striking fact of all is that, in **acute yellow atrophy** of the liver, the urea is enormously diminished in the urine, and may even disappear from it while its place is taken by the intermediate products, leucin and tyrosin (*v. Frerichs*). In poisoning by phosphorus, coincident with the atrophy of the liver, there is a fall in the urea excretion. Noël-Paton finds that some drugs which increase the quantity of bile in dogs in a state of N-equilibrium (§ 178), *e.g.*, sodic salicylate and benzoate, colchicum, mercuric chloride and eunonymin also increase the urea in the urine, he therefore concludes "that the formation of urea in the liver bears a very direct relationship to the secretion of bile by that organ."]

As to the **antecedents** of urea there is the greatest doubt (§ 256).

Uric Acid is formed Outside the Kidneys.—1. Birds' blood normally contains uric acid (*Meissner*). [The liver of the pigeon contains 6 to 14 times as much uric acid as the blood.] Ligature of the ureters or renal blood vessels (*Pawlinoff*), or gradual destruction of the renal secretory parenchyma by the subcutaneous injection of neutral potassium chromate (*Ebstein*), is followed by the deposition of uric acid in the joints and tissues, and it may even form a white incrustation on

the serous membranes. The brain remains free (*Zalesky, Oppler*). Acid urates of ammonia, soda, and magnesia are also similarly deposited. Extirpation of a snake's kidneys gives the same result, but to a less degree.

[Minkowski found that, after excluding the liver from the circulation, lactic acid took the place of uric acid in the urine (p. 474). Some uric acid still appears in the urine, which cannot be derived from the small amount in the blood, so that, according to v. Schroeder, there are perhaps other foci of formation of uric acid.]

[The latter experiment points to the formation of uric acid in the **liver** in birds, and this is supposed to be strengthened by the appearance of the deposition of urates in the urine in certain disorders of digestion.] Von Schroeder and Colasanti, however, as the result of their experiments upon snakes, come to the conclusion that there is no special organ concerned in the formation of uric acid.

Hippuric acid is partly formed in the **kidney,** for the blood of herbivora does not contain a trace of it (*Meissner and Shepard*). In rabbits, perhaps it is formed synthetically, in other tissues as well as in the kidney. If blood containing sodic benzoate and glycin be passed through the blood vessels of a fresh kidney, hippuric acid is formed (§ 260) (*Bunge, Schmiedeberg, Kochs*). [The other evidence is given in § 260.]

Kreatinin has intimate relations to kreatin of muscle, but where it is formed is not known. If *phenol* and pyrokatechin are digested along with fresh *renal substance, a compound of sulphuric acid* similar to that occurring in urine is formed (§ 262). The latter substance, however, is also formed by similarly digesting liver, pancreas, and muscle. It is concluded from these experiments that these substances are formed in the body within the kidneys and the other organs mentioned (*Kochs*).

Chemistry of the Kidney.—The kidneys contain a very large amount of *water*. Besides serum albumin, globulin, albumin soluble in sodium carbonate (*Gottwalt*), gelatin-yielding substances, fat in the epithelium, elastic substance derived from the membrana propria of the tubules, the kidneys contain leucin, xanthin, hypoxanthin, kreatin, taurin, inosit, cystin (the last in no other tissue), but only in very small amount. The occurrence of these substances points to a lively metabolism in the kidneys, which is also proved by the liberal supply of blood they receive.

Blood Vessels.—The kidneys receive a very large supply of blood, and during secretion the blood of the **renal vein is bright red.** [In the dog, the diameter of the renal artery may be diminished to .5 mm. without the amount of blood flowing through the kidney being thereby greatly interfered with. Hence, within wide limits, the amount of blood is independent of the size of the arterial lumen, and is therefore dependent on the blood pressure in the aorta, and the resistance to the blood current within and beyond the kidney (*Heidenhain*).]

The **reaction** of the kidneys is *acid*, even in those animals whose urine is alkaline. Perhaps this fact is connected with the retention of the albumin in the vessels.

275. PASSAGE OF VARIOUS SUBSTANCES INTO THE URINE.—1. The following substances pass **unchanged** into the urine: Sulphate, borate, silicate, nitrate, and carbonate of the alkalies; alkaline chlorides, bromides, iodides; potassium sulphocyanide and ferrocyanide; bile salts, urea, kreatinin; cumaric, oxalic, camphoric, pyrogallic, and carbolic acids. Many *alkaloids, e.g.*, morphia, strychnia, curara, quinine, caffein; *pigments*, sulphindigotate of soda, carmine, madder, logwood, coloring matter of cranberries, cherries, rhubarb; santonin; lastly, salts of gold, silver, mercury, antimony, arsenic, bismuth, iron (but not lead), although the greatest part of these is excreted by the bile and the fæces.

2. Inorganic acids reappear in man and carnivora as neutral salts of ammonia, in herbivora, as neutral salts of the alkalies.

3. Certain substances which, when injected in small amount, seem to be **decomposed** in the blood, pass in part into the urine, when they occur in such large amount in the blood that they cannot be completely decomposed—sugar, hæmoglobin, egg albumin, alkaline salts of the vegetable acids, alcohol, chloroform.

4. Many substances appear in an **oxidized form** in the urine—moderate quantities of organic alkaline salts as alkaline carbonates (*Wöhler*), uric acid in part as allantoin (*Salkowski*), sulphides and sulphites of soda, in part as sodium sulphate, potassium sulphide as potassium sulphate, some oxyduls as oxides, benzol as phenol (*Naumyn and Schulzen*).

5. Those bodies which are completely decomposed, as glycerin, resins, give rise to no special derivatives in the urine.

6. Many substances **combine** and appear as conjugated compounds in the urine, *e. g.*, the origin of the hippuric acid by conjugation (§ 260), the conjugation of sulphonic acid (§ 262), and the formation of urea by synthesis from carbamic acid and ammonia (*Drechsel*) (§ 256). After the use of

camphor, chloral; or butylchloral, a conjugated compound with glycuronic acid (an acid nearly related to sugar) appears in the urine. Taurin and sarcosin unite with sulphaminic acid. When bromophenol is given, it unites with mercapturic acid, a body nearly related to cystin (§ 268).

7. Tannic acid, $C_{14}H_{10}O_9$, takes up H_2O, and is decomposed into two molecules of gallic acid = 2 ($C_7H_6O_5$).

8. The iodates of potash and soda are **reduced** to iodides; malic acid ($C_4H_6O_5$) partly to succinic acid ($C_4H_6O_4$); indigo-blue ($C_{16}H_{10}N_2O_2$) takes up hydrogen and becomes indigo-white ($C_{16}H_{12}N_2O_2$).

9. Some substances **do not pass** into the urine at all, *e. g.*, oils, insoluble metallic salts and metals.

276. INFLUENCE OF NERVES AND OTHER CONDITIONS.—At present we are acquainted merely with the influence of the **vasomotor** nerves on the filtration of the urine through the renal vessels. *Each* kidney seems to be supplied with vasomotor nerves, which spring from *both* halves of the spinal cord (*Nicolaides*). As a general rule, dilatation of the branches of the renal artery, chiefly the vasa afferentia, must raise the pressure within the glomeruli, and thus increase the amount of water filtered through them. The more the dilatation is confined to the area of the renal artery alone, the greater is the amount of the urine. [As yet we know the nervous system influences the secretion of urine only in so far as it modifies the pressure and velocity of the blood current in the kidney. We have no satisfactory evidence of the existence of direct secretory nerves in the kidney.]

1. **Renal Plexus and its Centre.**—Section of the nerves of the renal plexus—the nerves around the renal artery—generally causes a considerable increase in the secretion of urine, **hydruria** or **polyuria**; sometimes, on account of the great rise of the pressure within the glomeruli, albumin passes into the urine, and there may be rupture of the vessels of the glomeruli, leading to the passage of blood into the urine. The **nerve centre** for the renal nerves lies in the floor of the fourth ventricle, in front of the origin of the vagus. Injury to this part of the floor of the fourth ventricle, *e. g.*, by puncture (piqûre), may increase the amount of urine (**diabetes insipidus**), which is sometimes accompanied by the simultaneous appearance of albumin and blood in the urine (*Cl. Bernard*). Section of the parts which lie directly in the course of these fibres, as they pass from their centre to the kidney, produces the same effects. Close to this centre in the medulla, lies the centre for the vasomotor nerves of the liver, whose injury causes **diabetes mellitus** (§ 175). Eckhard found that stimulation of the vermiform process of the cerebellum produced hydruria. In man, stimulation of these parts by tumors or inflammation, etc., produces similar results.

2. **Paralysis of Limited Vascular Areas.**—If, simultaneously with the paralysis of the nerves of the renal artery, the nerves of a neighboring large vascular area be paralyzed, necessarily the blood pressure in the renal artery area will not be so high, as more blood flows into the other paralyzed province. Under these circumstances, there may be only a temporary, or, indeed, no increase of urine, provided the paralyzed area be sufficiently large. There is a moderate increase of urine for several hours after **section of the splanchnic nerve.** This nerve contains the renal vasomotor nerves (which, in part, at least, leave the spinal cord at the first dorsal nerve and pass into the sympathetic nerve), but it also contains the vasomotor nerves for the large area of the intestinal and abdominal viscera. Stimulation of this nerve has the opposite effect (*Cl. Bernard, Eckhara*). [The polyuria thus produced is not so great as after section of the renal nerves, because the splanchnic supplies such a large vascular area, that much blood accumulates in that area, and also because all the renal nerves do not run in the splanchnics.]

3. **Paralysis of Large Areas.**—If, simultaneously with paralysis of the renal nerves, the great majority of the vasomotor nerves of the body be paralyzed [as by section of the medulla oblongata], then, owing to the great dilatation of all these vessels, the blood pressure falls at once throughout the arterial system. The result of this may be, provided the pressure is sufficiently low, that there is a great decrease,

or, it may be, entire cessation of the secretion of urine. The secretion is arrested when the cervical cord is completely divided, down even as far as the seventh cervical vertebra (*Eckhard*). The polyuria caused by injury to the floor of the fourth ventricle at once disappears when the spinal cord (even down to the twelfth dorsal nerve) is divided.

[4. **Other Conditions.**—As already stated, section of the renal nerves is followed by polyuria, owing to the increased pressure in the glomeruli, but this polyuria may be increased by stimulating the spinal cord below the medulla oblongata, because the contraction of the blood vessels throughout the body still further raises the blood pressure within the glomeruli. If, however, the spinal cord be divided below the medulla oblongata—the renal nerve being also divided—the polyuria ceases, because of the fall of the general blood pressure thereby produced. Division of the spinal cord in the dorsal region also diminishes or arrests the secretion of urine, owing to the fall of the blood pressure; but animals recover from this operation, the general blood-pressure rises, and with it the secretion of urine. Stimulation of the cord below the medulla arrests the secretion, as it causes contraction of the renal arteries along with the other arteries of the body.]

[**Volume of the Kidney—Oncometer.**—By means of the plethysmograph (§ 101) we can measure the variations in the size of a limb, while by the oncograph

FIG. 286.

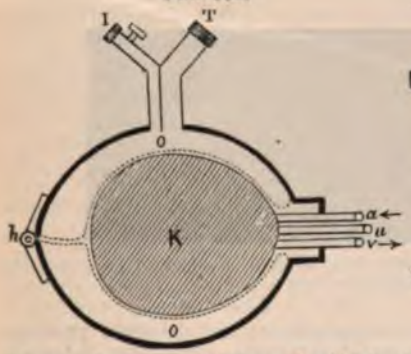

FIG. 287.

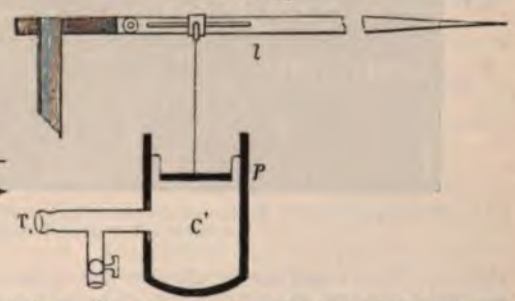

FIG. 286.—Oncometer. K, kidney; the thick line is the metallic capsule; *h*, hinge; I, tube for filling apparatus; T, tube to connect with T_1; *a*, *v*, *u*, artery, vein, ureter (*Stirling, after Roy*).
FIG. 287.—Oncograph. C', chamber filled with oil, communicating by T_1 with T; *p*, piston; *l*, writing lever (*Stirling, after Roy*).

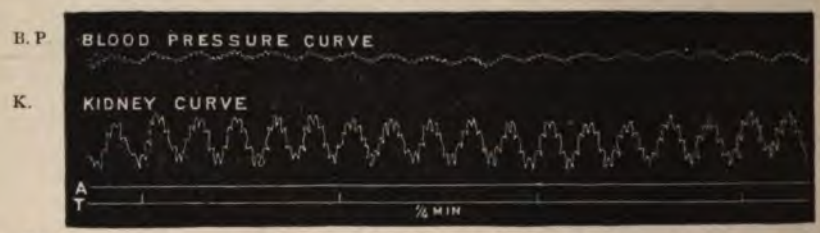
(ὄγκος, volume) similar variations in the volume of the spleen are measured (§ 103). Roy and Cohnheim have measured the variations in the volume of the kidney by means of an instrument which consists of two parts, one termed the **oncometer** or **renal plethysmometer**, in which the organ is enclosed, while the other part is the registering portion, or **oncograph**. The kidney is enclosed in a kidney-shaped metallic capsule (Fig. 286), composed of two halves which move on the hinge, *h*, to introduce the organ. The renal vessels pass out at *a*, *v*. The kidney is surrounded with a thin membrane, and between this membrane and the inner surface of the capsule is a space filled with warm *oil* through the tube, I, which is closed by means of a stop-cock after the space is filled with oil. The tube, T, can be made to communicate with another tube, T_1, leading into a metallic chamber, C', of the oncograph (Fig. 287), which is provided with a movable piston, *p*, attached by a thread to the writing-lever, *l*. Any increase in the size of the organ expels oil from the chamber, O, into C', and thus the piston is raised, while a diminution in the size of the kidney diminishes the fluid in C', and the lever falls. The actual volume of the living kidney depends upon the state of distention of its

structural elements, upon the amount of lymph in its lymph spaces, but chiefly upon the amount of blood in its blood vessels, and this again must depend upon the condition of the non-striped muscles in the renal arteries. When the vessels dilate, the kidney increases in size, and when they contract it contracts, so that we can register on the same revolving cylinder the variations of the volume at the same time that we record the general arterial blood pressure.]

[In the **normal circulation** through the kidney, the kidney curve, *i. e.*, the curve of the volume of the kidney, runs parallel with the blood-pressure curve, and shows the large respiratory undulations, as well as the smaller elevations due to the systole of the heart (Fig. 288). Usually, when the blood pressure falls, the kidney curve sinks, and when the blood pressure rises the volume of the kidney increases. When the blood-pressure curve is complicated by Traube-Hering waves (§ 85) the *opposite* effect is produced on the kidney curve; the highest blood pressure corresponds to the smallest size of the kidney, and conversely. This is due to the fact that, when these curves occur, all the small arterioles, including those in the kidney, are contracted. A kidney placed in an oncometer secretes urine like a kidney under natural conditions.]

[**Arrest of the respiration** in a curarized animal produces a rapid and great diminution of the volume of the kidney, caused by the venous blood stimulating the vasomotor centres, and thus contracting the small arterioles, including those of the

FIG. 288.



B. P., Blood-pressure curve; K., curve of the volume of the kidney; T, time curve, intervals indicate a quarter of a minute; A, abscissa (*Stirling, after Roy*).

kidney. This result occurs whether one or both splanchnics are divided, proving that all the vasomotor nerves of the kidney do not reach it through the splanchnics. When *all* the renal nerves at the hilum are divided, arrest of the respiration causes dilatation of the organ, which condition runs parallel with the rise of the blood pressure. Stimulation of a sensory nerve, *e. g.*, the central end of the sciatic nerve, while causing an increase of the blood pressure, makes the kidney shrink.]

[In poisoning with **strychnin**, the kidney shrinks while the blood pressure rises. Stimulation of the central or peripheral end of the **splanchnics**, divided at the diaphragm, causes contraction of the renal vessels of *both* sides; the former is a reflex, the latter a direct effect. Stimulation of the peripheral end of *one* splanchnic sometimes affects both kidneys. Stimulation of the peripheral end of the renal nerves always causes a diminution in the volume of the kidney, so that Cohnheim and Roy inferred that, although there was evidence of the existence of **vasomotor** and **sensory nerves** to the kidney, they found none of vaso-dilators. Each kidney acts independently of the other. Sudden compression of one renal artery has not the slightest effect upon the blood current of the other kidney. If a kidney be exposed in an animal, by making an incision in the lumbar region, on stimulating the medulla oblongata directly with electricity, we may observe the kidney itself becoming paler, the pallor appearing in a great many small spots on the surface of the organ, corresponding to the distribution of the interlobular arteries.]

[Cohnheim showed that the **composition of the blood** has a remarkable effect

on the renal circulation. Some substances (water and urea), when injected into the blood, cause the kidney first to shrink and then to expand, while sodic acetate dilates the kidney, even after all the renal nerves are divided—an operation which is very difficult indeed. Provided all the renal nerves be divided, these effects would indicate the existence of some local intra-renal vasomotor mechanism governing the renal blood vessels. The general blood pressure is not thereby modified; nor need we wonder at this, as ligature of one renal artery does not increase the pressure in the aorta.]

[The reciprocal relation between the **skin and the kidneys** is known to every one. On a cold day, when the skin is pallid, owing to contraction of the cutaneous vessels, the amount of urine secreted is great, and conversely, in summer less urine is passed than in winter. Washing the skin of a dog for two minutes with ice-cold water causes a great contraction of the kidney.]

The perfusion of blood through a living excised kidney is materially influenced by the substances mixed with the blood perfused. This effect may in part be due to the action of these chemical ingredients upon the nuclei of the endothelial lining of the blood vessels, especially the capillaries, or the effects upon the muscular fibres of the blood vessels.

[Strychnin seems to cause contraction of the renal vessels, independently of its action on the general vasomotor centre. Brunton and Power found that digitalis caused an increase of the blood pressure (dog), but the secretion of urine was either at the same time diminished, or it ceased altogether. The latter result was due to contraction of the renal blood vessels, but when the aortic blood pressure began to fall, the amount of urine secreted rose much above normal, *i. e.*, when the arteries had begun to relax.]

During **fever**, the renal vessels are probably contracted in consequence of the stimulation of the renal centre by the abnormally warm blood (*Mendelson*).

The repeated respiration of CO is said to produce polyuria, perhaps in consequence of paralysis of the renal vasomotor centre.

Action of the Vagus.—According to Cl. Bernard, stimulation of the vagus at the cardia increases the urinary secretion, while at the same time the blood of the renal vein becomes red. This nerve may contain vaso-dilator nerve fibres corresponding to the fibres in the facial nerve for the salivary glands (§ 145).

277. **URÆMIA—AMMONIÆMIA.—Symptoms of Uræmia.**—After excision of the kidneys, **nephrotomy**, or ligature of the ureter; in man, also, as a result of certain diseased conditions of the kidney, leading to the suppression of the secretion of urine, there is developed a series of characteristic symptoms which are followed by death. The condition is called uræmic intoxication or *uræmia*. There are marked cerebral phenomena, drowsiness, and deep coma, and occasionally local or more general *spasms*. Sometimes there is *delirium;* Cheyne-Stokes phenomenon is often observed (§ 111, 11), and there may be vomiting and diarrhœa, while in the fluids voided, as well as in the expired air, ammonia may sometimes be detected.

The **cause** of these phenomena has been ascribed to the retention in the blood of those substances which normally are excreted by the urine, but as yet it has not been definitely ascertained which of these substances cause the phenomena:—

1. The first thought is to ascribe them to the retention of the **urea.** v. Voit found that dogs exhibited uræmic symptoms if they were fed for a long time on food containing urea and little water. Meissner found that in nephrotomized animals, the uræmic symptoms were hastened by the injection of urea into the blood. The injection of a moderate amount of urea in perfectly healthy animals is not followed by uræmic symptoms, probably because the urea is rapidly excreted by the kidneys; 1 to 2 grms. [15 to 30 grains] so injected produce comatose symptoms in rabbits.

2. The injection of **ammonium carbonate** produces symptoms resembling those of uræmia, so that v. Frerichs thought that the urea was decomposed in the blood, yielding ammonium carbonate—**ammoniæmia.** Demjankow observed uræmic phenomena after nephrotomy, if at the time he injected urea ferment into the blood (§ 263). Feltz and Ritter obtained uræmic symptoms in dogs by injecting salts of ammonia.

3. As ligature of the ureters produces a comatose condition in those animals which excrete chiefly uric acid in the urine—*e. g.*, birds and snakes (*Zalesky*)—it is possible that other substances may produce the poisonous symptoms. The injection of kreatinin causes feebleness and contraction of the muscles in dogs (*Meissner*). Bernard, Traube, and more recently Feltz and Ritter, ascribe the symptoms to an accumulation of the neutral potassium salts in the blood (§ 54). The injection of kreatin, succinic acid (*Meissner*), uric acid, and sodic urate (*Ranke*), is without effect. Schottin and Oppler ascribe the results to an accumulation of normal or abnormal *extractives*. It is possible that several

substances and their decomposition products contribute to produce the result, so that there is a combined action of several factors, but perhaps the retention of the *potash salts* plays the most important part.

The direct application of some ordinary substances (kreatinin, kreatin, acid potassic phosphate, urates) to the surface of the cerebrum causes all the symptoms of uræmia. Urea is inactive, and slightly active are ammonium and sodic carbonate, leucin, NaCl, KCl (*Landois*).

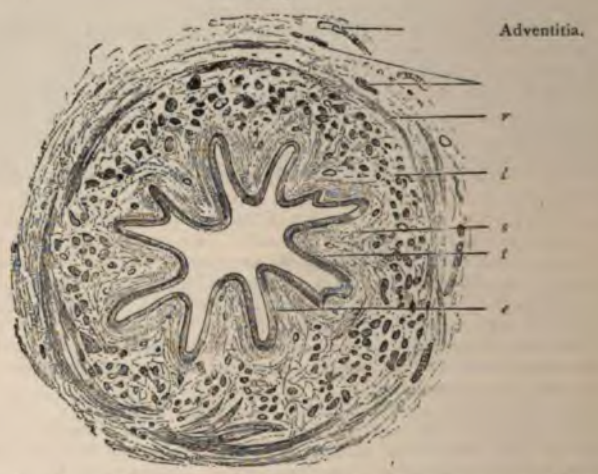
[**Alkaloids in Urine.**—Human urine, and especially febrile urine, when injected under the skin of frogs or rabbits, acts as a poison, and even causes death, by arresting the respiration. The alkaloids seem to be formed by the action of vegetable organisms in the intestine, whence they are absorbed into the blood and pass into the urine (§ 116). Urine rendered colorless by charcoal loses half its toxic power, and the poisonous substance is not volatile, and even resists boiling. These alkaloids are **increased** in the urine in typhoid fever, pneumonia, but not in diabetes.]

Ammoniæmia.—When urine undergoes the alkaline fermentation within the bladder, and ammonium carbonate is formed, the ammonia may be absorbed and produce this condition. The breath and excretions smell strongly of ammonia; the mouth, pharynx, and skin are very dry; there is vomiting, with diarrhœa or constipation, while ulcers may form in the intestine. The patient rapidly loses flesh, and death occurs without any disturbance of the mental faculties.

Uric Acid Diathesis.—When too much nitrogenous food, too much of any alcoholic fluid, is persistently used, and little muscular exercise taken, especially if the respiratory organs are interfered with, uric acid may not unfrequently accumulate in the blood (*Garrod*). It may be deposited in the joints and their ligaments, especially in the foot and hand, giving rise to painful inflammation, and forming gout stones or chalk stones. The heart, liver and kidneys are rarely affected. The tissues near these deposits undergo necrosis.

278. **STRUCTURE AND FUNCTIONS OF THE URETER.**—**Mucous Membrane.**—The pelvis of the kidney and the ureter are lined by a *mucous membrane*, consisting of connective tissue, and covered with several layers of stratified "**transitional**" epithelium (Fig. 290).

FIG. 289.



Transverse section of the lower part of human ureter, × 15. *e*, epithelium; *t*, tunica propria; *s*, sub-mucosa; *l* and *r*, longitudinal and circular fibres.

The cells are of various shapes, those of the lowest layer being usually more or less spherical and small, while many of the cells in the upper layers are irregular in shape, often with long processes passing into the deeper layers.

Sub-mucosa.—Under the epithelium there is a layer of adenoid tissue (*Hamburger, Chiari*), which may contain small lymph follicles [embedded in loose connective tissue]. In the pelvis of the kidney and ureter there are a few small mucous glands lined by a single layer of columnar epithelium (*Unruh, Egli*).

The **muscular coat** consists of an inner somewhat stronger layer of *longitudinal* non-striped fibres, and an outer *circular* layer (Fig. 289). In the lowest third of the ureter there are in addition a number of scattered muscular fibres. All these layers are surrounded and supported by connective tissue. The outer layers of the connective tissue form an outer coat or **adventitia**, which contains the

large vessels and nerves. The various coats of the ureter can be followed up to the pelvis of the kidney, and to its calices. The papillæ are covered only by the mucous membrane, while the muscular layer ceases at the apex of the pyramids, where they are disposed circularly, to form a kind of *sphincter* muscle for each papilla (*Henle*).

The **blood vessels** supply the various coats, and form a capillary plexus under the epithelium. The **nerves** are not very numerous, but they contain medullated (few) and non-medullated fibres, with numerous ganglia scattered in their course. They are partly *motor*, and supply the muscular layers, and some pass toward the epithelium, and are *sensory* and *excito-reflex* in function. These nerves are excited when a calculus passes along the ureter, and thus give rise to severe pain. The ureter perforates the wall of the bladder *obliquely*. The inner opening is a narrow slip in the mucous membrane, directed downward and inward, and provided with a pointed, valve-like process (Fig. 291).

Movement of the Urine. — The urine is propelled along the ureter thus: (1) The secretion, which is continually being formed under a high pressure in the kidney, propels the urine onward in front of it, as the urine is under a low pressure in the ureter. (2) *Gravity* aids the passage of the urine when the person is in the erect posture. (3) The muscles of the ureter contract rhythmically and peristaltically, and so propel it toward the bladder. This movement is reflex, and is due to the presence of the urine in the ureter. Every three-quarters of a minute several drops of urine pass into the bladder. But the fibres may also be excited directly. The contraction passes along the tube at the rate of 20 to 30 mm. per second, always from above downward. The greater the tension of the ureter due to the urine, the more rapid is the peristaltic movement.

FIG. 290.

Transitional epithelium from the bladder. Many of the large cells lie upon the summit of the columnar and caudate cells, and depressions are seen on their under surface.

Local Stimulation.—On applying a stimulus to the ureter directly, the contraction passes both upward and downward. Engelmann observed that the movements occur in parts of the ureter where neither nerves nor ganglia were to be found, and he concluded that the movement was propagated by "**muscular conduction.**" If this be so, then an impulse may be propagated from one non-striped muscular cell to another without the intervention of nerves (see Heart, § 58, I, 3).

Prevention of Reflux.—The urine is prevented from exerting a backward pressure toward the kidneys: (1) The urine which collects in the pelvis of the kidney is under a high pressure, and thus tends uniformly to compress the pyramids, so that the urine cannot pass into the minute orifices of the urinary tubules. (2) When there is a considerable accumulation of urine in a ureter, *e. g.*, from the presence of an impacted calculus or other cause, there is also more energetic peristalsis, and, at the same time, the circular muscular fibres round the apices of pyramids compress the pyramids and prevent the reflux of urine through the collecting tubules. The urine is prevented from passing back from the bladder into the ureter, the wall of the bladder itself, and the part of the ureter which passes through it, are compressed, so that the edges of the slit-like opening of the ureter are rendered more tense, and are thus approximated toward each other (Fig. 291).

279. **URINARY BLADDER AND URETHRA.—Structure.—The mucous membrane** of the bladder resembles that of the ureter; the upper layers of the stratified transitional epithelium are flattened. It is obvious that the form of the cells must vary with the state of distention or contraction of the bladder. [The mucous membrane and muscular coats are thicker than in the ureter. There are mucous glands in the mucous membrane, especially near the neck of the bladder.]

Sub-mucous Coat.—There is a layer of delicate fibrillar connective tissue mixed with elastic fibres between the mucous and muscular layers.

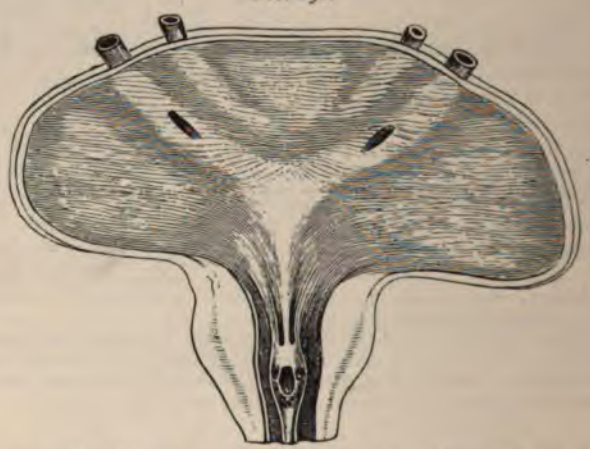
[The **serous coat** is continuous with and has the same structure as the peritoneum, and it covers only the posterior and upper half of the organ.]

Musculature.—The *non-striped* muscular fibres are arranged in bundles in several layers, an *external longitudinal* layer, best developed on the anterior and posterior surfaces, and an *inner circular* layer. [Between these two is an *oblique* layer.] There are other bundles of muscular fibres arranged in different directions. **Physiologically**, the musculature of the bladder represents a single or common hollow muscle, whose function when it contracts is to diminish uniformly the size of the bladder, and thus to expel its contents (§ 306).

The **blood vessels** resemble those of the ureter. The **nerves** form a plexus, and are placed partly in the mucous membrane and partly in the muscular coat, and, like all the extra-renal parts of the urinary apparatus, are provided with **ganglia**, lying in the mucosa, sub-mucosa, and connected to each other by fibres (*Maier*). Ganglia occur in the course of the motor nerve fibres in the bladder (*W. Wolff*). Their functions are **motor, sensory, excito-motor,** and **vasomotor.** [Sympathetic nerve ganglia also exist underneath the serous coat (*F. Darwin*).]

A too minute dissection of the several layers and bundles of the musculature of the bladder has given rise to erroneous inferences. Thus, we speak of a **detrusor urinæ**, which, however, consists chiefly of fibres running on the anterior and posterior surfaces, from the vertex to the fundus. There does not seem to be a special **sphincter vesicæ internus**; it is merely a thicker circular (6 to 12 mm.) layer of non-striped muscle which surrounds the beginning of the urethra, and which, from its shape, helps to form the funnel-like exit of the bladder. Numerous muscular bundles, connected

FIG. 291.



Lower part of the human bladder laid open, showing clear part, or trigone, the slit-like openings of the ureters, the divided ureters, and vesiculæ seminales; the sinus prostaticus, and on each side of it the openings of the ejaculatory ducts, and below both numerous small apertures of the prostate ducts.

partly with the longitudinal and partly with the circular fibres of the bladder, exist, especially in the trigone, between the orifice of the ureters.

In the **female**, the urethra serves merely for the passage of urine. The mucous membrane consists of connective tissue with many elastic fibres, and provided with papillæ. It is covered by stratified epithelium and contains several mucous glands (*Littré*). Outside this is a layer of longitudinal, smooth, muscular fibres, and outside this again a layer of circular fibres. Many elastic fibres exist in all the layers, which are traversed by numerous wide venous channels.

The proper **sphincter urethræ** is a *transversely striped* muscle subject to the will, and consists of completely circular fibres which extend downward as far as the middle of the urethra, and partly of longitudinal fibres, which extend only on the posterior surface toward the base of the bladder, where they become lost between the fibres of the circular layer.

In the **male urethra**, the **epithelium** of the prostatic part is the same as that in the bladder; in the membranous portion it is stratified, and in the cavernous part the simple cylindrical form. The mucous membrane, under the epithelium itself, is beset with *papillæ*, chiefly in the posterior part of the urethra, and contains the mucous glands of Littrè.

Non-striped muscle occurs in the prostatic part arranged longitudinally, chiefly at the colli[illegible]

seminalis; in the membranous portion the direction of the fibres is chiefly circular, with a few longitudinal fibres intercalated; the cavernous part has a few circular fibres posteriorly, but anteriorly the muscular fibres are single and placed obliquely and longitudinally.

Closure of the Bladder.—The so-called internal vesical sphincter of the anatomists, which consists of non-striped muscle, is in reality an integral part of the muscular coat of the bladder and surrounds the orifice of the urethra as far down as the prostatic portion, just above the colliculus seminalis. It is, however, not the sphincter muscle. The proper **sphincter urethræ** (sph. vesicæ externus) lies below the latter. It is a completely circular muscle disposed around the urethra, close above the entrance of the urethra into the septum urogenitale at the apex of the prostate, where it exchanges fibres with the deep transverse muscle of the perineum which lies under it.

Some longitudinal fibres, which run along the upper margin of the prostate from the bladder, belong to this sphincter muscle. Single transverse bundles passing forward from the surface of the neck of the bladder, the transverse bands which lie within the prostate, the apex of the colliculus seminalis, and a strong transverse bundle passing in front of the origin of the urethra into the substance of the prostate—all belong to the sphincter muscle (*Henle*). In the male urethra, the *blood vessels* form a rich capillary plexus under the epithelium, below which is a wide-meshed *lymphatic* plexus.

[**Tonus of Sphincter Urethræ.**—Open the abdomen of a rabbit, ligature one ureter, tie a cannula in the other, and pour water into the bladder until it runs out through the urethra, which is usually under a pressure of 16 to 20 inches. If the spinal cord be divided between the fifth and seventh lumbar vertebræ, a column of 6 inches is sufficient to overcome the resistance of the sphincter, while section at the fourth lumbar vertebra has no effect on the height of the pressure. In such an animal the bladder becomes distended, but in one with its cord divided between the fifth and seventh lumbar vertebræ, there is incontinence of urine—in the former case because the excito-motor impulses are cut off from the centre (5 to 7 vert.), and in the latter because the tonus of the sphincter is destroyed (*Kupressow*). This tonus is denied by Landois and others.]

280. ACCUMULATION OF URINE—MICTURITION.—After emptying the bladder, the urine slowly collects again, the bladder being thereby gradually distended. [A healthy bladder may be said to be full when it contains 20 oz.] As long as there is a moderate amount of urine in the bladder, the elasticity of the elastic fibres surrounding the urethra, and that of the sphincter of the urethra (and in the male of the prostate), suffice to retain the urine in the bladder. This is shown by the fact that the urine does not escape from the bladder after death. If the bladder be greatly distended (1.5 to 1.8 litre), so that its apex projects above the pubes, the sensory nerves in its walls are stimulated and cause a feeling of a full bladder, while at the same time the urethral opening is dilated, so that a few drops of urine pass into the beginning of the urethra. Besides the subjective feeling of a full bladder, this tension of the walls of the bladder causes a *reflex* effect, so that the urinary bladder contracts periodically upon its fluid contents, and so do the sphincter of the urethra and the muscular fibres of the urethra, and thus the urethra is closed against the passage of these drops of urine. As long as the pressure within the bladder is not very high, the reflex activity of the transversely striped sphincter overcomes the other (as during sleep); but, as the pressure rises and the distention increases, the contraction of the walls of the bladder overcomes the closure produced by the sphincter, and the bladder is emptied, as occurs normally in young children.

As age advances, the sphincter urethræ comes under the control of the will, so that it can be contracted voluntarily, as occurs in man when he forcibly contracts the bulbo-cavernosus muscle to retain urine in the bladder. The sphincter ani usually contracts at the same time. The reflex activity of the sphincter may also be inhibited voluntarily, so that it may be completely relaxed. This is the condition when the bladder is emptied voluntarily.

Slight **movements**, confined to the bladder, occur during psychical or emotional disturbances (*e.g.*, anger, fear), [the bladder may be emptied involuntarily during a fright], after stimulation of sensory nerves, auditory impressions, restraining the respiration, and by arrest of the heart's action. There are slight periodic variations coincident with variations in the blood pressure. The contractions of the bladder cease after deep inspiration, and also during apnœa (*Mosso and Pellacani*). The excised

bladder of the frog, and even portions free from ganglia, exhibit rhythmical contractions, which are increased by heat (*Pfalz*). [Ashdown found in dogs that the bladder exhibits regular rhythmical contractions, which were influenced by the degree of distention of the bladder, being most marked with moderate dilatation and least when the bladder was feebly or over-distended. The contractions could be registered by means of a water manometer communicating with the interior of the bladder.]

Nerves.—The nerves concerned in the retention and evacuation of the urine are: 1. The **motor** nerves of the sphincter urethræ, which lie in the pudendal nerve (anterior roots of the third and fourth sacral nerves). When these nerves are divided, as soon as the bladder becomes so distended as to dilate the urethral opening, the urine begins to trickle away (incontinence of urine). 2. The **sensory** nerves of the urethra, which excite these reflexes, leave the spinal cord by the posterior roots of the third, fourth and fifth sacral nerves. Section of these nerves causes incontinence of urine. The **centre** in dogs lies opposite the fifth, and in rabbits, opposite the seventh lumbar vertebra (*Budge*). 3. Fibres pass from the cerebrum —those that convey voluntary impulses through the peduncles, and the anterior columns of the spinal cord (according to Mosso and Pellacani, through the posterior columns and the posterior part of the lateral columns), to the motor fibres of the sphincter urethræ. 4. The **inhibitory fibres** concerned in the reflex inhibition of the sphincter urethræ, take the same course (perhaps from the optic thalamus?) downward through the cord to where the third, fourth, and fifth sacral nerves leave it. 5. Sensory nerves proceed from the urethra and bladder to the brain, but their course is not known. Some of the motor and sensory fibres lie for a part of their course in the sympathetic.

Transverse section of the spinal cord above where the nerves leave it, is always followed in the first instance by retention of urine, so that the bladder becomes distended. This occurs because (1) the section of the spinal cord increases the reflex activity of the urethral sphincter; and (2), because the inhibition of this reflex can no longer take place. As soon, however, as the bladder becomes so distended, as in a purely mechanical manner to cause dilatation of the urethral orifice, then the urine trickles away, but the amount of urine which trickles out in drops is small. Thus the bladder becomes more and more distended, as the continuously distended walls of the organ yield to the increased tension, so that the bladder may become distended to an enormous extent. The urine very frequently becomes ammoniacal, accompanied by catarrh and inflammation of the bladder (§ 263).

Voluntary Micturition.—Observers are not agreed as to the mechanism concerned in emptying the bladder when it is only partially full. It is stated by some that a voluntary impulse passes from the brain along a cerebral peduncle, and the cord, to the anterior roots of the 3d and 4th sacral nerves, and partly through motor fibres from the 2d to the 5th lumbar nerves (especially the 3d), to act directly upon the smooth muscular fibres of the bladder. This is assumed, because electrical stimulation of any part of this nervous channel causes contraction of the bladder. This view, however, does not seem to be the true one. It is to be remembered that Budge showed that the sensory nerves of the wall of the bladder are contained in the first, second, third, and fourth sacral nerves, and also in part in the course of the hypogastric plexus, whence they ultimately pass by the rami communicantes into the spinal cord.

According to Landois, the smooth musculature of the bladder cannot be excited directly by a voluntary impulse, but it is always caused to contract reflexly. If we wish to micturate when the urinary bladder contains a small quantity of urine, we first excite the sensory nerves of the opening of the urethra, either by causing contraction or relaxation of the sphincter urethræ, or by means of slight abdominal pressure, and thus force a little urine into the urethral orifice. This sensory stimulation causes a reflex contraction of the walls of the urinary bladder. At the same time, this condition is maintained voluntarily, by the action of the intra-cranial

reflex-inhibitory centre of the sphincter urethræ. The **centre** for the reflex stimulation of the movements of the *walls of the urinary bladder* is placed somewhat higher in the spinal cord than that for the sphincter urethræ. In dogs, it is opposite the 4th lumbar vertebra (*Gianuzzi, Budge*).

[Two centres are assumed to exist in the cord, Fig. 293, one the automatic (A.C.) at the segment corresponding to the 2d, 3d, and 4th sacral nerves, which maintains the tonic action of the sphincter; the other, a reflex centre (R. C.), is situated higher, and through it the detrusor urinæ is excited to contraction. Both centres are connected to and governed or controlled by a cerebral centre (C.). The automatic centre is connected with the sphincter, and the other with the urine-expelling fibres. They are also connected with afferent fibres from the bladder and elsewhere. The afferent or sensory fibres are also connected with the brain. The automatice centre maintains the closure of the bladder, but if the latter be distended, different impulses proceeding from it reach the spinal centre, and it may be the cerebrum. The impulses reaching the automatic centre inhibit its action and those to the reflex centre excite it, so that the detrusor urinæ contracts. If the afferent impulses be powerful, a desire to urinate is excited, and voluntary impulses are excited which act upon the spinal centres as the afferent impulses do, and thus the act of urination is more easily accomplished.]

We may conceive a voluntary impulse to pass down special fibres to an inhibitory centre, which may either act directly on the motor centre, or possibly may send branches directly to the sphincter muscles.

Painful stimulation of sensory nerves causes reflex contraction of the bladder and evacuation of the urine (in children during teething). Reflex contraction of the bladder can be brought about in cats, by stimulation of the inferior mesenteric ganglion. After section of all the nerves going to the bladder, hemorrhage and asphyxia cause contraction by a direct effect upon the structures in the wall of the bladder. As yet no one has succeeded in exciting artificially the inhibitory centre in the brain for the sphincter muscle (*Sokowin and Kowalesky*).

It seems probable that, as in the case of the anal sphincter (§ 160), there is not a *continuous tonic* reflex stimulation of the sphincter urethræ; the reflex is excited each time by the contents. The sphincter vesicæ of the anatomists, which consists of smooth muscular tissue, does not seem to take part in closing the bladder. Budge and Landois found that, after removal of the transversely striped sphincter urethræ, stimulation of the smooth sphincter did not cause occlusion of the bladder, nor could L. Rosenthal or v. Wittich convince themselves of the presence of tonus in this muscle. Indeed, its very existence is questioned by Henle.

Changes of the Urine in the Bladder.—When the urine is retained in the bladder for a considerable time, according to Kaupp, there is an increase in the sodium chloride and a decrease in the urea and water. Urine which remains for a long time in the bladder is prone to undergo ammoniacal decomposition.

Absorption.—Many observers have shown that the mucous membrane of the bladder is capable of absorbing substances—potassium iodide and other soluble salts. [Ashdown has shown that poisons, such as watery solutions of strychnin, curare, eserin, emulsions of chloroform and ether, are absorbed when injected into the bladder of rabbits. In rabbits, KI injected into the bladder through a catether was found in the urine obtained from the divided ureters. Water and urea are also absorbed—the latter in larger proportion than the former.]

As the ureters enter near the base of the bladder, the last secreted urine is always lowest. If a person remain perfectly quiet, strata of urine are thus formed, and the urine may be voided so as to prove this (*Ealefsen*).

The **pressure within the bladder,** when in the supine position = 13 to 15 centimetres of water. Increase of the intra-abdominal pressure (by inspiration, forced expiration, coughing, bearing-down) increases the pressure within the bladder. The erect posture also increases it, owing to the pressure of the viscera from above (*Schatz, Dubois*). [James obtained 4 to 4.5 inches Hg as the highest expulsive power of the bladder including the abdominal pressure, voluntary and involuntary. In paraplegia, where there is merely the expulsive power of the bladder, he found 20 to 30 inches of water.]

[**Hydronephrosis** occurs when the ureters and pelvis of the kidney become dilated, owing to partial and gradual obstruction of the outflow of urine from the ureters: if the obstruction become complete, there is cessation of the urinary secretion. James has shown that the bladder remains contracted for several seconds after it is emptied, and this is specially

the case in irritable bladder; so that this condition may also give rise to hydronephrosis by damming up the urine in the ureters.]

Rapidity of Micturition.—The amount of urine voided at first is small, but it increases with the time, and toward the end of the act it again diminishes. In men, the last drops of urine are ejected from the urethra by voluntary contractions of the bulbo-cavernosus muscle. Adult dogs increase the stream rhythmically by the action of this muscle.

281. **RETENTION AND INCONTINENCE OF URINE.**—**Retention of urine or ischuria** occurs: 1. When there is obstruction of the urethra, from foreign bodies, concretions, stricture, swelling of the prostate. 2. Paralysis or exhaustion of the musculature of the bladder; the latter sometimes occurs after delivery, in consequence of the pres ure of the child against the bladder. 3. After section of the spinal cord (p. 484). 4. Where the voluntary impulses are unable to act upon the inhibitory apparatus of the sphincter urethræ reflex, as well as when the sphincter urethræ reflex is increased.

Incontinence of urine (stillicidium urinæ) occurs in consequence of—1. Paralysis of the sphincter urethræ. 2. Loss of sensibility of the urethra, which of course abolishes the reflex of the sphincter. 3. Trickling of the urine is a secondary consequence of section of the spinal cord, or of its degeneration.

Strangury is an excessive reflex contraction of the walls of the bladder and sphincter, due to stimulation of the bladder and urethra; it is observed in inflammation, neuralgia [and after the use of some poisons, *e. g.*, cantharides].

Enuresis nocturna, or involuntary emptying of the bladder at night, may be due to an increased reflex excitability of the wall of the bladder, or weakness of the sphincter.

282. **COMPARATIVE AND HISTORICAL.**—Among **vertebrates,** the urinary and genital organs are frequently combined, except in the osseous fishes. The Wolffian bodies which act as organs of excretion during the embryonic period, remain throughout life in fishes and amphibians and continue to act as such. **Fishes.**—The *myxinoids* (cyclostomata) have the simplest kidneys; on each side is a long ureter with a series of short-stalked glomeruli with capsules arranged along it. Both ureters open at the genital pore. In the other fishes, the kidneys lie often as elongated compact masses along both sides of the vertebral column. The two ureters unite to form a urethra, which always opens behind the anus, either united with the opening of the genital organs, or behind this. In the sturgeon and hag-fish, the anus and orifice of the urethra together form a cloaca. Bladder-like formations, which, however, are morphologically homologous with the urinary bladder of mammals, occur in fishes, either on each ureter (ray, hag-fish), or where both join. In **amphibians,** the vasa efferentia of the testicles are united with the urinary tubules; the duct in the frog unites with the one on the other side, and both conjoined opens into the cloaca, while the capacious *urinary bladder* opens through the anterior wall of the cloaca. From **reptiles** upward, the kidney is no longer a persistent Wolffian body, but a new organ. In reptiles, it is usually flattened and elongated; the ureters open singly into the cloaca. Saurians and tortoises have a urinary bladder. In **birds,** the isolated ureters open into the uro-genital sinus, which opens into the cloaca, internal to the excretory ducts of the genital apparatus. The urinary bladder is always absent. In **mammals,** the kidneys often consist of many lobules, *e. g.*, dolphin, ox.

Among **invertebrates,** the **mollusca** have excretory organs in the form of canals, which are provided with an outer and an inner opening. In the mussel, this canal is provided with a sponge-like organ, often with a central cavity, and consisting of ciliated secretory cells, placed at the base of the gills (organ of Bojanus). In gasteropods, with analogous organs, uric acid has been found. **Insects, spiders,** and **centipedes** have the so-called Malpighian vessels, which are excretory organs, partly for uric acid and partly for bile. These vessels are long tubes, which open into the first part of the large intestine. In crabs, blind tubes connected with the intestinal tube, perhaps have the same functions. The **vermes** also have renal organs.

Historical.—Aristotle directed attention to the relatively large size of the human bladder—he named the ureters. Massa (1552) found lymphatics in the kidney. Eustachius († 1580) ligatured the ureters and found the bladder empty. Cusanus (1565) investigated the color and weight of the urine. Rousset (1581) described the muscular nature of the walls of the bladder. Vesling described the trigone (1753). The first important **chemical** investigations on the urine date from the time of van Helmont (1644). He isolated the solids of the urine and found among them common salt; he ascertained the higher specific gravity of fever urine, and ascribed the origin of urinary calculi to the solids of the urine. Scheele (1766) discovered uric acid and calcium phosphate; Arand and Kunckel, phosphorus; Rouelle (1773), urea; and it got its name from Fourcroy and Vauquelin (1799). Berzelius found lactic acid; Seguin, albumin in pathological urine; Liebig, hippuric acid; Heintz and v. Pettenkofer, kreatin and kreatinin; Wollaston (1810), cystin. Marcet found xanthin; and Lindbergson, magnesic carbonate.

FUNCTIONS OF THE SKIN.

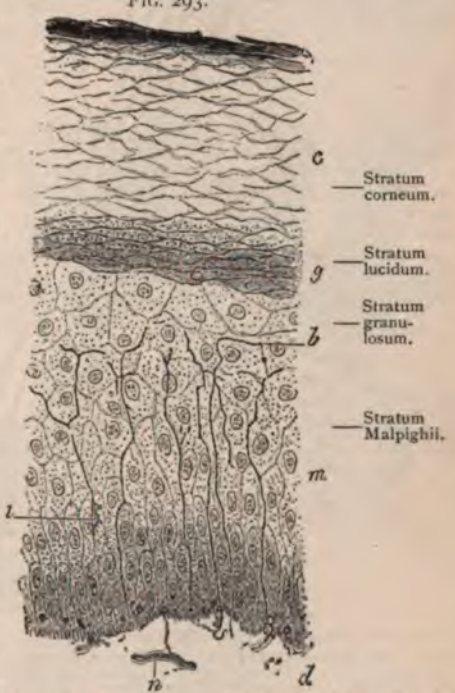
283. STRUCTURE OF THE SKIN, HAIRS, AND NAIL.—The **skin** (3.3 to 2.7 mm. thick; specific gravity, 1057) consists of—

[1. The **epidermis**;

2. The **chorium**, or **cutis vera**, with the papillæ (Fig. 294).]

The **epidermis** (0.08 to 0.12 mm. thick) consists of many layers of stratified epithelial cells united to each other by cement substance (Figs. 293, 294). The superficial layers—**stratum corneum**—consist of several layers of dry, horny, non-nucleated squames, which swell up in solution of caustic soda (Fig. 294, E). [It is always thickest where intermittent pressure is applied, as on the sole of the foot and palm of the hand.] The next layer is the **stratum lucidum**, which is clear and transparent in a section of skin, hence the name, and consists of compact layers of clear cells with vestiges of nuclei. Under this is the **rete mucosum** or rete Malpighii (Fig. 294, *d*), consisting of many layers of nucleated protoplasmic epithelial cells which contain pigment in the dark races, and in the skin of the scrotum, and around the anus. [The superficial cells are more fusiform and contain granules which stain deeply with carmine. They constitute, 3, the **stratum granulosum**. In these cells the formation of keratin is about to begin, and the granules have been called **eleidin** granules by Ranvier. They are chemically on the way to be transformed into keratin. All corneous structures contain similar granules in the area where the cells are becoming corneous. Then follow several layers of more or less polyhedral cells, softer and more plastic in their nature, and exhibiting the characters of so-called "**prickle cells**" (Fig. 294, R). [The spaces between the fibrils connecting adjacent cells are lymph spaces.] The deepest layers of cells are more or less columnar, and the cells are placed vertically upon the papillæ. Granular **leucocytes** or wandering cells are sometimes found between these cells. This, the fourth layer, has been called the **stratum Malpighii**. The rete Malpighii dips down between adjacent papillæ and forms interpapillary processes. According to Klein, a delicate **basement membrane** separates the epidermis from the true skin.] The superficial layers of the epidermis are continually being thrown off, while new cells are continually being formed in the deeper layers of the skin by proliferation of the cells of the rete Malpighii. There is a gradual change in the microscopic and chemical characters of the cells from the deepest to the superficial layers of the epidermis. [In a vertical section of the skin **stained with picro-carmine**, the S. granulosum is deeply stained red, and is thus readily distinguished among the other layers of the epidermis.]

FIG. 293.



Vertical section of the human epidermis: the nerve fibrils, *n*, *b*, stained with gold chloride.

[Epidermis (Fig. 293), { (1) *Stratum corneum*, (2) *Stratum lucidum*, } Cuticle. { (3) *Stratum granulosum*, (4) *Stratum Malpighii*, } Rete Mucosum.]

No **pigment** is formed within the epidermis itself; when it is present, it is carried by leucocytes from the subcutaneous tissue (*Riehl, Ehrmann, Aeby*). This explains how it is that a piece of white skin, transplanted to a negro, becomes black (*Karg*).

The **chorium** (Fig. 294, I, C) is beset over its entire surface by numerous (0.5 to 0.1 mm. high) **papillæ** (Fig. 294), the largest being upon the volar surface of the hand and foot, on the nipple and glans penis. Most of the papillæ contain a looped **capillary** (*g*), while in certain regions some of them contain a **touch corpuscle** (Fig. 295, *a*). The papillæ are disposed in groups, whose

Epidermis and chorium shortened—1, outer, 2, inner fibrous layer of the hair follicle; 3, its hyaline layer; 4, outer root sheath; 5, Huxley's layer of the inner root sheath; 6, Henle's layer of the same; *p*, root of the hair, with its papilla; A, arrector pili muscle; C, chorium; *a*, subcutaneous fatty tissue; *b*, epidermis (horny layer); *d*, rete Malpighii; *g*, blood vessels of papillæ; *v*, lymphatics of the same; *h*, horny or corneous substance; *i*, medulla or pith; *k*, epidermis or cuticle of hair; K, coil of sweat gland; E, epidermal scales (seen from above and *en face*) from the stratum corneum; R, prickle cells from the rete Malpighii; *n*, superficial, and *m*, deep cells from the nail; H, hair magnified: *c*, cuticle; *c*, medulla, with cells; *f*, *f*, fusiform fibrous cells of the substance of the hair; *x*, cells of Huxley's layer; *l*, those of Henle's layer; S, transverse section of a sweat gland from the axilla; *a*, smooth muscular fibres surrounding it; *t*, cells from a sebaceous gland, some of them containing granules of oil.

arrangement varies in different parts of the body. In the palm of the hand and sole of the foot they occur in rows, which are marked out by the existence of delicate furrows on the surface visible to the naked eye. The chorium consists of a dense network of bundles of white fibrous tissue mixed with a network of **elastic fibres**, which are more delicate in the papillæ. In silversmiths the elastic fibres are blackened by the partial deposition of reduced silver, and the same obtains in those who take silver nitrate in such quantity as to produce argyria. The connective tissue contains many connective-tissue corpuscles and numerous leucocytes. The deeper connective tissue layer

of the chorium gradually pass into the **subcutaneous tissue**, where they form a trabecular arrangement of bundles, leaving between them elongated rhomboidal spaces filled for the most part with groups of **fat cells** (Fig. 294, *a*, *a*). [In microscopic sections, after the action of alcohol, the fat cells not unfrequently contain crystals of **margarin**.] The long axis of the rhomb corresponds to the greater tension of the skin at that part (*C. Langer*). In some situations the subcutaneous tissue is devoid of fat [penis, eyelids]. In many situations, the skin is fixed by solid fibrous bands to subjacent structures, as fasciæ, ligaments or bones (tenacula cutis); in other parts, as over bony prominences, bursæ partially lined with endothelium and filled with synovia-like fluid, occur.

Smooth muscular fibres occur in the chorium in certain situations on extensor surfaces (*Neumann*); nipple, areola mammæ, prepuce, perinæum, and in special abundance in the tunica dartos of the scrotum.

[**Guanin in the Skin.**—The skin of many amphibians and reptiles contains brown or black pigment granules, and other granules of a white, silvery, or chalky appearance. Ewald and Krukenberg have shown that the latter consists of guanin, and that this substance is very widely diffused in the skin of fishes, amphibians, and reptiles. **Test:** Select a piece of skin from the belly of a frog; place it in a porcelain capsule as for the murexide test; add concentrated nitric acid, and heat to dryness, when a yellow residue is obtained; on adding a drop of caustic soda a red color is struck. The yellow residue gives no reaction with ammonia. If to the fluid more water be added, and it be then heated, distributed over the surface of the capsule, and cooled by blowing upon it, various shades of purple and violet are obtained.]

The **nails** (specific gravity 1.19) consist of numerous layers of solid, horny, homogeneous, epidermal, or nail cells, which may be isolated with a solution of caustic alkali, when they swell up and exhibit the remains of an elongated nucleus (Fig. 294, *n*, *m*). The whole under surface of the nail rests upon the **nail bed**; the lateral and posterior edges lie in a deep groove, the **nail groove** (Fig. 296, *e*). The chorium under the nail is covered throughout its entire extent by longitudinal rows of **papillæ** (Fig. 296, *d*). Above this there lies, as in the skin, many layers of prickle cells like those in the rete Malpighii (Fig. 294, *a*), and above this again is the substance of the nail (Fig. 296, *a*). [The stratum granulosum is rudimentary in the nail bed. The substance of the nail represents the stratum lucidum, there being no stratum corneum (*Klein*).] The posterior part of the nail groove and the half moon, brighter part or **lunule**, form the *root* of the nail. They are, at the same time, the **matrix**, from which growth of the nail takes place. The lunule is present in an isolated nail, and is due to diminished transparency of the posterior part of the nail, owing to the special thickness and uniform distribution of the cells of the rete Malpighii (*Toldt*).

FIG. 295.

Papillæ of the skin, epidermis removed, blood vessels injected; some contain a Wagner's touch corpuscle, *a*, the others a capillary loop.

FIG. 296.

Transverse section of one-half of a nail. *a*, nail substance; *b*, more open layer of cells of the nail bed; *c*, stratum Malpighii of the nail bed; *d*, transversely divided papillæ; *e*, nail groove; *f*, horny layer of *e* projecting over the nail; *g*, papillæ of the skin on the back of the finger.

Growth of the Nail.—According to Unna, the matrix extends to the front part of the lunule. The nail grows continually from behind forward, and is formed by layers secreted or formed by the

matrix. These layers run parallel to the surface of the matrix. They run obliquely from above and behind, downward and forward, through the thickness of the substance of the nail. The nail is of the same thickness from the anterior margin of the lunule forward to its free margin. Thus the nail does not grow in thickness in this region. In the course of a year the fingers produce about 2 grms. of nail substance, and relatively more in summer than in winter.

Development—1. From the second to the eighth month of fœtal life, the position of the nail is indicated by a partial but marked horny condition of the epidermis on the back of the first phalanx, the "**eponychium.**" The remainder of this substance is represented during life by the normally formed epidermal layer, which separates the future nail from the surface of the furrow. 2. The future nail is formed under the eponychium, with its first nail cells still in front of the nail groove; then the nail grows and pushes forward toward the groove. At the seventh month, the nail (itself covered by the eponychium) covers the whole extent of the nail bed. 3. When, at a later period, the eponychium splits off, the nail is uncovered. After birth the papillæ are formed on the bed of the nail, while simultaneously the matrix passes backward to the most posterior part of the groove (*Unna*).

Absence of Hairs.—The whole of the skin, with the exception of the palmar surface of the hand, sole of the foot, dorsal surface of the third phalanx of the fingers and toes, outer surface of the eyelids, glans penis, inner surface of the prepuce, and part of the labia is covered with hairs, which may be strong or fine (lanugo).

A Hair (specific gravity 1.26) is fixed by its lower extremity (root) in a depression of the skin or a **hair follicle** (Fig. 294, I, *p*) which passes obliquely through the thickness of the skin, sometimes as far as the subcutaneous tissue. The structure of a hair follicle is the following: 1. The **outer fibrous layer** (Figs. 294, 1, 293), composed of interwoven bundles of connective tissue, arranged for the most part longitudinally, and provided with numerous blood vessels and nerves. [It is just the connective tissue of the surrounding chorium.] 2. The **inner fibrous layer** (Figs. 294, 2, 297) consists of a layer of fusiform cells (? smooth muscular fibres) arranged circularly. [It does not extend throughout the whole length of the follicle.] 3. Inside this layer is a transparent, hyaline, glass-like **basement membrane** (Figs. 292, 3, 297), which ends at the neck of the hair follicle; while above it is continued as the basement membrane which exists between the epidermis and chorium. In addition to these coverings, a hair follicle has epithelial coverings which must be regarded in relation to the layers of the epidermis. Immediately within the glass-like membrane is the **outer root sheath** (Figs. 294, 4, 297, 298), which consists of so many layers of epithelial cells that it forms a conspicuous covering. It is, in fact, a direct continuation of the stratum Malpighii, and consists of many layers of soft cells, the cells of the outer layer being cylindrical. Toward the base of the hair follicle it becomes narrower, and is united to, and continues with the cells of the root of the hair itself, at least in fully developed hairs. The horny layer of the epidermis continues to retain its properties as far down as the orifice of the sebaceous follicle; below this point, however, it is continued as the **inner root sheath.** This consists of (1) a single layer of elongated, flat, homogeneous, non-nucleated cells (Figs. 294, 6, 297, *f—Henle's layer*) placed next and within the outer root sheath. Within this lies (2) *Huxley's layer* (Figs. 294, 5, 297, *g*), consisting of nucleated elongated polygonal cells (Fig. 294, *x*, and 3), while the *cuticle* of the hair follicle is composed of cells analogous to those of the surface of the hair itself. Toward the bulb of the hair these three layers become fused together.

FIG. 297.

[**Coverings of a hair follicle** arranged from without inward—

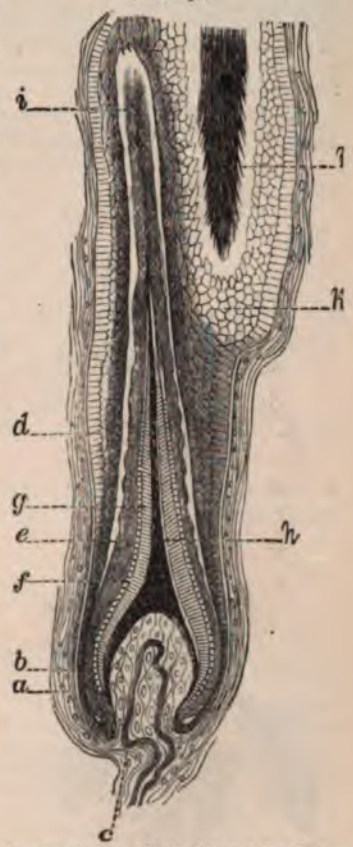
1. Fibrous layers, { (*a*) Longitudinally arranged fibrous tissue. (*b*) Circularly arranged spindle cells.
2. Glass-like (hyaline) membrane.
3. Epithelial layers, { (*a*) Outer root sheath. (*b*) Inner root sheath. { Henle's layer. Huxley's layer. (*c*) Cuticle of the hair.
4. The hair itself.]

The **arrector pili muscle** (Fig. 294, A) is a fan-like arrangement of a layer of smooth muscular fibres, attached below to the side of a hair follicle and extending toward the surface of the chorium; as it stretches obliquely upward, it subtends the obtuse angle formed by the hair follicle and the surface of the skin [or, in other words, it forms an acute angle with the hair follicle, and between it and the

follicle lies the **sebaceous gland**]. When these muscles contract, they raise and erect the hair follicles, producing the condition of **cutis anserina** or *gooseskin*. As the sebaceous gland lies in the angle between the muscle and the hair follicle, contraction of the muscle compresses the gland and favors the evacuation of the sebaceous secretion. It also compresses the blood vessels of the papilla (*Unna*).

The **hair** with its large bulbous extremity—**hair bulb**—sits upon or rather embraces, the **papilla**. It consists of (1) the *marrow* or **medulla** (Fig. 294, *i*), which is absent in woolly hair and in the hairs formed during the first year of life. It is composed of two or three rows of cubical cells (H, *c*). (2) Outside this lies the thicker **cortex** (*k*), which consists of elongated, rigid, horny, fibrous cells (H, *f*, *f*), while in and between these cells lie the pigment granules of the hair. (3) The surface of the hair is covered with a **cuticle** (*k*), and consists of imbricated layers of non-nucleated squames.

FIG. 298.



Section of a hair follicle while a hair is being shed. *a*, outer and middle sheaths of hair follicle; *b*, hyaline membrane; *c*, papilla, with a capillary; *d*, outer, *e*, inner root sheath; *f*, cuticle of the latter; *g*, cuticle of the hair; *h*, young non-medullated hair; *i*, tip of new hair; *l*, hair knob of the shed hair, with *k*, the remainder of the cast-off outer root sheath.

Gray Hair.—When the hair becomes *gray*, as in old age, this is due to defective formation of pigment in the cortical part. The silvery appearance of white hair is increased when small air cavities are developed, especially in the medulla and to a less extent in the cortex, where they reflect the light. Landois records a case of the hair becoming *suddenly* gray, in a man whose hair became gray during a single night, in the course of an attack of delirium tremens. Numerous hair spaces were found throughout the entire marrow of the (blond) hairs, while the hair pigment still remained.

[**Blood Pigment in Hairs.**—The feelers of albino rabbits contain in some part of their substances blood pigment (*Sig. Mayer*).]

Development of Hair.—According to Kölliker, from the 12th to 13th week of intra-uterine life, solid finger like processes of the epidermis are pushed down into the chorium. The process becomes flask-shaped, while the central cells of the cylinder become elongated and form a conical body, arising, as it were, from the depth of the recess. It soon differentiates into an inner darker part, which becomes the hair, and a thinner, clearer layer covering the former, the inner rooth sheath. The outer cells, *i. e.*, those lying next the wall of the sac, form the outer root sheath. Outside this, again, the fibrous tissue of the chorium forms a rudimentary hair follicle, while one of the papillæ grows up against it, indents it, and becomes embraced by the bulb of the hair. This is the hair papilla, which contains a loop of blood vessels. The cells of the bulb of the hair proliferate rapidly, and thus the hair grows in length. The point of the hair is thereby gradually pushed upward, pierces the inner root sheath, and passes obliquely through the epidermis. The hairs appear upon the forehead at the 19th week; at the 23d to 25th week the lanugo hairs appear free, and they have a characteristic arrangement on different parts of the body.

Physical Properties.—Hair has very considerable **elasticity** (stretching to 0.33 of its length), considerable cohesion (carrying 3 to 5 lbs.), **resists putrefaction** for a long time, and is highly **hygroscopic.** The last property is also possessed by epidermal scales, as is proved by the pains that occur in old wounds and scars during damp weather.

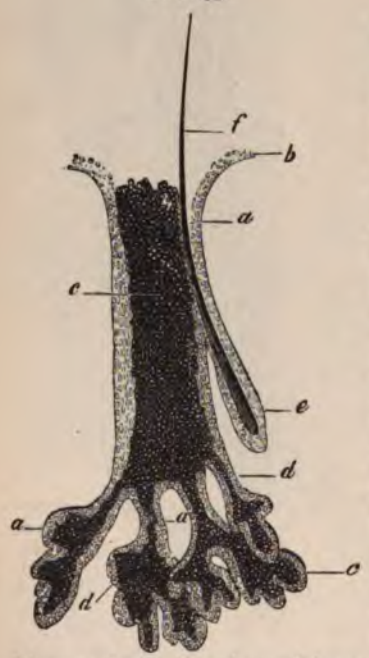
Growth of a hair occurs by proliferation of the cells on the surface of the hair papilla, these cells representing the matrix of the hair. Layer after layer is formed, and gradually the hair is raised higher within its follicle.

Change of the Hair.—According to one view, when the hair has reached its full length, the process of formation on the surface of the hair papilla is interrupted; the root of the hair is raised from the papilla, becomes horny, remains almost devoid of pigment, and is gradually more and more lifted upward from the surface of the papilla, while its lower bulbous end becomes split up like a brush. The lower empty part of the hair follicle becomes smaller, while on the old papilla a new formation of a hair begins, the old hair at the same time falling out (*Unna*). According to Stieda, the old papilla disappears, while a new one is formed in the hair follicle, and from it the new hair is developed. According to Kölliker, again, both processes obtain.

284. THE GLANDS OF THE SKIN.—The **sebaceous glands** (Fig. 294, I, T) are simple acinous glands, which open by a duct into the hair follicles of large hairs near their upper part; in the case of small hairs, they may project from the duct of the gland (Fig. 299). In some situations, the ducts of the glands open free upon the surface, *e. g.*, the glands of labia minora, glans, prepuce (Tyson's glands), and the red margins of the lips. The largest glands occur in the nose and in the labia; they are absent only from the vola manus and planta pedis. The oblong alveoli of the gland consist of a basement membrane lined with small polyhedral nucleated granular secretory cells (Fig. 294, *t*). Within this are other polyhedral cells, whose substance contains numerous oil globules; the cells become more fatty as we proceed toward the centre of the alveolus. The cells lining the duct are continuous with those of the outer root sheath. The detritus formed by the fatty metamorphosis of the cells constitutes the **sebum** or sebaceous secretion. [If the "oil or coccygeal gland" of a duck be removed, it is found that, when the animal is submerged, it takes up between its feathers about the same amount of water as an intact duck; but it retains 2 to 2½ times as much water in its feathers (*Max Joseph*).]

The **sweat glands** (Fig. 294, I, *k*), sometimes called **sudoriparous** glands, consist of a long blind tube, whose lower end is arranged in the form of a coil placed in the areolar tissue under the skin, while the somewhat smaller upper end or excretory portion winds in a vertical, slightly wave-like manner, through the chorium, and in a corkscrew or **spiral manner** through the epidermis, where it opens with a free, somewhat trumpet-shaped, mouth. The glands are very numerous and large in the palm of the hand, sole of the foot, axilla, forehead, and around the nipple; few on the back of the trunk, and are absent on the glans, prepuce, and margin of the lips. The **circumanal** glands and the **ceruminous glands** of the external auditory meatus, and **Moll's glands**, which open into the hair follicles of the eyelashes, are modifications of the sweat glands.

FIG. 299.



Sebaceous gland, with a lanugo hair. *a*, granular epithelium; *b*, rete Malpighii continuous with *a*; *c*, fatty cells and free fat; *d*, acini; *e*, hair follicle, with a small hair, *f*.

Each gland tube consists of a basement membrane lined by cells; the **excretory** part or **sweat canal** of the tube is lined by *several* layers of cubical cells, whose surface is covered by a delicate cuticular layer, a small central lumen being left. Within the coil the structure is different. The first part of the coil resembles the above, but as the coil is the true **secretory part** of the gland, its structure differs from the sweat canal. This, the so-called *distal* portion of the tube, is lined by a *single* layer of moderately tall, clear, nucleated, cylindrical epithelium (Fig. 294, S), often containing oil globules. Smooth muscular fibres are arranged longitudinally along the tube in the large glands (Fig. 294, S, *a*). There is a distinct lumen present in the tube. As the duct passes through the epidermis, it winds its way between the epidermal cells without any independent membrane lining it (*Heynold*). A network of **capillaries** surrounds the coil. Before the arteries split up into capillaries, they form a true rete mirabile around the coil (*Brücke*). This is comparable to the glomerulus of the kidney, which may also be regarded as a rete mirabile. Numerous **nerves** pass to form a plexus, and terminate in the glands (*Tomsa*).

The **total number** of sweat glands is estimated by Krause at 2½ millions, which gives a secretory surface of nearly 1800 square metres. *These glands secrete sweat.* Nevertheless, an oily or fatty substance is often mixed with the sweat. In some animals (glands in the sole of the foot of the dog, and in birds) this oily secretion is very marked.

Numerous **lymphatics** occur in the cutis, some arise by a blind end, and others from loops within the papilla on a plane lower than the vascular capillary. [These open into more or less horizontal networks of tubular lymphatics in the cutis, and these again into the wide lymphatics of the subcutaneous tissue, which are well provided with valves.] Special lymphatic spaces are disposed in relation with the hair follicles and their glands (*Neumann*), [and also with the fat (*Klein*). The lymphatics of the skin are readily injected with Berlin blue by the puncture method].

The **blood vessels** of the skin are arranged in several systems. There is a superficial system, from which proceed the capillaries for the papillæ. There is a deeper system of vessels which supplies special blood vessels to (*a*) the fatty tissue; (*b*) the hair follicles, each of which has a special vascular arrangement of its own, and in connection with this each sebaceous gland receives a special artery; (*c*) an artery goes also to each coil of a sweat gland, where it forms a dense plexus of capillaries (*Tomsa*).
